Relations.—The uppermost part of the Psoas major lies behind the diaphragm and occupies the lowest part of the posterior mediastinum. It may be in contact with the posterior, lower limit of the pleural sac. In the abdomen the Psoas major is in relation by its *anterolateral surface* with the medial arcuate ligament (medial lumbocostal arch), the fascia covering the muscle, the extraperitoneal tissue and peritoneum, the kidney, Psoas minor, renal vessels, ureter, testicular (or ovarian) vessels, and genitofemoral nerve. In front the right Psoas is overlapped by the inferior vena cava and crossed by the terminal portion of the ileum, and the left is crossed by the colon. Its *posterior surface* is in relation with the transverse processes of the lumbar vertebræ, and the medial edge of the Quadratus lumborum. The lumbar plexus is situated in the posterior part of the substance of the muscle. *Medially*, the muscle is in relation with the bodies of the lumbar vertebræ and the lumbar vessels. Along its anterior (or medial) margin the muscle is in relation with the sympathetic trunk, and the aortic lymph-glands and, along the brim of the pelvis, with the external iliac artery. This margin is covered by the inferior vena cava on the right side, and on the left side lies posterior and lateral to the abdominal aorta.

In the thigh it is in relation, *in front*, with the fascia lata and the femoral artery; *behind*, with the capsule of the hip-joint, from which it is separated by a bursa; by its *medial border*, with the Pectineus and medial circumflex femoral artery, and also with the femoral vein, which may overlap it slightly; by its *lateral border*, with the femoral nerve and the Iliacus.

The femoral nerve descends at first through the fibres of Psoas major, and then lies between it and the Iliacus.

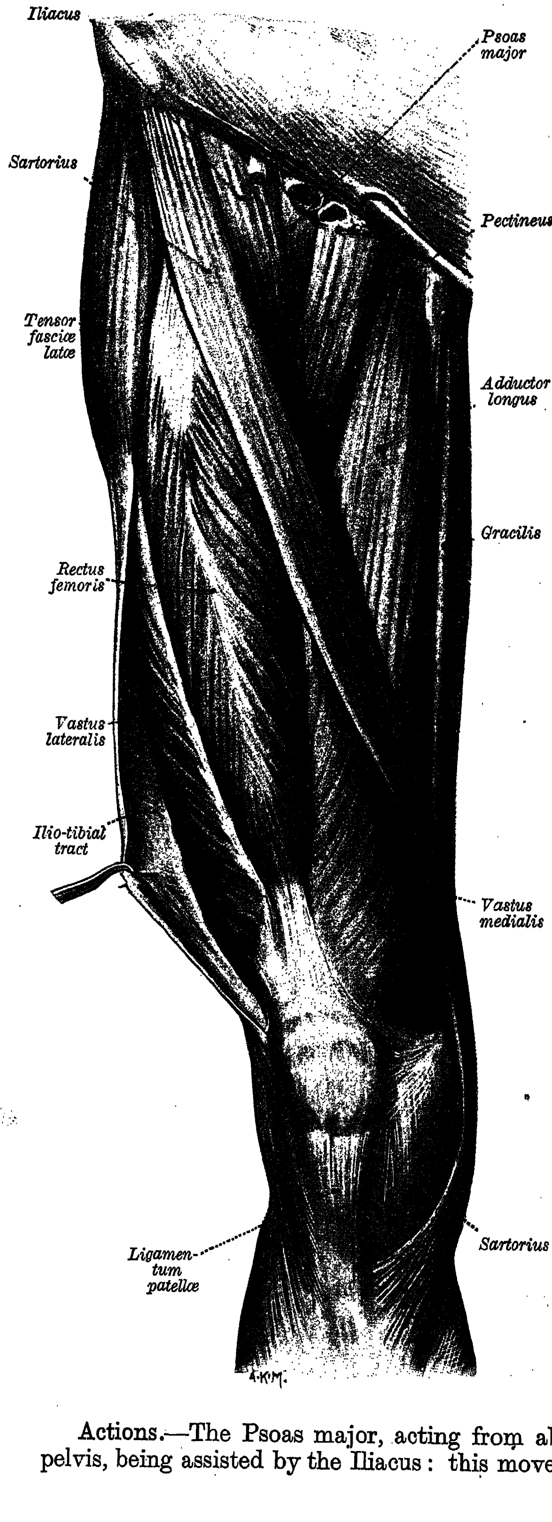
Nerve-supply.—The Psoas major is supplied by branches from the second and third lumbar nerves.

Actions.—The Psoas major acts conjointly with the Iliacus (p. 622).

The **Psoas minor** (fig. 638) is placed in front of the Psoas major within the abdomen. It arises from the sides of the bodies of the twelfth thoracic and first

lumbar vertebræ and from the disc between them. It ends in a long, flat tendon which is inserted into the pectineal line and iliopubic eminence, and, by its lateral border, into the iliac fascia. This muscle is absent in about 40 per cent. of subjects.

FIG. 638.—Muscles on the front of the thigh, superficial dissection. (From Quain's *Anatomy*, XI. Edition.)



Nerve-supply.—The Psoas minor is supplied by a branch from the first lumbar nerve.

Action.—The Psoas minor is a tensor of the iliac fascia and a weak flexor of the trunk.

The **Iliacus** (fig. 638) is a flat, triangular muscle which fills the iliac fossa. It arises from the upper two-thirds of the iliac fossa, from the inner lip of the iliac crest, from the anterior sacro-iliac and ilio-lumbar ligaments, and from the upper surface of the lateral mass of the sacrum (fig. 276); in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsular ligament of the hip-joint. Most of its fibres converge to be inserted into the lateral side of the tendon of the Psoas major, but some of them are attached to the shaft of the femur for 2·5 cm. below and in front of the lesser trochanter.

Relations.—Within the abdomen, the Iliacus is in relation, by its *anterior surface*, with the iliac fascia, which separates the muscle from the extraperitoneal tissue and peritoneum, and with the lateral femoral cutaneous nerve; on the right side, with the cæcum; on the left side, with the iliac part of the descending colon; by its *posterior surface*, with the iliac fossa; by its *medial border*, with the Psoas major and femoral nerve.

In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus femoris, Sartorius and arteria profunda femoris; by its *posterior surface*, with the capsule of the hip-joint, a bursa common to it and the Psoas major being interposed.

Nerve-supply.—The Iliacus is supplied by branches of the femoral nerve (L. 2 and 3).

Actions.—The Psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by the Iliacus: this movement imposes a slight degree of

medial rotation on the femur; acting from below, with the femur fixed, the Psoas major bends the lumbar portion of the vertebral column forwards and to its own side, and then, in conjunction with the Iliacus, tilts the pelvis forwards. When the Psoas major and Iliacus of both sides act from below, they serve to maintain the erect posture by supporting the vertebral column and pelvis upon the femora, or in continued action bend the trunk and pelvis forwards, as in raising the trunk from the recumbent posture.

Applied Anatomy.—When an abscess forms beneath the fascia covering the Psoas and Iliacus, as often happens, the pus is contained in an osseofibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscles into the thigh. When the disease is in the thoracic vertebræ, the pus tracks down the posterior mediastinum in front of the bodies of the vertebræ, and, passing behind the medial arcuate ligament, enters the sheath of the Psoas, down which it travels as far as the pelvic brim; it then passes deep to the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the arcuate line (linea terminalis), it rarely finds its way into the true pelvis, but passes by a narrow opening behind the inguinal ligament into the thigh, lateral to the femoral vessels. When the lumbar vertebræ are the seat of the disease, the pus finds its way directly into the substance of the Psoas. The muscular fibres are destroyed, and the nerves contained in the abscess are isolated and exposed in its interior; the iliac vessels, which lie in front of the fascia, remain intact, and the peritoneum seldom becomes implicated. All psoas abscesses do not, however, pursue this course; the pus may leave the sheath of the muscle above the crest of the ilium, and tracking backwards may point in the loin (*lumbar abscess*); or it may point above the inguinal ligament in the inguinal region; or it may follow the course of the branches of the internal iliac vessels into the true pelvis, and, passing through the greater sciatic foramen into the gluteal region, may discharge itself on the back of the thigh.

II. The Muscles of the Thigh

1. The Anterior Femoral Muscles (fig. 638)

Tensor fasciæ latæ.	Quadriceps femoris	Rectus femoris.
Sartorius.		Vastus lateralis.
		Vastus medialis.
		Vastus intermedius.

Articularis genus.

The **superficial fascia** forms a continuous layer over the whole of the thigh; it consists of areolar tissue containing much fat in its meshes, and may be separated into two or more layers, between which the superficial vessels and nerves are found. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from each other by the superficial inguinal lymph-glands, the long saphenous vein and several smaller vessels. The superficial layer is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous stratum, best marked on the medial side of the long saphenous vein and below the inguinal ligament. It is placed behind the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below the inguinal ligament. It covers the saphenous opening (fossa ovalis), being closely united to its circumference, and is connected to the sheath of the femoral vessels. The portion covering the opening is perforated by the long saphenous vein, small blood-vessels and lymph-vessels, hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. A large subcutaneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is named, from its great extent, the *fascia lata* (fig. 639); it invests the whole of this region of the limb, but varies in thickness in different parts. Thus, it is thicker in the upper and lateral parts of the thigh, where it receives a fibrous expansion from the Gluteus maximus and where the Tensor fasciæ latæ is inserted between its layers; it is very thin behind and at the upper and medial parts, where it covers the Adductor muscles, but

becomes stronger around the knee, where it receives fibrous expansions from the tendon of the Biceps femoris laterally, from the Sartorius medially, and from the Quadriceps femoris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; laterally, to the iliac crest; in front, to the inguinal ligament and to the superior ramus of the pubis; and medially, to the inferior ramus of the pubis, to the ramus and tuberosity of the ischium, and to the lower border of the sacrotuberous ligament. From its attachment to the iliac crest it descends as a dense fascia over the Gluteus medius to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial and the other deep to this muscle; at the lower border of the muscle the two layers reunite. Over the lateral surface of the thigh the fascia lata is specially thickened and forms a strong band which is termed the *iliotibial tract*. At its upper limit, where it splits into two layers, the tract receives the insertion of the Tensor fasciæ latæ and, posteriorly, it receives the insertion of the greater part of the tendon of the Gluteus maximus. Of the two layers the more superficial ascends on the lateral surface of the Tensor fasciæ latæ to reach the iliac crest; the deeper layer passes upwards and medially, under cover of the muscle, and blends with the lateral part of the capsule of the hip-joint. At its lower limit the iliotibial tract is attached to the lateral condyle of the tibia, but in this situation it is intimately blended with an aponeurotic expansion from the Vastus lateralis. Below, the fascia lata is attached to all the prominent points around the knee-joint, viz. the condyles of the femur and tibia, and the head of the fibula. On each side of the patella it is strengthened by transverse fibres from the lower parts of the Vasti, which are attached to and support this bone; of these fibres the lateral are the stronger and are continuous with the iliotibial tract. The fascia lata gives off two intermuscular septa, which are attached to the whole length of the linea aspera of the femur and its prolongations above and below: the lateral and stronger septum, which extends from the insertion of the Gluteus maximus to the lateral condyle, separates the Vastus lateralis in front from the short head of the Biceps femoris behind, and gives partial origin to these muscles; the medial and thinner septum separates the Vastus medialis from the Adductors and the Pectineus. Besides these there are numerous smaller septa, separating the individual muscles and enclosing each in a distinct sheath.

The saphenous opening (fossa ovalis) (fig. 639).—At the upper and medial part of the thigh, a little below the medial end of the inguinal ligament, the fascia lata presents a large oval aperture; it transmits the long saphenous vein and other smaller vessels, and is termed the *saphenous opening*. The cribriform fascia, which is pierced by the structures passing through the opening, covers the aperture and must be removed to expose it. The fascia lata in this part of the thigh is described as consisting of a superficial and a deep portion.

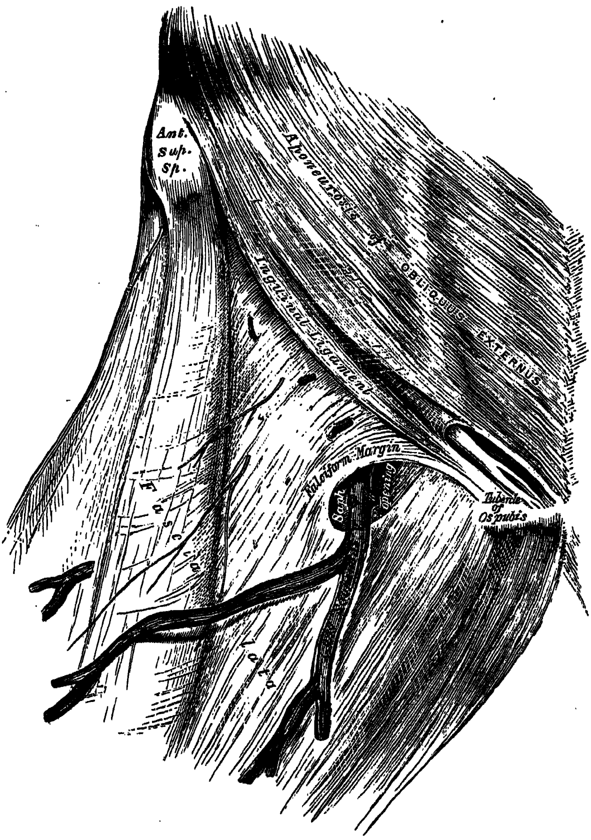
The *superficial portion* of the fascia lata is the part on the lateral side of the saphenous opening. It is attached to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pectineal line of the pubis (pecten pubis) in conjunction with the pectineal part of the inguinal ligament (lacunar ligament). From the pubic tubercle it is reflected downwards and laterally, as the arched *falciform margin*, which forms the anterior, lateral and lower boundaries of the saphenous opening (fig. 639); this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels, and the cribriform fascia is attached to it. The upward and medial prolongation of the falciform margin is named the *superior cornu*; its downward and medial prolongation, the *inferior cornu*. The latter is well defined, and is continuous behind the long saphenous vein with the deep portion of the fascia.

The *deep portion* is situated on the medial side of the saphenous opening, and is continuous with the superficial portion at the lower margin of the fossa; traced upwards, it covers the Pectineus, Adductor longus and Gracilis, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the iliopectineal fascia, and is attached to the pectineal line of the pubis.

From this description it may be observed that the superficial portion of the fascia lata lies in front of the femoral vessels, and the deep portion behind them, so that an apparent aperture (the saphenous opening) exists between the two.

The **Tensor fasciæ latæ** (fig. 638) arises from the anterior 5 cm. of the outer lip of the iliac crest; from the outer surface of the anterior superior iliac spine, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius; and from the deep surface of the fascia lata. It is inserted between the two layers of the iliotibial tract of the fascia lata about the junction of the middle with the upper one-third of the thigh.

FIG. 639.—The right saphenous opening (fossa ovalis).



Nerve-supply.—The Tensor fasciæ latæ is supplied by the superior gluteal nerve (L. 4 and 5 and S. 1).

Actions.—The Tensor fasciæ latæ tightens the fascia lata and so assists in extension of the knee; it assists also in abduction and in medial rotation of the thigh. In the erect posture, acting from below, it serves to steady the pelvis on the head of the femur; through the iliotibial tract it steadies the condyles of the femur on the tibia and helps to maintain the erect attitude by keeping the knee extended.

The **Sartorius** (figs. 638, 640, 642), which is the longest muscle in the body, is narrow and ribbon-like; it arises by tendinous fibres from the anterior superior iliac spine and the upper one-half of the notch below it. It crosses the upper and anterior parts of the thigh obliquely, from the lateral to the medial side, then descends vertically as far as the medial side of the knee, where a thin, flattened tendon replaces the fleshy belly. This tendon curves obliquely forwards and expands into a broad aponeurosis which is inserted, in front of the Gracilis and Semitendinosus, into the upper part of the medial surface of the shaft of the tibia (fig. 468). The upper part of the aponeurosis is curved backwards over

the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset, from its upper margin, blends with the capsule of the knee-joint, and another, from its lower border, with the fascia on the medial side of the leg.

The relations of this muscle to the femoral artery are important, as it constitutes the chief guide in tying the vessel. In the upper one-third of the thigh it forms the lateral side of the *femoral triangle*, the medial side of which is formed by the medial border of the Adductor longus, and the base by the inguinal ligament; the femoral artery passes through the middle of this triangle from its base to its apex. In the middle one-third of the thigh, the femoral artery is contained in the subsartorial canal (*adductor canal*), on the roof of which the Sartorius lies (fig. 642).

Nerve-supply.—The Sartorius is supplied by the femoral nerve (L. 2 and 3).

Actions.—The Sartorius flexes the leg on the thigh, and the thigh on the pelvis; it also abducts the thigh and rotates it laterally. Acting from below it flexes the pelvis on the thigh and rotates it towards the opposite side.

The **Quadriceps femoris** (figs. 638, 640, 642) is the great extensor muscle of the leg, and consists of a large fleshy mass which covers the front and sides of the femur. It is subdivided into separate portions, which have received distinctive names. One occupies the middle of the thigh, and arises from the ilium; from its straight course it is called the *Rectus femoris*. The other three take origin from the body of the femur, which they cover from the trochanters to the condyles; that on the lateral side of the femur is termed the *Vastus lateralis*; that on the medial side, the *Vastus medialis*; and that in front, the *Vastus intermedius*.

The **Rectus femoris** (figs. 638, 640, 642) is fusiform in shape, and its superficial fibres are arranged in a bipennate manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendinous heads: a straight head from the anterior inferior iliac spine, and a reflected head, from a groove above the brim of the acetabulum. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downwards on the anterior surface of the muscle, and from this the muscular fibres arise. The muscle ends in a broad and thick aponeurosis which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the base of the patella.

The **Vastus lateralis** (figs. 638, 640, 642) is the largest part of the Quadriceps femoris. It arises by a broad aponeurosis, which is attached to the upper part of the trochanteric line, to the anterior and inferior borders of the greater trochanter, to the lateral lip of the gluteal tuberosity, and to the upper one-half of the lateral lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its deep surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the lateral intermuscular septum between the Vastus lateralis and short head of the Biceps femoris. The fibres form a large fleshy mass which is attached to a strong aponeurosis placed on the deep surface of the lower part of the muscle: this aponeurosis contracts into a flat tendon which is inserted into the lateral border of the patella, blending with the Quadriceps femoris tendon. It gives to the capsule of the knee-joint an expansion which extends downwards to be attached to the lateral condyle of the tibia and blends with the iliotibial tract.

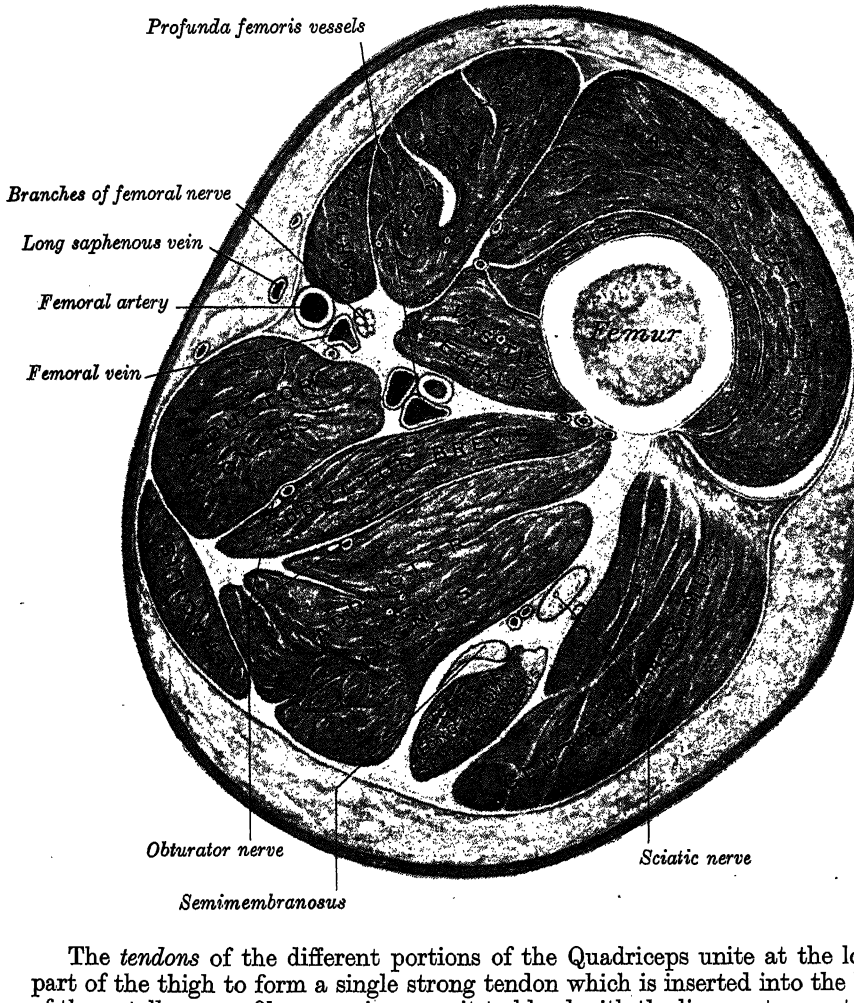
The Vastus medialis and Vastus intermedius appear to be inseparably united, but when the Rectus femoris has been reflected a narrow interval will be observed extending upwards from the medial border of the patella between the two muscles, and the separation may be carried to the lower part of the trochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus medialis** (figs. 638, 640, 642) arises from the lower part of the trochanteric line, the spiral line, the medial lip of the linea aspera, the upper part of the medial supracondylar line, the tendons of the Adductor longus and Adductor magnus, and the medial intermuscular septum. Its fibres are directed downwards and forwards, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the medial border of the

patella and the Quadriceps femoris tendon. An expansion from this tendon reinforces the capsule of the knee-joint and is attached below to the medial condyle of the tibia.

The **Vastus intermedius** (figs. 640, 642) arises from the front and lateral surfaces of the upper two-thirds of the shaft of the femur, and from the lower part of the lateral intermuscular septum. Its fibres end in a superficial aponeurosis which forms the deep part of the Quadriceps femoris tendon and, in addition, gains attachment to the lateral border of the patella and the lateral condyle of the tibia.

FIG. 640.—A transverse section through the thigh at the level of the apex of the femoral triangle. Four-fifths of natural size.



The *tendons* of the different portions of the Quadriceps unite at the lower part of the thigh to form a single strong tendon which is inserted into the base of the patella, some fibres passing over it to blend with the ligamentum patellæ. The patella may be regarded as a sesamoid bone developed in the tendon of the Quadriceps; and the ligamentum patellæ, which is continued from the apex of the patella to the tubercle of the tibia, may be regarded as the proper tendon of insertion of the muscle, the medial and lateral patellar retinacula (p. 493) being expansions from its borders. The suprapatellar bursa, which usually communicates with the cavity of the knee-joint, is situated between the femur and the portion of the Quadriceps tendon above the patella; the deep infrapatellar bursa is interposed between the ligamentum patellæ and the upper part of the front of the tibia (fig. 560).

The **Articularis genus** is a small muscle, usually distinct from the Vastus intermedius, but occasionally blended with it; it consists of several muscular

bundles which arise from the anterior surface of the lower part of the shaft of the femur and are inserted into the upper part of the synovial membrane of the knee-joint.

Nerve-supply.—The Quadriceps femoris and the Articularis genus are supplied by the femoral nerve (L. *2*, 3 and 4).

Actions.—The Quadriceps femoris extends the leg upon the thigh. The Rectus femoris assists the Psoas major and Iliacus in supporting the pelvis and trunk upon the femur; it also assists in flexing the thigh on the pelvis, or, if the thigh be fixed, it helps to flex the pelvis. The Vastus medialis draws the patella medially as well as upwards. The Articularis genus pulls the synovial membrane of the knee-joint upwards during extension of the leg.

2. The Medial Femoral Muscles

Gracilis.	Adductor longus.	Adductor magnus.
Pectineus.	Adductor brevis.	

The **Gracilis** (figs. 638, 640, 642) is the most superficial muscle on the medial side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis from the medial margins of the lower one-half of the body of the pubis and the upper one-half of the inferior ramus. The fibres run vertically downwards, and end in a rounded tendon which passes across the medial condyle of the femur posterior to the tendon of Sartorius. It then curves round the medial condyle of the tibia, where it becomes flattened, and is inserted into the upper part of the medial surface of the shaft of the tibia, below the condyle. A few fibres from the lower part of the tendon are prolonged into the deep fascia of the leg. At its insertion the tendon is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. It is separated from the medial (tibial collateral) ligament of the knee-joint by the tibial intertendinous bursa (p. 499).

Nerve-supply.—The Gracilis is supplied by the obturator nerve (L. *2*, 3 and 4).

Actions.—The Gracilis flexes the leg and rotates it medially; it may also act as an adductor of the thigh, when necessary.

The **Pectineus** (fig. 638) is a flat, quadrangular muscle, situated at the front of the upper and medial part of the thigh. It arises from the pectineal line of the pubis, and to a slight extent from the surface of bone in front of it, between the iliopubic eminence (iliopectineal eminence) and pubic tubercle, and from the fascia covering the anterior surface of the muscle; the fibres pass downwards, backwards and laterally, to be inserted into the femur along a line leading from the lesser trochanter to the linea aspera.*

Relations.—Its *anterior surface* is in relation with the fascia lata, which separates it from the femoral vessels and long saphenous vein; its *posterior surface*, with the capsule of the hip-joint, the Adductor brevis, Obturator externus and the anterior branch of the obturator nerve; its *lateral border*, with the Psoas major and the medial circumflex femoral vessels; its *medial border*, with the upper or lateral margin of the Adductor longus.

Nerve-supply.—The Pectineus is supplied by the femoral nerve (L. 2 and 3); and by the accessory obturator (L. 3), when this nerve is present. Occasionally it receives a branch from the obturator nerve.

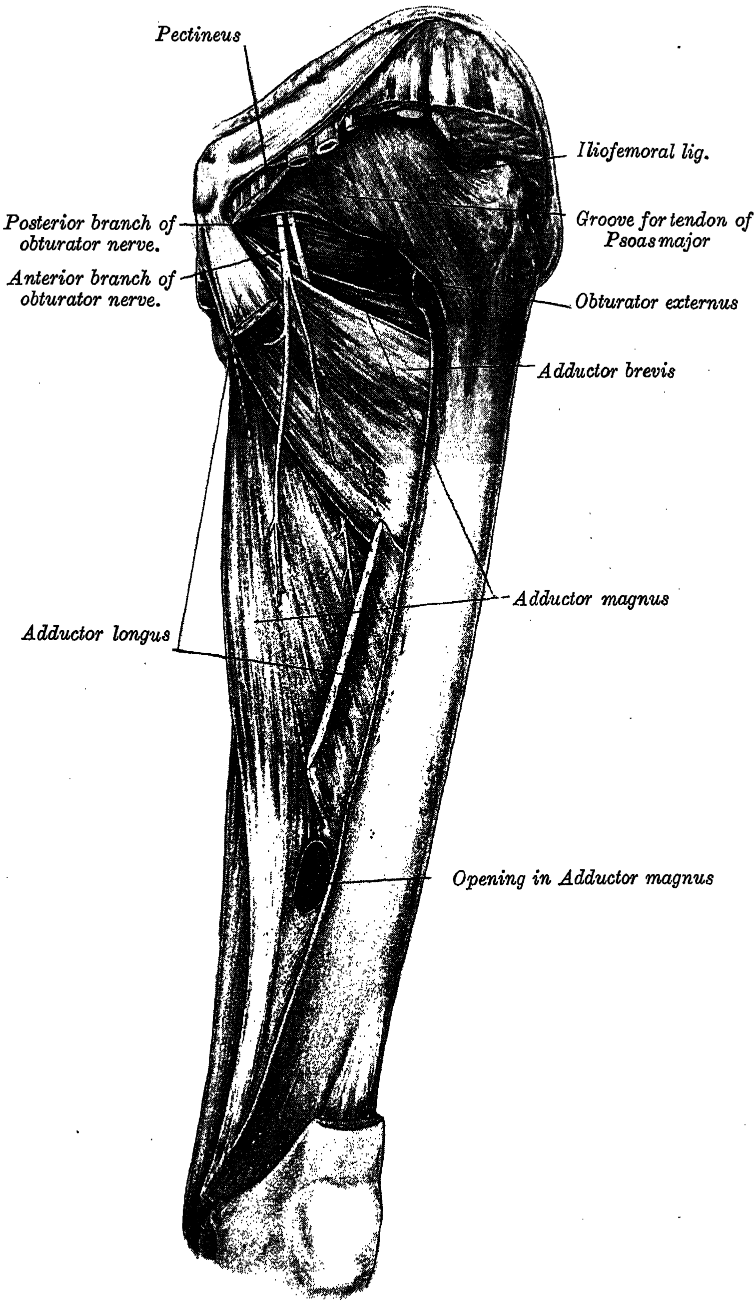
Actions.—The Pectineus adducts the thigh and flexes it on the pelvis.

The **Adductor longus** (figs. 641, 642), the most superficial of the three adductors, is a triangular muscle, lying in the same plane as the Pectineus. It arises by a flat, narrow tendon which is attached to the front of the pubis in the angle between the crest and the symphysis. It soon expands into a broad fleshy belly which passes downwards, backwards, and laterally, and is inserted, by an

* The Pectineus may consist of two incompletely separated strata: the lateral or dorsal stratum, which is constant, is supplied by a branch from the femoral nerve, or in the absence of this branch by the accessory obturator nerve; the medial or ventral stratum, when present, is a derivative of the adductor group of muscles and is supplied by the obturator nerve.—A. M. Paterson, *Journal of Anatomy and Physiology*, vol. xxvi. p. 43.

aponeurosis, into the middle one-third of the linea aspera of the femur, between the Vastus medialis and the Adductor magnus, with both of which it is usually blended.

Fig. 641.—The adductor muscles of the left thigh.



A portion of the Adductor longus has been excised, and the two heads of the Rectus femoris, which are not labelled, have been divided above the point where they unite.

Relations.—Its *anterior surface* is in relation with the spermatic cord, the fascia lata, by which it is separated from the long saphenous vein, and, near its insertion, with the femoral artery and vein and the Sartorius: its *posterior surface*, with the Adductores brevis et magnus, the anterior branch of the obturator nerve, and near its insertion with the

profunda femoris vessels; its *lateral border*, with the Pectineus; its *medial border*, with the Gracilis.

Nerve-supply.—The Adductor longus is supplied by the anterior division of the obturator nerve (L. 2 and 3).

Actions.—The Adductor longus adducts the thigh, flexes it on the pelvis, and rotates it laterally.

Applied Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or it may be ruptured by suddenly gripping the saddle. Occasionally, especially in cavalry soldiers, the tendon of origin becomes ossified, constituting the 'rider's bone.'

The **Adductor brevis** (figs. 640, 641) is situated behind the Pectineus and Adductor longus. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the inferior ramus of the pubis, between the Gracilis and Obturator externus. Its fibres, passing backwards, laterally, and downwards, are inserted by an aponeurosis into the femur, along the line leading from the lesser trochanter to the linea aspera, and into the upper part of the linea aspera immediately behind the Pectineus and the upper part of the Adductor longus.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductor longus, arteria profunda femoris, and anterior branch of the obturator nerve; its *posterior surface*, with the Adductor magnus, and posterior branch of the obturator nerve; its *upper border*, with the medial circumflex femoral artery, the Obturator externus, and conjoined tendon of the Psoas major and Iliacus; its *lower* or *medial border*, with the Gracilis and Adductor magnus. It is pierced near its insertion by the second, or first and second, perforating arteries.

Nerve-supply.—The Adductor brevis is supplied by the obturator nerve (L. 2, 3 and *4*).

Actions.—The Adductor brevis adducts the thigh, flexes it on the pelvis and rotates it laterally.

The **Adductor magnus** (figs. 640, 641, 642) is a large triangular muscle, situated on the medial side of the thigh. It arises from a small part of the inferior ramus of the pubis, from the ramus of the ischium, and from the lateral portion of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the pubis are short, horizontal in direction, and are inserted into the medial margin of the gluteal tuberosity of the femur, medial to the Gluteus maximus *; those from the ramus of the ischium are directed downwards and laterally with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of the medial supracondylar line. The medial portion of the muscle, composed principally of the fibres arising from the tuberosity of the ischium, forms a thick fleshy mass which descends almost vertically, and ends about the lower one-third of the thigh in a rounded tendon. This tendon is inserted into the adductor tubercle on the medial condyle of the femur, and is connected by a fibrous expansion to the medial supracondylar line. At the insertion of the muscle, there is a series of osseo-aponeurotic openings, formed by tendinous arches attached to the bone. The upper four openings are small, and give passage to the perforating branches of the arteria profunda femoris. The lowest is of large size, and transmits the femoral vessels to the popliteal fossa.

Relations.—Its *anterior surface* is in relation with the Pectineus, Adductores brevis et longus, the femoral and profunda vessels, and the posterior branch of the obturator nerve; a bursa intervenes between the highest part of the muscle and the lesser trochanter of the femur; its *posterior surface*, with the sciatic nerve, the Gluteus maximus, Biceps femoris, Semitendinosus and Semimembranosus. Its *superior border* lies parallel with the Quadratus femoris, the transverse branch of the medial circumflex femoral artery passing between them; its *medial border* is in relation with the Gracilis, Sartorius and fascia lata.

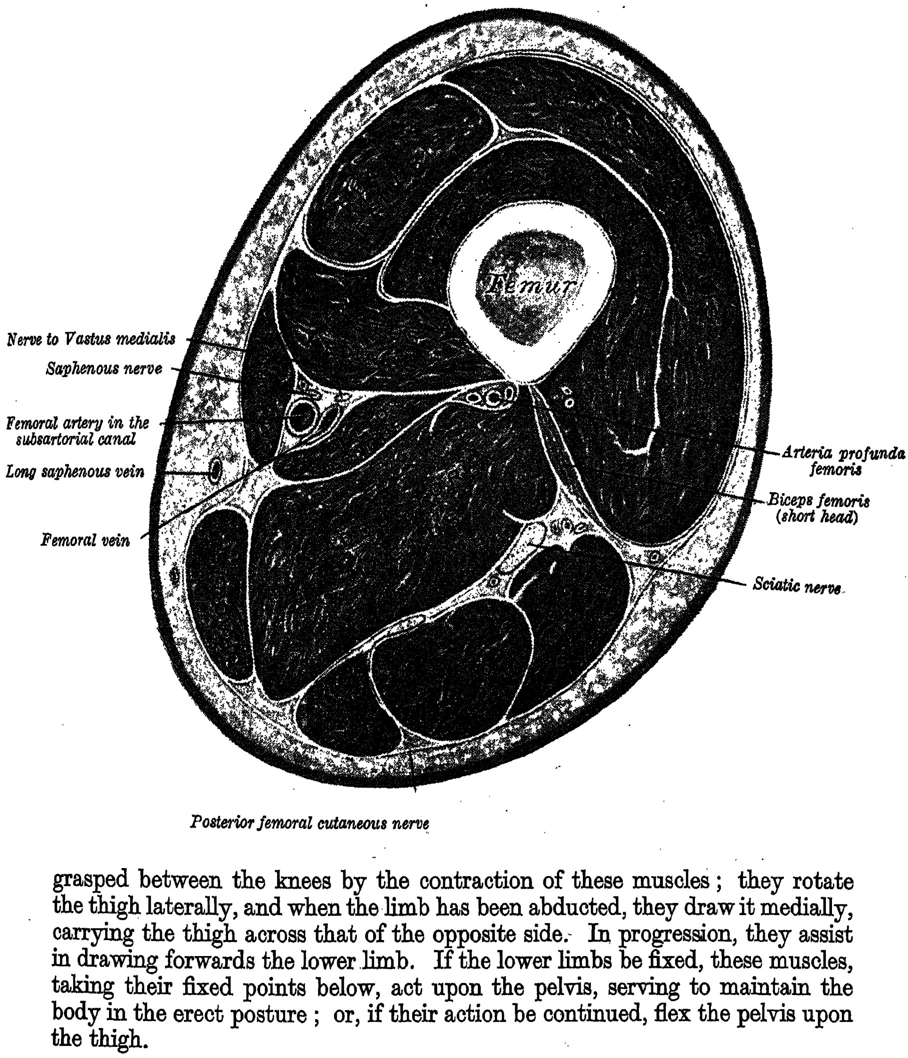
Nerve-supply.—The Adductor magnus is a composite muscle and derives its nerve-supply from two sources. The true adductor part of the muscle is

* These uppermost fibres are sometimes described as a separate muscle—the *Adductor minimus*—which is situated somewhat in front of the other parts of the muscle.

supplied by the obturator nerve (L. 3 and 4); the part which takes origin from the tuberosity of the ischium is a derivative of the hamstring muscles and is supplied by the sciatic nerve (L. 4 and 5).

Actions.—The Adductor magnus adducts the thigh and rotates it laterally; the pubic fibres flex the thigh on the pelvis, but the ischial fibres have the opposite action. The Pectineus and the Adductores adduct the thigh powerfully; they are especially used in horse exercise, the sides of the saddle being

FIG. 642.—A transverse section through the middle of the thigh. Four-fifths of natural size.



grasped between the knees by the contraction of these muscles; they rotate the thigh laterally, and when the limb has been abducted, they draw it medially, carrying the thigh across that of the opposite side. In progression, they assist in drawing forwards the lower limb. If the lower limbs be fixed, these muscles, taking their fixed points below, act upon the pelvis, serving to maintain the body in the erect posture; or, if their action be continued, flex the pelvis upon the thigh.

3. The Muscles of the Gluteal Region (figs. 643, 644)

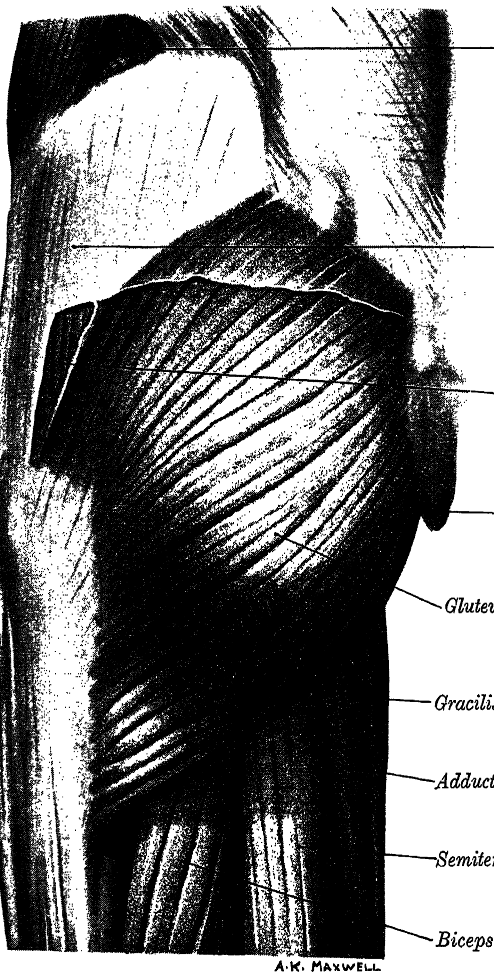
Gluteus maximus.	Obturator internus.
Gluteus medius.	Gemellus superior.
Gluteus minimus.	Gemellus inferior.
Piriformis.	Quadratus femoris.

Obturator externus.

The **Gluteus maximus** (fig. 643) is the largest and most superficial muscle in the gluteal region. It is a broad and thick fleshy mass of a quadrilateral shape,

and forms the prominence of the buttock. Its large size is one of the most characteristic features of the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect position. The muscle is remarkably coarse in structure, being made up of fasciculi lying parallel with one another, and collected into large bundles separated by fibrous septa. It arises from the posterior gluteal line of the ilium, and the rough portion of bone, including the crest, immediately above and behind it; from the aponeurosis of the Sacrospinalis; from the posterior surface of the lower part of the sacrum and the side of the coccyx; from the sacrotuberous ligament, and from the

FIG. 643.—The left Gluteus maximus muscle.



A portion of the strong gluteal fascia has been removed to expose the Gluteus medius.

fascia (gluteal aponeurosis) covering the Gluteus medius. The fibres run obliquely downwards and laterally; those forming the upper and larger portion of the muscle, together with the superficial fibres of the lower portion, end in a thick tendinous lamina which passes across the greater trochanter, and is inserted into the iliotibial tract of the fascia lata; the deeper fibres of the lower portion of the muscle are inserted into the gluteal tuberosity of the femur between the Vastus lateralis and Adductor magnus.

Three *bursæ* are usually found in relation with the deep surface of this muscle. One, of large size (*trochanteric bursa of Gluteus maximus*), and generally multilocular, separates it from the greater trochanter; a second is found between

the tendon of the muscle and that of the Vastus lateralis (*gluteofemoral bursa*); a third, often wanting (*ischial bursa of Gluteus maximus*), is situated on the tuberosity of the ischium.

Relations.—Its *superficial surface* is in relation with a thin fascia which separates it from the subcutaneous tissue; its *deep surface*, with the ilium, sacrum, coccyx, and sacrotuberous ligament, part of the Gluteus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, greater trochanter, the origins of the Biceps femoris, Semitendinosus, Semimembranosus and the Adductor magnus. The superficial part of the superior gluteal artery reaches the deep surface of the muscle by passing between the Piriformis and the Gluteus medius; the inferior gluteal and internal pudendal vessels and the sciatic, pudendal, and posterior femoral cutaneous nerves and muscular branches from the sacral plexus, issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also found under cover of the lower part of the muscle. Its *upper border* is thin, and overlies the Gluteus medius. Its *lower border* is free and prominent, and is crossed by the fold of the nates.

Nerve-supply.—The Gluteus maximus is supplied by the inferior gluteal nerve (L. 5 and S. 1 and 2).

Actions.—When the Gluteus maximus takes its fixed point from the pelvis, it extends the thigh and brings it into line with the trunk. Taking its fixed point below, it supports the pelvis and the trunk upon the head of the femur. Its most powerful action is to raise the trunk after stooping by drawing the pelvis backwards. It is a tensor of the fascia lata, and through the iliotibial tract it steadies the femur on the tibia during standing, when the extensor muscles are relaxed.

The **Gluteus medius** is a broad, thick muscle which is situated on the outer surface of the pelvis. Its posterior one-third is covered by the Gluteus maximus; its anterior two-thirds is superficial and is covered only by a strong layer of deep fascia (fig. 643). It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line above, and the middle gluteal line below; it also arises from the strong fascia which covers the upper part of its outer surface. The fibres converge to a flattened tendon which is inserted into the oblique ridge directed downwards and forwards on the lateral surface of the greater trochanter of the femur. A bursa (*trochanteric bursa of Gluteus medius*) separates the tendon from the anterosuperior part of the lateral surface of the trochanter, over which it glides.

The **Gluteus minimus** (fig. 644), the smallest of the Glutei, is placed immediately under cover of the preceding. It is fan-shaped, arising from the outer surface of the ilium between the middle and inferior gluteal lines, and, behind, from the margin of the greater sciatic notch. The fibres converge to the deep surface of an aponeurosis, and this ends in a tendon which is inserted into a ridge on the lateral part of the anterior surface of the greater trochanter of the femur, and gives an expansion to the capsule of the hip-joint. A bursa (*trochanteric bursa of Gluteus minimus*) is interposed between the tendon and the medial part of the anterior surface of the greater trochanter.

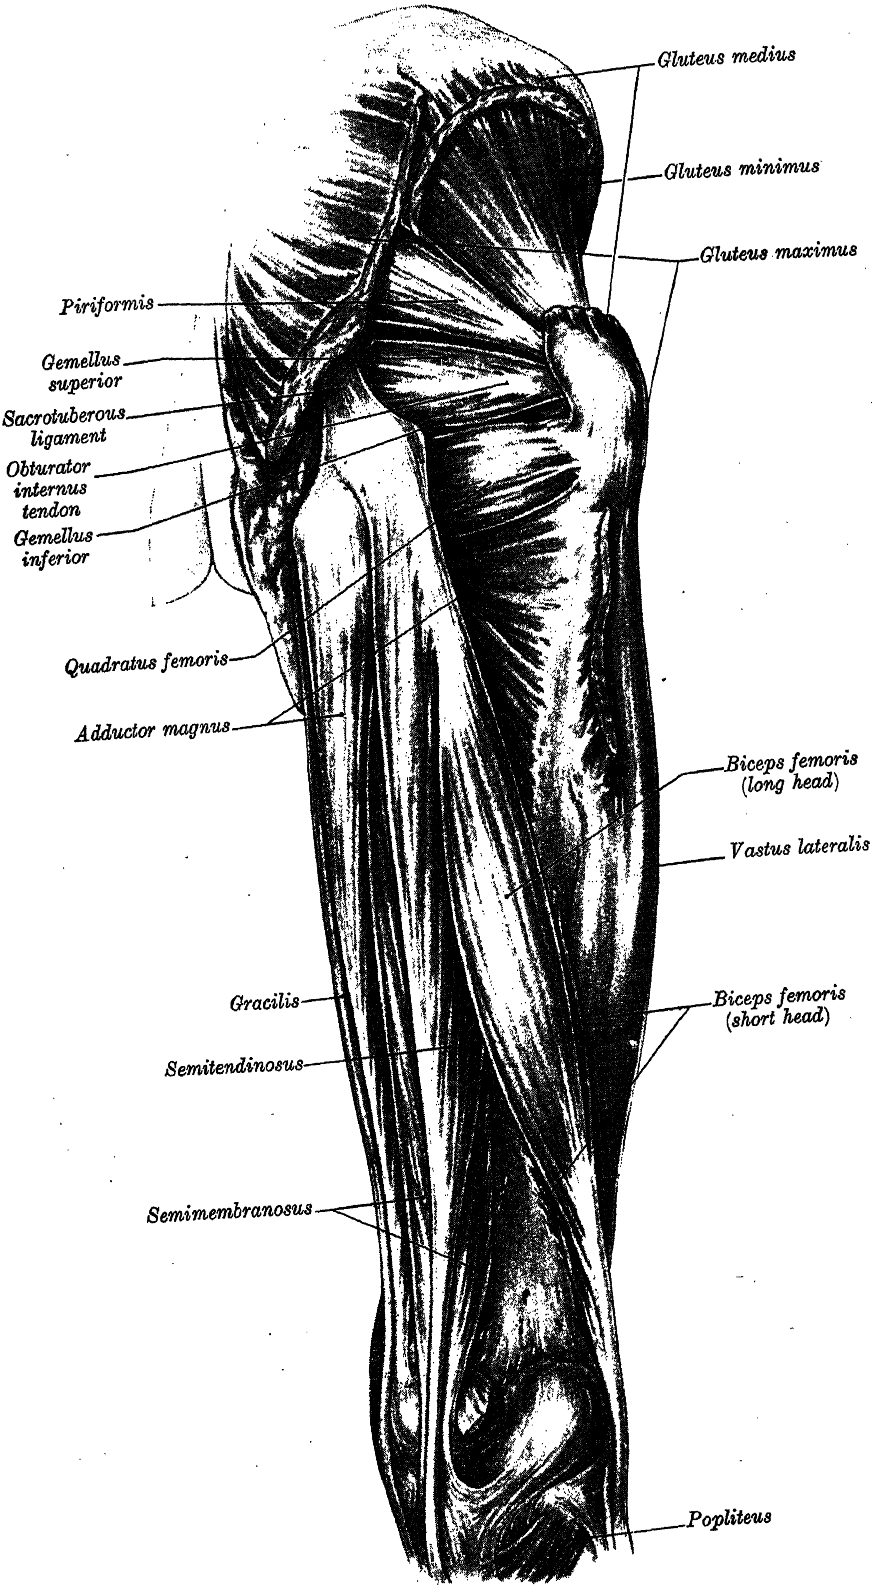
Between the Gluteus medius and Gluteus minimus are the deep branches of the superior gluteal vessels, and the superior gluteal nerve. The reflected tendon of the Rectus femoris and the capsule of the hip-joint are placed deep to the Gluteus minimus.

Nerve-supply.—Both the Gluteus medius and the Gluteus minimus are supplied by the superior gluteal nerve (L. 4 and 5 and S. 1).

Actions.—Both the preceding muscles, acting from the pelvis, abduct the thigh and rotate it medially. Acting from the femur, they produce the slight rotation of the pelvis which occurs in walking and running, and keep the transverse axis of the pelvis horizontal, or nearly horizontal, while the opposite limb is unsupported, e.g. when the foot is off the ground in walking or running.

The **Piriformis** (fig. 644) lies almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis on its posterior wall, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the anterior sacral foramina, and to the grooves leading from the foramina (fig. 276): a few

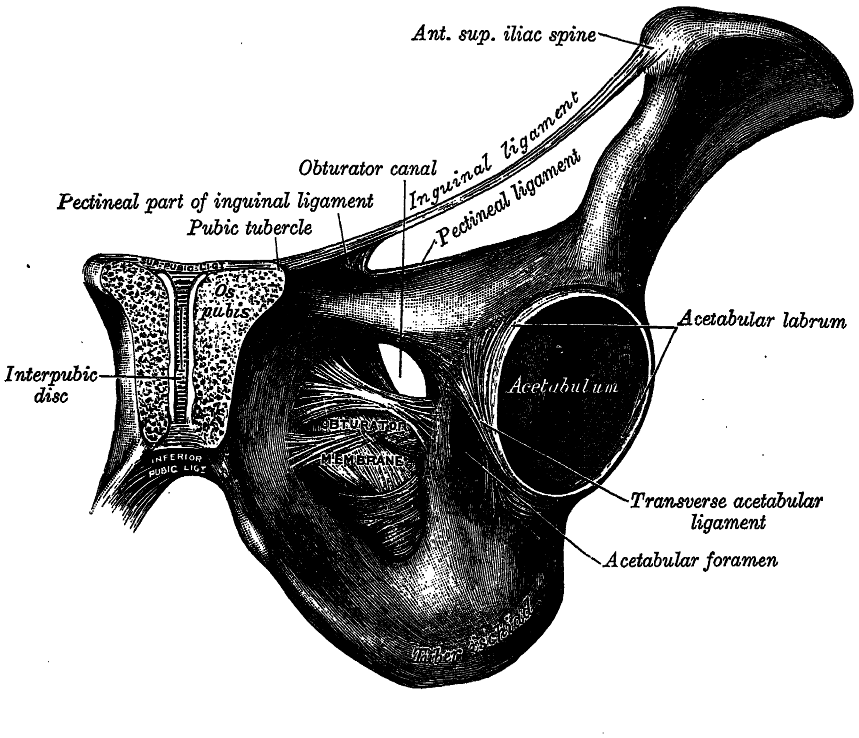
Fig. 644.—The muscles of the gluteal region and the posterior muscles of the thigh. Right side.



fibres also arise from the margin of the greater sciatic foramen, and from the upper part of the anterior surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, and is inserted by a rounded tendon into the upper border of the greater trochanter of the femur, behind and above, but often partly blended with, the common tendon of the Obturator internus and Gemelli.

Relations.—*Within the pelvis* the *anterior surface* of the Piriformis is in relation with the rectum (especially on the left side), the sacral plexus of nerves and branches of the internal iliac vessels; its *posterior surface*, with the sacrum. *Outside the pelvis*, its *anterior surface* is in contact with the posterior surface of the ischium and capsule of the hip-joint; and its *posterior surface*, with the Gluteus maximus. Its *upper border* is in relation with the Gluteus medius, and the superior gluteal vessels and nerve; its *lower border*, with the Coccygeus and Gemellus superior. The inferior gluteal and internal pudendal vessels, and

Fig. 645.—The left Obturator membrane. External surface.



the sciatic, posterior femoral cutaneous and pudendal nerves, and muscular branches from the sacral plexus, appear in the buttock between the Piriformis and Gemellus superior. The muscle is frequently pierced by the lateral popliteal (common peroneal nerve).

Nerve-supply.—The Piriformis is supplied by twigs from the first and second sacral nerves.

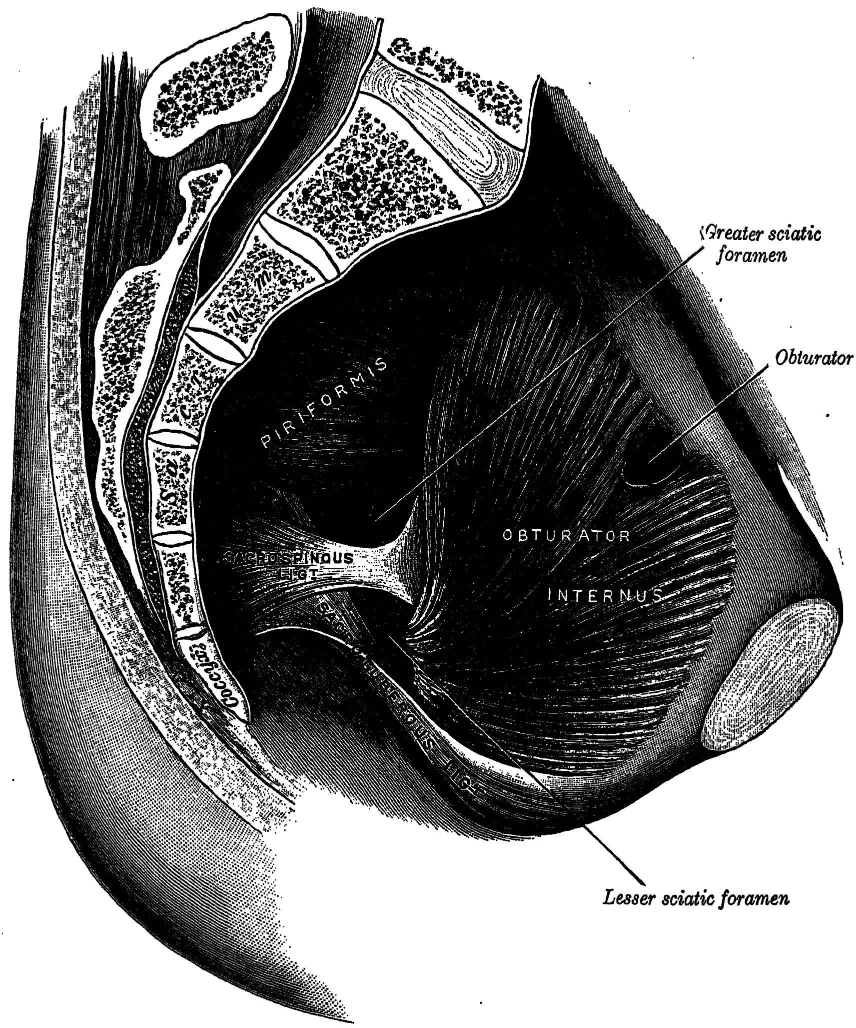
Actions.—The Piriformis rotates the thigh laterally.

The **obturator membrane** (fig. 645) is a thin, fibrous sheet which nearly closes the obturator foramen. Its fibres are arranged in interlacing bundles mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal for the passage of the obturator vessels and nerve. The membrane is attached to the sharp margin of the obturator foramen except at its lower lateral angle, where it is fixed to the pelvic surface of the ramus of the ischium, i.e. within the margin of the foramen. Both Obturator muscles take origin from this membrane, and some of the fibres of the pubofemoral ligament of the hip-joint are attached to its inferior surface.

The **Obturator internus** (fig. 646) is situated partly within the true pelvis,

and partly at the back of the hip-joint. It arises from the inner surface of the anterolateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the inferior ramus of the pubis, the ramus of the ischium and to the inner surface of the hip-bone below and behind the pelvic brim, reaching from the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front (fig. 440). It also arises from the medial part of the pelvic surface of the obturator membrane,

FIG. 646.—The left Obturator internus. Pelvic surface.



from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve, and to a slight extent from the obturator fascia, which covers the muscle. The fibres converge rapidly towards the lesser sciatic foramen and end in four or five tendinous bands in the deep surface of the muscle; these bands make a right-angled bend over the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered by smooth cartilage, which is separated from the tendon by a bursa, and presents one or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite into a single flattened tendon, which passes horizontally across the capsule of the hip-joint, and, after receiving the attachments of the Gemelli, is inserted into the fore part of the medial surface of the greater trochanter of the femur,

above and in front of the trochanteric fossa. A bursa, narrow and elongated in form, is usually found between the tendon and the capsule of the hip-joint; it occasionally communicates with the bursa between the tendon and the ischium.

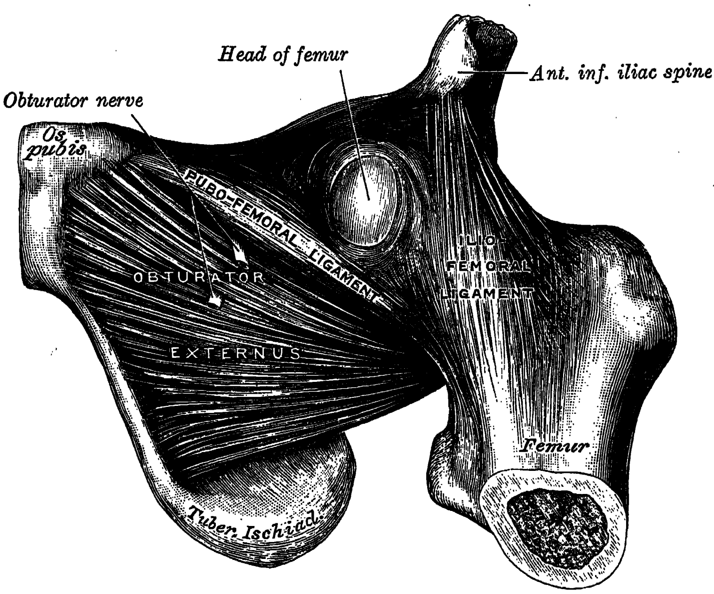
Relations.—*Within the pelvis,* the *anterolateral surface* of the muscle is in relation with the obturator membrane and inner surface of the lateral wall of the pelvis; its *pelvic surface,* with the obturator fascia, and the origin of the Levator ani, and with the internal pudendal vessels and pudendal nerve, which cross it. The pelvic surface forms the lateral boundary of the ischiorectal fossa. *Outside the pelvis,* the muscle is covered by the Gluteus maximus, is crossed by the sciatic nerve, and rests on the back of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sciatic foramen it is overlapped both in front and behind by the two Gemelli, which form a muscular canal for it; near its insertion the Gemelli pass in front of the tendon and form a groove in which it lies.

Nerve-supply.—The nerve to Obturator internus derives its fibres from L. 5 and S. 1 and 2.

The **Gemelli** (fig. 644) are two small muscular fasciculi, accessories to the tendon of the Obturator internus.

The **Gemellus superior,** the smaller of the two, arises from the outer surface

FIG. 647.—The left Obturator externus.



of the spine of the ischium, blends with the upper part of the tendon of the Obturator internus, and is inserted with it into the medial surface of the greater trochanter of the femur. It is sometimes wanting.

Nerve-supply.—The Gemellus superior is supplied by the nerve to the Obturator internus (L. 5 and S. 1 and 2).

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, immediately below the groove for the Obturator internus tendon. It blends with the lower part of the tendon of the Obturator internus, and is inserted with it into the medial surface of the greater trochanter.

Nerve-supply.—The Gemellus inferior is supplied by the nerve to the Quadratus femoris (L. 4 and 5 and S. 1).

Actions.—The Obturator internus and the Gemelli rotate the thigh laterally.

The **Quadratus femoris** (fig. 644) is a flat, quadrilateral muscle, between the Gemellus inferior and the upper margin of the Adductor magnus; it is separated from the latter by the transverse branch of the medial circumflex femoral artery. It arises from the upper part of the external border of the tuberosity of the ischium, and is inserted into a small tubercle on the upper part of the trochanteric crest of the femur, and for a short distance into the bone below. As it passes to its insertion the muscle lies posterior to the articular capsule

of the hip-joint and the neck of the femur, but it is separated from them by the tendon of the Obturator externus and the ascending branch of the medial circumflex femoral artery. A bursa is often found between the front of this muscle and the lesser trochanter.

Nerve-supply.—The nerve to Quadratus femoris derives its fibres from L. 4 and 5 and S. 1.

Action.—The Quadratus femoris is a lateral rotator of the thigh.

The **Obturator externus** (fig. 647) is a flat, triangular muscle which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone immediately around the medial side of the obturator foramen, viz. from the rami of the pubis, and the ramus of the ischium; it also arises from the medial two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres springing from the ramus of the ischium extend for a short distance on to the pelvic surface of the bone, where they obtain a narrow origin between the margin of the foramen and the attachment of the obturator membrane (p. 635). The fibres converge and pass backwards, laterally and upwards, and end in a tendon which runs across the back of the neck of the femur and lower part of the capsule of the hip-joint and is inserted into the trochanteric fossa of the femur. The obturator vessels lie between the muscle and the obturator membrane; the anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Nerve-supply.—The Obturator externus is supplied by the posterior branch of the obturator nerve (L. 3 and 4).

Action.—The Obturator externus is a lateral rotator of the thigh.

4. The Posterior Femoral Muscles (fig. 644)

Biceps femoris. Semitendinosus. Semimembranosus.

The **Biceps femoris** (figs. 640, 642, 644) is situated on the posterolateral surface of the thigh. It has two heads of origin: one, the long head, arises from the lower and medial impression on the upper part of the ischial tuberosity (fig. 442) by a tendon common to it and the Semitendinosus, and from the lower part of the sacrotuberous ligament; the other, the short head, from the lateral lip of the linea aspera of the femur, between the Adductor magnus and Vastus lateralis, extending up almost as high as the insertion of the Gluteus maximus; from the lateral supracondylar line to within 5 cm. of the lateral condyle; and from the lateral intermuscular septum. The fibres of the long head form a fusiform belly which passes downwards and laterally across the sciatic nerve to end in an aponeurosis; this aponeurosis covers the posterior surface of the muscle, receives on its deep surface the fibres of the short head, and gradually contracts into a tendon which is inserted into the lateral side of the head of the fibula, and by a small slip into the lateral condyle of the tibia. This tendon forms the lateral hamstring and divides into two portions, which embrace the lateral ligament of the knee-joint; from its posterior border a thin expansion is given off to the fascia of the leg. The lateral popliteal (common peroneal) nerve descends along the medial border of the tendon and separates it, below, from the lateral head of the gastrocnemius.

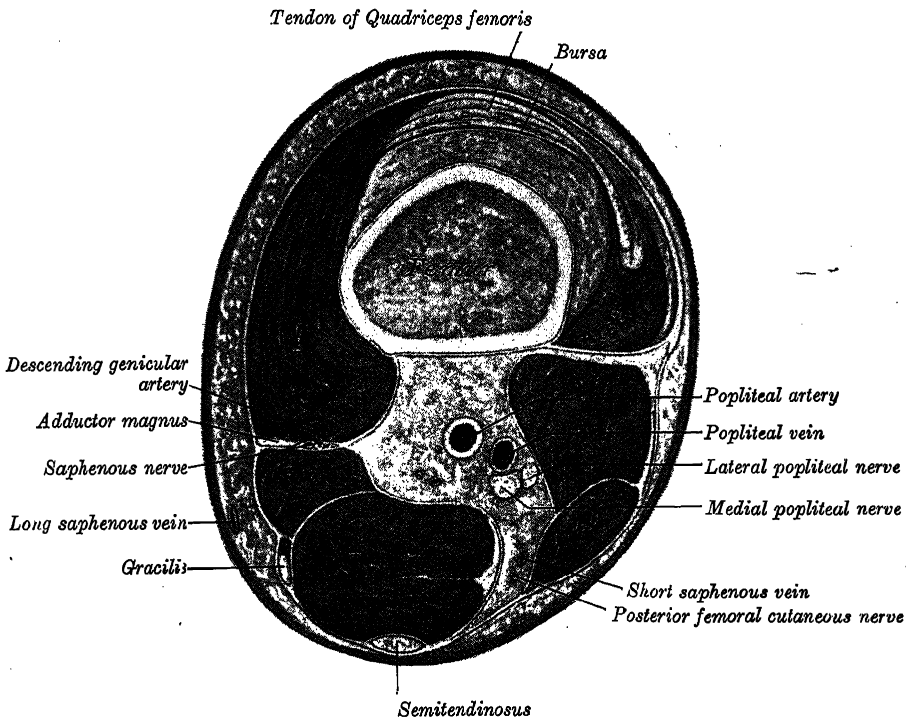
Nerve-supply.—The Biceps femoris is supplied by the sciatic nerve; the long head through the medial popliteal (tibial) nerve (L. 5 and S. 1), the short head through the lateral popliteal (common peroneal) nerve (S. 2 and S. 3).

Actions.—The Biceps femoris, acting from above, flexes the leg on the thigh, and when the knee is semiflexed rotates the leg slightly laterally. Acting from below, it serves to support the pelvis on the head of the femur and draws the trunk backwards as in raising it from the stooping position.

The **Semitendinosus** (figs. 642, 644), remarkable for the great length of its tendon of insertion, is situated at the posteromedial surface of the thigh. It arises from the lower and medial impression on the upper part of the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps femoris;

it also arises from an aponeurosis connecting the adjacent surfaces of the two muscles to the extent of about 7·5 cm. from their origin. The muscle is fusiform and ends a little below the middle of the thigh in a long, round tendon which lies on the surface of the Semimembranosus muscle ; the tendon curves around the medial condyle of the tibia, passes over the medial ligament of the knee-joint, from which it is separated by a bursa, and is inserted into the upper part of the medial surface of the shaft of the tibia behind the insertion of the Sartorius and below that of the Gracilis. At its insertion it is united with the tendon of the Gracilis and gives off a prolongation to the deep fascia of the leg. A tendinous intersection is usually observed about the middle of the muscle.

FIG. 648.—A transverse section through the thigh, 4 cm. above the adductor tubercle of the femur. Four-fifths of natural size.



Nerve-supply.—The Semitendinosus is supplied by the sciatic nerve through the medial popliteal (tibial) portion (L. *4* and 5 and S. 1 and *2*).

Actions.—Acting from above, it flexes the knee-joint and, when the joint is semiflexed, rotates the leg slightly medially. When its fixed point is below, its action is similar to that of the Biceps femoris.

The **Semimembranosus** (figs. 642, 644, 648), so called from its membranous tendon of origin, is situated at the back and medial side of the thigh. It arises by a thick tendon from the upper and lateral impression on the tuberosity of the ischium (fig. 442), above and lateral to the Biceps femoris and Semitendinosus, and is inserted into the groove on the back of the medial condyle of the tibia. The tendon of origin expands into an aponeurosis which passes downwards under cover of the Semitendinosus and long head of the Biceps femoris ; from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of the posterior surface of the muscle and contracts into the tendon of insertion. The tendon of insertion gives off certain fibrous expansions : one, of considerable size, passes upwards and laterally to be inserted into the intercondylar line and lateral condyle of the femur, forming the oblique posterior (oblique popliteal) ligament of the knee-joint ; a second is continued downwards to the fascia which covers the Popliteus muscle ; while a few fibres join the medial ligament of the knee-joint and the fascia of the leg. The

muscle overlaps the upper part of the popliteal vessels and is itself overlapped and partly hidden by the Semitendinosus muscle throughout its whole extent (fig. 644).

The tendons of insertion of the Semitendinosus and Semimembranosus form the medial hamstrings.

Nerve-supply.—The Semimembranosus is supplied by the sciatic nerve through the medial popliteal (tibial) portion (L. 4 and 5 and S. *1*).

Actions.—The actions of the Semimembranosus are similar to those of the Semitendinosus.

Applied Anatomy.—In disease of the knee-joint, contraction of the hamstring tendons is a frequent complication; this causes flexion of the leg, and a partial dislocation of the tibia backwards, with a slight degree of lateral rotation, probably due to the action of the Biceps femoris. The hamstring tendons occasionally require subcutaneous division. The relation of the lateral popliteal nerve, which lies in close apposition to the medial border of the tendon of the Biceps femoris, must always be borne in mind in dividing this tendon, and a free incision with exposure of the tendon, before division, is the safer proceeding.

III. The Muscles of the Leg

The muscles of the leg may be divided into three groups: anterior, posterior, and lateral.

1. The Anterior Crural Muscles (fig. 650)

Tibialis anterior.	Extensor digitorum longus.
Extensor hallucis longus.	Peroneus tertius.

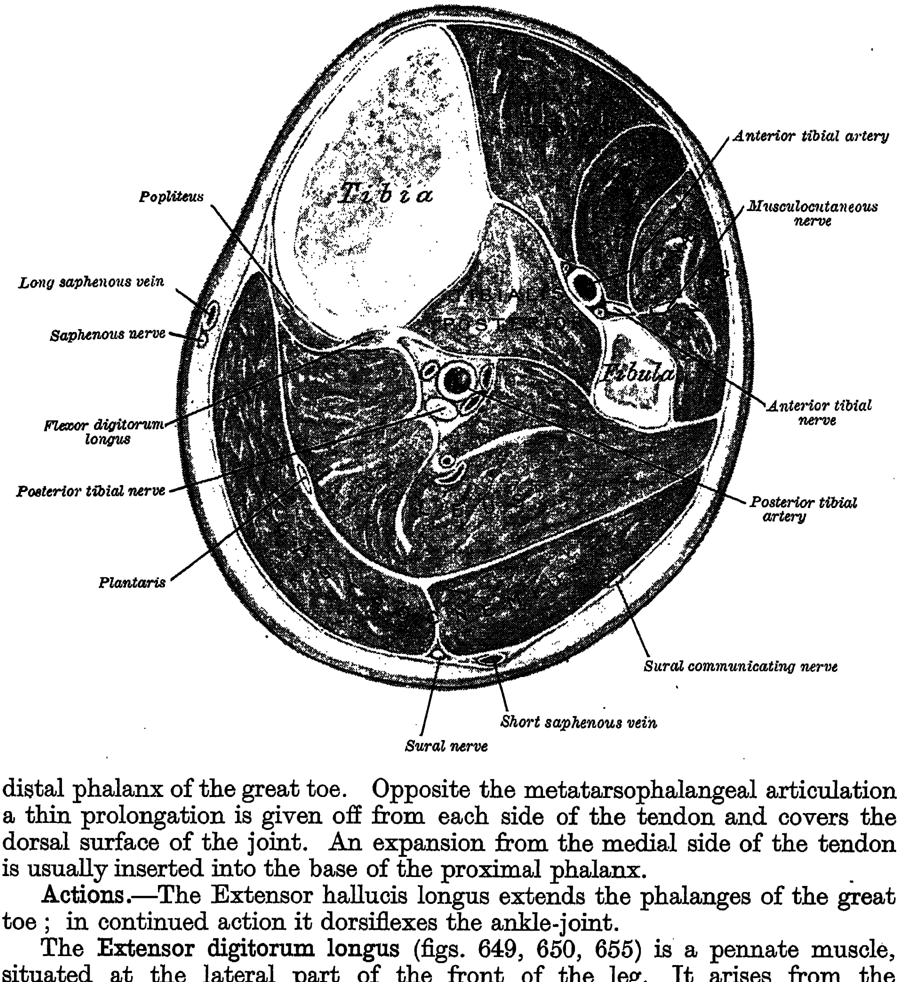
The **fascia cruris** or deep fascia of the leg is continuous above with the fascia lata, and is attached around the knee to the patella, the ligamentum patellæ, the tubercle and condyles of the tibia and the head of the fibula. Behind, it forms the popliteal fascia, which covers the popliteal fossa; here it is strengthened by transverse fibres, and perforated by the short saphenous vein. It receives an expansion from the tendon of the Biceps femoris laterally, and expansions from the tendons of the Sartorius, Gracilis, Semitendinosus and Semimembranosus medially; it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and malleolus of the fibula; below, it is continuous with the extensor and flexor retinacula (transverse crural and laciniate ligaments). It is thick and dense in the upper and anterior part of the leg, and gives origin, by its deep surface, to some fibres of the Tibialis anterior and Extensor digitorum longus; it is thinner behind, where it covers the Gastrocnemius and Soleus. On the lateral side of the leg it gives off the *anterior* and *posterior crural intermuscular septa*, which are attached respectively to the anterior and posterior borders of the fibula; in the anterior and posterior crural regions the fascia also gives off several slender processes which enclose the individual muscles. A broad, transverse, intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep muscles on the back of the leg.

The **Tibialis anterior** (figs. 649, 650) is situated on the lateral side of the tibia; it is thick and fleshy above, tendinous below. It arises from the lateral condyle and upper one-half or two-thirds of the lateral surface of the shaft of the tibia; from the adjoining part of the anterior surface of the interosseous membrane; from the deep surface of the fascia cruris; and from the intermuscular septum between it and the Extensor digitorum longus. The fibres run vertically downwards, and end in a tendon which is apparent on the anterior surface of the muscle at the lower one-third of the leg; it passes through the medial compartments of the superior and inferior extensor retinacula (transverse and cruciate crural ligaments), inclines towards the medial side of the foot, and is inserted into the medial and under surfaces of the medial cuneiform bone, and the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and nerve in the upper part of the leg.

Actions.—The Tibialis anterior is a dorsiflexor of the ankle-joint; it also raises the medial border of the foot, i.e. inverts the foot.

The **Extensor hallucis longus** (figs. 650, 655) lies between, and is partly hidden by, the Tibialis anterior and the Extensor digitorum longus. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, medial to the origin of the Extensor digitorum longus; it also arises from the anterior surface of the interosseous membrane to a similar extent. The anterior tibial vessels and nerve lie between it and the Tibialis anterior. The fibres pass downwards, and end in a tendon which occupies the anterior border of the muscle. It passes deep to the superior and through the inferior extensor retinaculum, crosses to the medial side of the anterior tibial vessels near the ankle-joint, and is inserted into the dorsal aspect of the base of the

FIG. 649.—A transverse section through the leg, 9 cm. below the knee-joint.



distal phalanx of the great toe. Opposite the metatarsophalangeal articulation a thin prolongation is given off from each side of the tendon and covers the dorsal surface of the joint. An expansion from the medial side of the tendon is usually inserted into the base of the proximal phalanx.

Actions.—The Extensor hallucis longus extends the phalanges of the great toe; in continued action it dorsiflexes the ankle-joint.

The **Extensor digitorum longus** (figs. 649, 650, 655) is a pennate muscle, situated at the lateral part of the front of the leg. It arises from the lateral condyle of the tibia, the upper three-fourths of the anterior surface of the shaft of the fibula, the upper part of the anterior surface of the interosseous membrane, the deep surface of the fascia cruris, the anterior crural intermuscular septum and the septum between it and the Tibialis anterior. In the upper part of the leg the anterior tibial vessels and nerve intervene between the muscle and the Tibialis anterior and, at a lower level, the Extensor hallucis longus also intervenes between them. The tendon of the Extensor digitorum longus passes behind the superior extensor retinaculum and within the loop of the inferior extensor retinaculum in company with the Peroneus tertius (fig. 656). It divides into four slips, which run forward on the dorsum of the foot, and are inserted into the middle and distal phalanges of the four lesser toes. Opposite the metatarsophalangeal

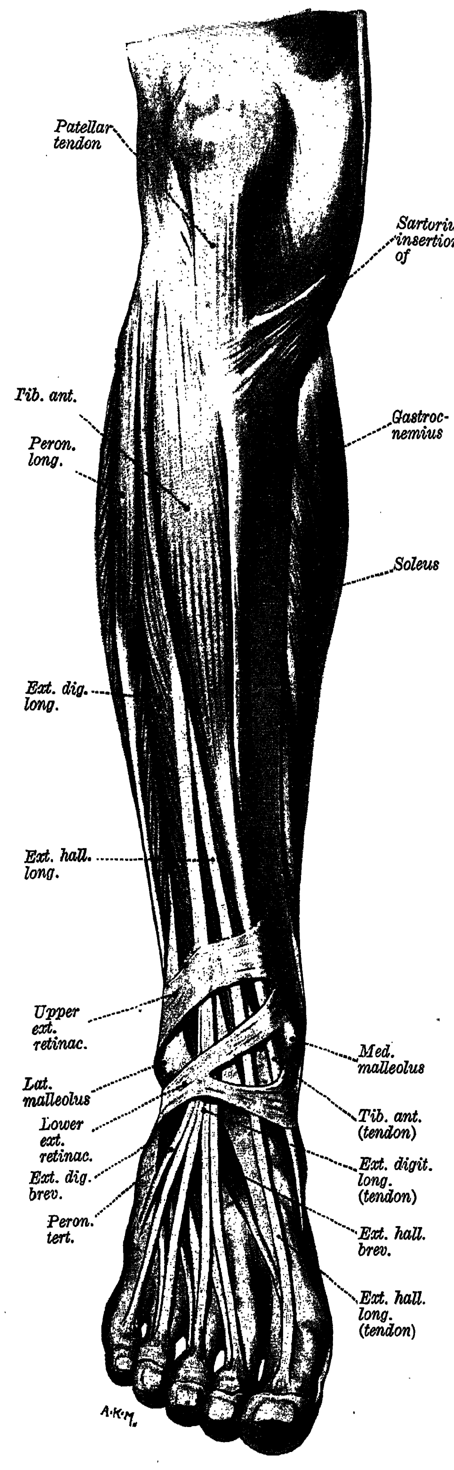


FIG. 650.—Muscles on extensor aspect of leg. (From Quain's *Anatomy*, XI. Edition.)

joints the tendons to the second, third, and fourth toes are each joined on the lateral side by a tendon of the Extensor digitorum brevis. The tendons are inserted as follows : each receives a fibrous expansion from the corresponding Lumbrical and Interosseous muscles, and then spreads out into a broad aponeurosis which covers the dorsal surface of the proximal phalanx ; at the joint of the proximal with the middle phalanx this aponeurosis divides into three slips—an intermediate, which is inserted into the base of the middle phalanx ; and two collateral slips, which, after uniting with each other on the dorsal surface of the middle phalanx, are inserted into the base of the distal phalanx.

Actions.—The Extensor digitorum longus extends the toes at the metatarsophalangeal joints, and when its action is continued dorsiflexes the ankle joint.

The Peroneus tertius (figs. 650, 657) is a part of the Extensor digitorum longus, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower one-third or more of the anterior surface of the fibula, the lower part of the anterior surface of the interosseous membrane and the anterior crural intermuscular septum. The tendon passes behind the superior and within the loop of the inferior extensor retinaculum in company with the Extensor digitorum longus (fig. 656), and is inserted into the medial part of the dorsal surface of the base of the fifth metatarsal bone, but often spreads into a thin sheet which extends forwards along the medial border of the shaft of the bone. This muscle is sometimes wanting.

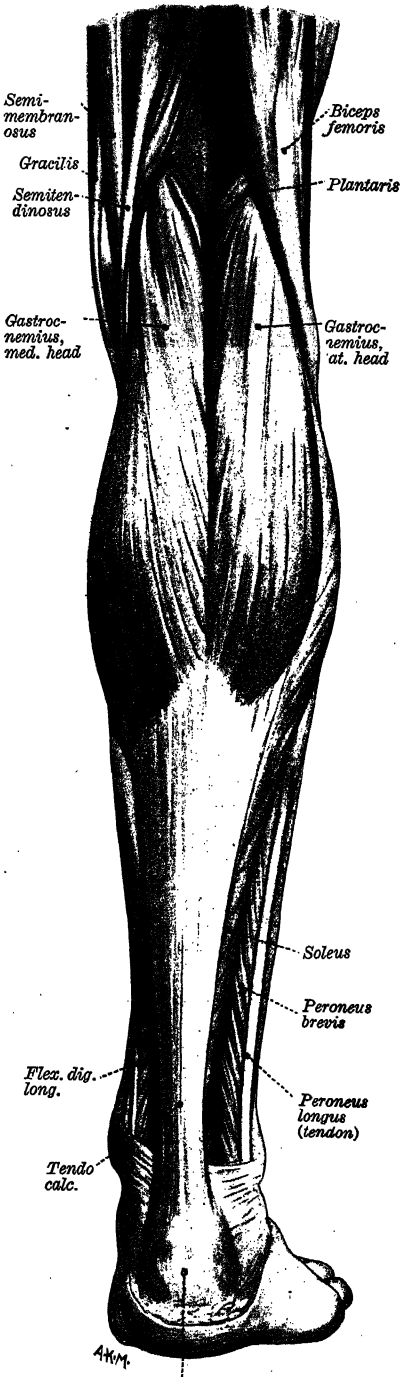
Actions.—The Peroneus tertius dorsiflexes the ankle-joint ; it also raises the lateral border of the foot, i.e. everts the foot.

Nerve-supply.—All the anterior crural muscles are supplied by the anterior tibial (deep peroneal) nerve (L. 4 and 5 and S. 1).

2. The Posterior Crural Muscles

The muscles of the back of the leg are subdivided into two groups—superficial and deep. Those of the superficial group constitute a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct relation to his erect attitude and his mode of progression.

Fig. 651.—Muscles of calf; superficial layer. (From Quain's *Anatomy*, XI. Edition.)



Superficial Group (fig. 651)

Gastrocnemius. Soleus. Plantaris.

The **Gastrocnemius** (figs. 649, 651), which is the most superficial muscle of the group, forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by strong, flat tendons. The medial and larger head takes its origin from a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and from a rounded tubercle on the popliteal surface of the femur just above the medial condyle. The lateral head arises from an impression on the lateral surface of the lateral condyle and from the lower part of the corresponding supracondylar line. Both heads also arise from the subjacent part of the capsular ligament of the knee-joint. Each head spreads out into a tendinous expansion which covers the posterior surface of the corresponding part of the muscle. From the anterior surfaces of these tendinous expansions, muscular fibres are given off; those of the medial head extending lower than those of the lateral. The two heads remain separate and their fibres are inserted into a broad aponeurosis which is developed on the anterior surface of the muscle. The aponeurosis, gradually contracting, unites with the tendon of the Soleus, and forms with it the *tendo calcaneus*, p. 644.

Relations.—The fascia cruris separates the *superficial surface* of the muscle from the short saphenous vein, and the sural communicating and sural nerves; the lateral popliteal nerve crosses the lateral head of the muscle, lying partly under cover of Biceps femoris. The *deep surface* is in relation with the oblique posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels and medial popliteal nerve. A bursa which, in some cases, communicates with the cavity of the knee-joint is placed in front of the tendon of the medial head. The tendon of the lateral head sometimes contains a sesamoid fibrocartilage or bone, where it plays over the corresponding condyle; and one is occasionally found in the tendon of the medial head.

Nerve-supply.—The Gastrocnemius is supplied by the medial popliteal (tibial) nerve (S. 1 and 2).

Actions.—Acting from above the Gastrocnemius plantar-flexes the ankle-joint; acting from below it flexes the knee-joint.

The **Soleus** (figs. 649, 651) is a broad flat muscle situated immediately in front of the Gastrocnemius. It arises by tendinous fibres from the back of the head, and from the upper one-fourth of the posterior surface of the shaft of the fibula; from the soleal line (popliteal line) and the middle one-third of the medial border of the tibia; and from a fibrous band which stretches between

the tibia and fibula, and arches over the popliteal vessels and medial popliteal (tibial) nerve. The muscular fibres end in a flat tendon which covers the posterior surface of the muscle, and, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo calcaneus.

Relations.—Its *superficial surface* is in relation with the Gastrocnemius and Plantaris; its *deep surface*, with the Flexor digitorum longus, Flexor hallucis longus, Tibialis posterior, and posterior tibial vessels and nerve, from all of which it is separated by the deep transverse fascia of the leg.

Nerve-supply.—The Soleus is supplied by the medial popliteal nerve (S. 1 and 2).

Actions.—The Soleus is a plantar-flexor of the ankle-joint; in standing, the Soleus, taking its fixed point from below, steadies the leg on the foot.

The Gastrocnemius and Soleus form a muscular mass which is occasionally described as the *Triceps suræ*; its tendon of insertion is the tendo calcaneus.

The **tendo calcaneus** (fig. 651), the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest tendon in the body. It is about 15 cm. long, and begins near the middle of the leg, but its anterior surface receives fleshy fibres from the Soleus, almost to its lower end. It gradually narrows and thickens until it reaches a level about 4 cm. above the calcaneum; below this it expands and is inserted into the middle of the posterior surface of the calcaneum, a bursa being interposed between the tendon and the upper part of this surface.

Actions.—The muscles of the calf are the chief plantar-flexors of the ankle-joint. They possess considerable power, and are called into use in standing, walking, dancing and leaping; hence they are usually of large size. In walking, these muscles raise the heel from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forwards.

The **Plantaris** (fig. 651) arises from the lower part of the lateral supracondylar line, and from the oblique posterior ligament of the knee-joint. It forms a small, fusiform belly, from 7 cm. to 10 cm. long; this ends in a long slender tendon, which crosses obliquely between the Gastrocnemius and Soleus and runs along the medial border of the tendo calcaneus to be inserted with it into the posterior part of the calcaneum. This muscle is sometimes double, and at other times wanting. Occasionally, its tendon is lost in the flexor retinaculum (laciniate ligament), or in the fascia of the leg.

Nerve-supply.—The Plantaris is supplied by the medial popliteal (tibial) nerve (L. *4* and 5 and S. 1).

Actions.—The Plantaris is the rudiment of a large muscle, the tendon of which in some of the lower animals is inserted into the plantar aponeurosis: in man it is an accessory to the Gastrocnemius, plantar-flexing the ankle-joint if the foot be free, or flexing the knee-joint if the foot be fixed.

Deep Group (fig. 652).

Popliteus.	Flexor digitorum longus.
Flexor hallucis longus.	Tibialis posterior.

The **deep transverse fascia** of the leg is a septum between the superficial and deep muscles of the back of the leg. At the sides it is connected to the medial margin of the tibia and the posterior border of the fibula. Above, where it is thick and dense, it is attached to the soleal ridge of the tibia and to the fibula, below and medial to the origin of the Soleus. Between these two attachments it is continuous with the fascia covering the Popliteus and receives an expansion from the tendon of the Semimembranosus; it is thin in the middle of the leg; but below, where it covers the tendons passing behind the malleoli, it is thick and continuous with the flexor retinaculum and the superior peroneal retinaculum.

The **Popliteus** (fig. 652) is a flat, triangular muscle, which forms the floor of the lower part of the popliteal fossa. It arises by a strong tendon about 2·5 cm. long, from a depression at the anterior part of the groove on the lateral condyle of the femur, and to a small extent from the oblique posterior ligament of the knee-joint. It is inserted into the medial two-thirds of the triangular area above the soleal line (popliteal line) on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the muscle.

Relations.—Its tendon of origin is intracapsular and is covered by the lateral ligament of the knee, and the tendon of the Biceps femoris (fig. 566). Invested on its deep surface by the synovial membrane, it grooves the posterior border of the lateral semilunar cartilage and the adjoining part of the tibia, and emerges from under cover of the posterior band of the arcuate ligament (fig. 556). On the floor of the popliteal fossa it is covered by a strong layer of fascia which is derived for the most part from the tendon of the Semimembranosus.

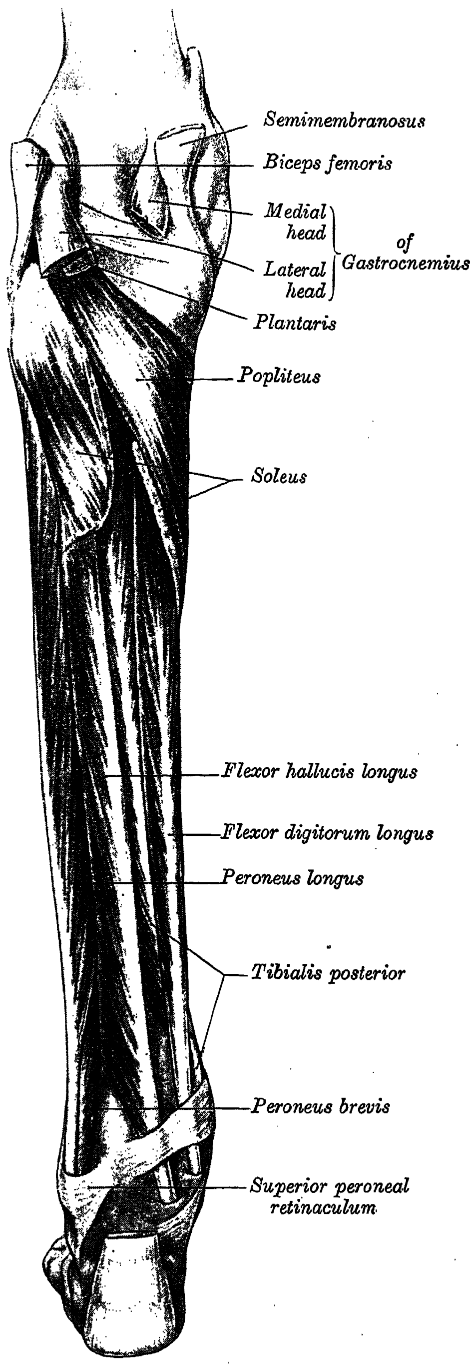


FIG. 652.—The left posterior crural muscles. Deep group.

Nerve-supply.—The Popliteus is supplied by the medial popliteal (tibial) nerve (L. *4* and *5* and S. 1).

Actions.—The Popliteus flexes the knee-joint; when the joint is flexed, it rotates the tibia medially. It is usually regarded as the muscle which 'unlocks' the joint at the beginning of flexion of the fully extended knee-joint (p. 501).

The **Flexor hallucis longus** (figs. 652, 655) is situated on the fibular side of the leg. It arises from the inferior two-thirds of the posterior surface of the shaft of the fibula, with the exception of about 2·5 cm. at its lowest part; from the lower part of the posterior surface of the interosseous membrane; from the posterior crural intermuscular septum, and from the fascia covering the Tibialis posterior, which it overlaps to a considerable extent. The fibres pass obliquely downwards and backwards, and end in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove which crosses the posterior surface of the lower end of the tibia, the posterior surface of the talus, and the under surface of the sustentaculum tali of the calcaneum (figs. 653, 656). In the sole of the foot it runs forwards between the two heads of the Flexor hallucis brevis, and is inserted into the plantar surface of the base of the distal phalanx of the great toe. The grooves on the talus and calcaneum which contain the tendon of the muscle are converted by tendinous fibres into a canal, which is lined by a synovial sheath. As the tendon passes forwards in the sole of the foot, it is situated above, and crosses from the lateral to the medial side of, the tendon of the Flexor digitorum longus, to which it is connected by a fibrous slip. This slip varies considerably in size; it is usually

distributed to the tendons for the second and third toes, but is sometimes restricted to that for the second, and occasionally is distributed to the tendon for the fourth toe, in addition.

Relations.—Its *superficial surface* is in relation with the Soleus and tendo calcaneus, from which it is separated by the deep transverse fascia; its *deep surface*, with the fibula, Tibialis posterior, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; its *lateral border*, with the Peronei; its *medial border*, with the Tibialis posterior, posterior tibial vessels and nerve.

Nerve-supply.—The Flexor hallucis longus is supplied by the posterior tibial nerve (L. 5 and S. 1 and 2).

Actions.—The Flexor hallucis longus flexes the great toe, and, continuing its action, plantar-flexes the ankle-joint.

The **Flexor digitorum longus** (fig. 652) is situated on the tibial side of the leg. Its upper part is thin and pointed, but the muscle gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia, medial to the tibial origin of the Tibialis posterior; this origin extends from just below the soleal line (popliteal line) to within 7 cm. or 8 cm. of the lower extremity of the bone; it also arises from the fascia covering the Tibialis posterior. The fibres end in a tendon which runs nearly the whole length of the posterior surface of the muscle. This tendon gradually crosses the Tibialis posterior and passes behind the medial malleolus, in a groove common to it and the Tibialis posterior, but separated from the latter by a fibrous septum; each tendon being contained in a special compartment lined by a separate synovial sheath. It passes obliquely forwards and laterally, in contact with the medial side of the sustentaculum tali (fig. 653) and deep to the flexor retinaculum (laciniate ligament) and enters the sole of the foot (fig. 662), where it crosses below (i.e. superficial to) the tendon of the Flexor hallucis longus, and receives from it a strong slip. It then expands and is joined by the Flexor digitorum accessorius (Quadratus plantæ), and finally divides into four tendons, which are inserted into the plantar surfaces of the bases of the distal phalanges of the second, third, fourth, and fifth toes, each tendon passing through an opening in the corresponding tendon of the Flexor digitorum brevis opposite the base of the proximal phalanx.

Relations.—In the leg its *superficial surface* is in relation with the deep transverse fascia, which separates it from the Soleus, and, distally, with the posterior tibial vessels and nerve; its *deep surface*, with the tibia and Tibialis posterior. In the foot, it is covered by the Abductor hallucis and Flexor digitorum brevis, and crosses superficial to the Flexor hallucis longus.

Nerve-supply.—The Flexor digitorum longus is supplied by the posterior tibial nerve (L. 5 and S. 1).

Actions.—The Flexor digitorum longus flexes the phalanges of the toes, and in continued action plantar-flexes the ankle-joint. In consequence of the oblique direction of its tendons it draws the toes medially, but this is counteracted by the Flexor digitorum accessorius (Quadratus plantæ), which is inserted into the lateral side of the tendon.

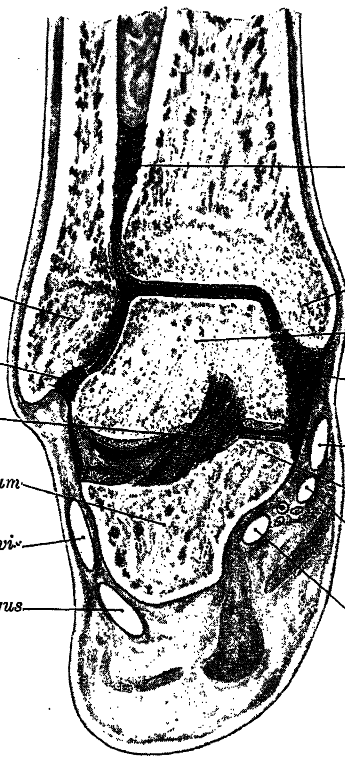
Both the Flexor hallucis longus and the Flexor digitorum longus play important parts in maintaining the longitudinal arch of the foot (p. 517).

The **Tibialis posterior** (figs. 649, 652) takes origin between the Flexor hallucis longus and Flexor digitorum longus, and is overlapped by both muscles, but especially by the Flexor hallucis longus; it is the deepest muscle on the back of the leg. It begins above by two pointed processes, separated by an angular interval through which the anterior tibial vessels pass to the front of the leg. It arises from the posterior surface of the crural interosseous membrane, with the exception of its lowest part; from the lateral portion of the posterior surface of the shaft of the tibia, between the commencement of the soleal line above and the junction of the middle with the lower one-third of the shaft below; and from the upper two-thirds of the medial part of the posterior surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles. In the lower one-fourth of the leg its tendon passes in front of (i.e. deep to) that of the Flexor digitorum longus

and lies with it in a groove behind the medial malleolus, but enclosed in a separate sheath; it next passes deep to the flexor retinaculum (laciniate ligament) and superficial to the deltoid ligament (fig. 653) into the foot, and then below the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. It is inserted into the tuberosity of the navicular bone, and gives off fibrous slips, one of which passes backwards and is attached to the sustentaculum tali of the calcaneum, while others pass forwards and laterally and are fixed to the three cuneiform bones, the cuboid bone, and the bases of the second, third and fourth metatarsal bones (fig. 569).

Relations.—Its *superficial surface* is in relation with the Soleus, from which it is separated by the deep transverse fascia, the Flexor digitorum longus, the Flexor hallucis longus, the

FIG. 653.—A coronal section through the left ankle and talocalcanean joints.



posterior tibial vessels, nerve, and the peroneal vessels; its *deep surface* with the interosseous membrane, the tibia, fibula and ankle-joint.

Nerve-supply.—The Tibialis posterior is supplied by the posterior tibial nerve (L. 5 and S. 1).

Actions.—The Tibialis posterior plantar-flexes the ankle-joint; it also pulls up the medial border of the foot, i.e. inverts the foot. In the sole of the foot its tendon lies inferomedial to the plantar calcaneonavicular ligament, and, together with its additional slips of insertion, is an important factor in maintaining the longitudinal arch of the foot (p. 517).

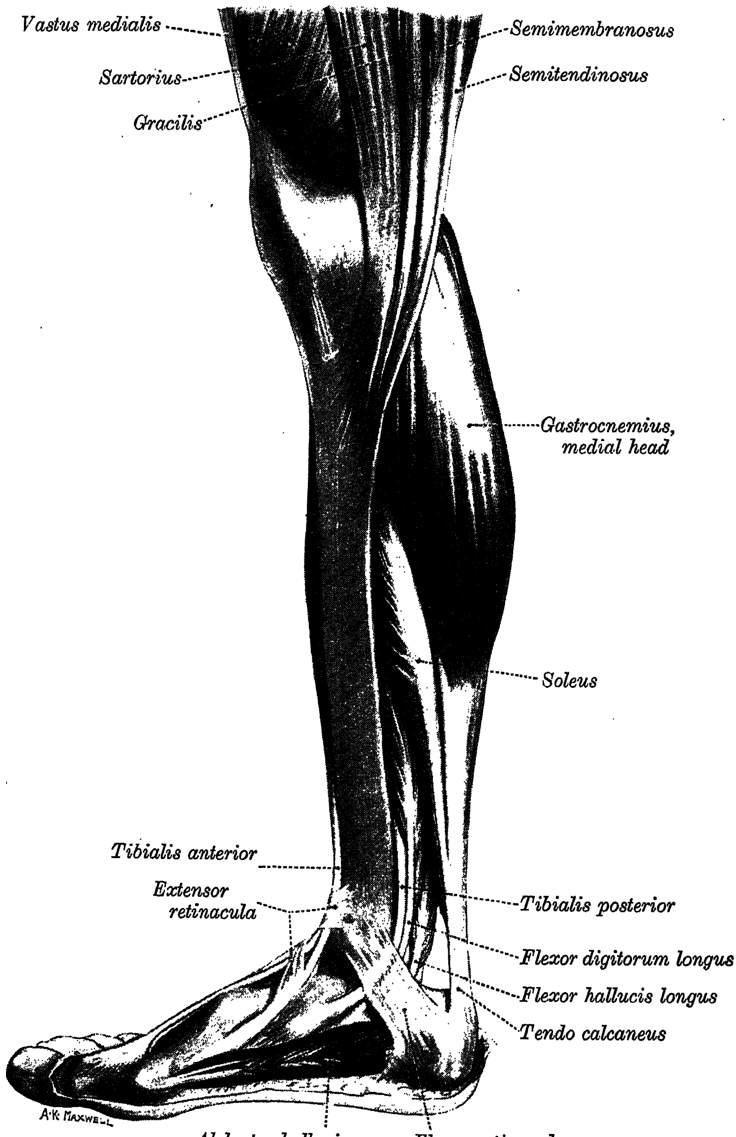
3. The Lateral Crural Muscles.

Peroneus longus. Peroneus brevis.

The **Peroneus longus** (figs. 649, 651, 652), which is the more superficial of the two muscles, is situated at the upper part of the lateral side of the leg. It arises from the head and upper two-thirds of the lateral surface of the shaft of the fibula, from the deep surface of the fascia cruris, and from the anterior and posterior crural intermuscular septa: occasionally also by a few fibres from

the lateral condyle of the tibia. Between its attachments to the head and body of the fibula, there is a gap through which the lateral popliteal (common peroneal) nerve passes. It ends in a long tendon, which runs behind the lateral malleolus, in a groove common to it and the tendon of the Peroneus brevis, behind which it lies; the groove is converted into a canal by the superior

FIG. 654.—The muscles of the right leg, viewed from the medial side. (From Quain's *Anatomy*, XI. Edition.)



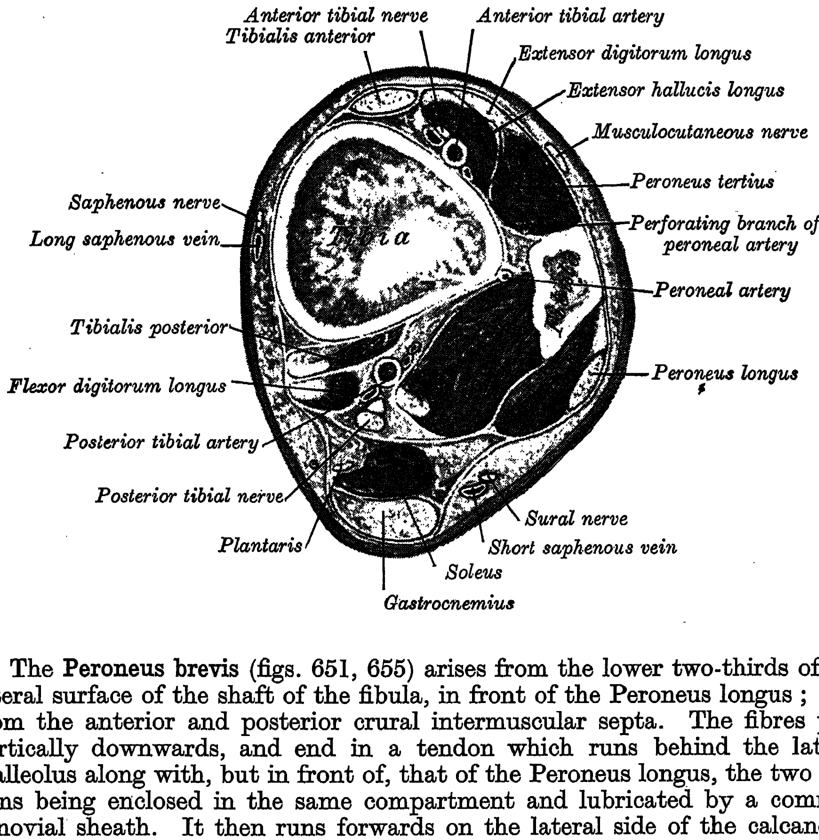
peroneal retinaculum, and the tendons in it are contained in a common synovial sheath. The tendon then runs obliquely forwards across the lateral side of the calcaneum, below the peroneal tubercle and the tendon of the Peroneus brevis, and under cover of the inferior peroneal retinaculum; it crosses the lateral side of the cuboid bone, and then runs on the under surface of that bone in a groove which is converted into a canal by the long plantar ligament (fig. 663). It crosses the sole of the foot obliquely, and is inserted by two slips into (*a*) the lateral side of the base of the first metatarsal bone and (*b*) the lateral side of the medial cuneiform bone; occasionally a third slip is attached to the

base of the second metatarsal bone. The tendon changes its direction at two points: (*a*) below the lateral malleolus, (*b*) on the cuboid bone; in both of these situations it is thickened, and, in the latter, a sesamoid fibrocartilage (sometimes a bone) is usually developed in its substance.

Nerve-supply.—The Peroneus longus is supplied by the musculocutaneous (superficial peroneal) nerve (L. *4* and 5 and S. 1).

Actions.—The Peroneus longus plantar-flexes the ankle-joint and everts the foot, so long as it is not bearing weight. As a consequence of the oblique direction of its tendon across the sole it is an important agent in maintaining the transverse and lateral longitudinal arches of the foot. In the active erect posture (p. 517) it produces depression and medial rotation of the first metatarsal and medial cuneiform bones and so enables the inverted foot to remain plantigrade. Taking its fixed point below, the Peroneus longus serves to steady the leg on the foot; this is especially the case in standing on one leg, when the tendency of the superincumbent weight is to throw the leg medially.

FIG. 655.—A transverse section through the leg, 6 cm. above the tip of the medial malleolus.



The **Peroneus brevis** (figs. 651, 655) arises from the lower two-thirds of the lateral surface of the shaft of the fibula, in front of the Peroneus longus; and from the anterior and posterior crural intermuscular septa. The fibres pass vertically downwards, and end in a tendon which runs behind the lateral malleolus along with, but in front of, that of the Peroneus longus, the two tendons being enclosed in the same compartment and lubricated by a common synovial sheath. It then runs forwards on the lateral side of the calcaneum above the peroneal tubercle (trochlear process) and the tendon of the Peroneus longus, and is inserted into the tubercle on the base of the fifth metatarsal bone, on its lateral side.

On the lateral surface of the calcaneum the tendons of the Peronei longus et brevis occupy separate, osseo-aponeurotic canals formed by the calcaneum and the inferior peroneal retinaculum; each tendon is enveloped by a forward prolongation of the common synovial sheath.

Nerves.—The Peroneus brevis is supplied by the musculocutaneous (superficial peroneal) nerve (L. *4* and 5 and S. 1).

Action.—The Peroneus brevis plantar-flexes the foot upon the leg, and assists the Peroneus longus to evert the foot.

Applied Anatomy.—Rigidity and contraction of the tendons of the various muscles of the leg give rise to one or other of the kinds of deformity known as *club foot.* The most simple and common deformity, and one that is rarely, if ever, congenital, is *talipes equinus,* the heel being raised by the rigidity and contraction of the Gastrocnemius so that the patient walks upon the ball of the foot. In *talipes varus,* the foot is forcibly adducted and the medial side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibiales anterior et posterior. In *talipes valgus,* the lateral edge of the foot is raised by the Peronei, and the patient walks on the medial side of the foot. In *talipes calcaneus* the toes are raised by the extensor muscles, the heel is depressed and the patient walks upon it. Other varieties of deformity are met with, as *talipes equinovarus, equinovalgus* and *calcaneovalgus,* names which sufficiently indicate their nature. Of these, talipes equinovarus is the most common congenital form; the heel is raised by the tendo calcaneus, the medial border of the foot drawn upwards by the Tibialis anterior, the anterior two-thirds twisted medially by the Tibialis posterior, and the arch increased by the contraction of the plantar aponeurosis, so that the patient walks on the middle of the lateral border of the foot.

Rupture of a few fibres of the Gastrocnemius, or rupture of the Plantaris tendon, not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn-tennis, and is hence known as 'lawn-tennis leg.' The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo calcaneus is also sometimes ruptured. It is stated that John Hunter ruptured his tendo calcaneus while dancing, at the age of forty.

THE FASCIA ROUND THE ANKLE

As the tendons of the muscles of the leg cross the ankle-joint on their way to the foot, they are bound down by localised thickenings in the deep fascia which constitute retinacular bands comparable, both in mode of formation and in function, to the flexor and extensor retinacula of the wrist (p. 609). They comprise the superior and inferior extensor retinacula (transverse and cruciate crural ligaments), the flexor retinaculum (laciniate ligament), and the superior and inferior peroneal retinacula.

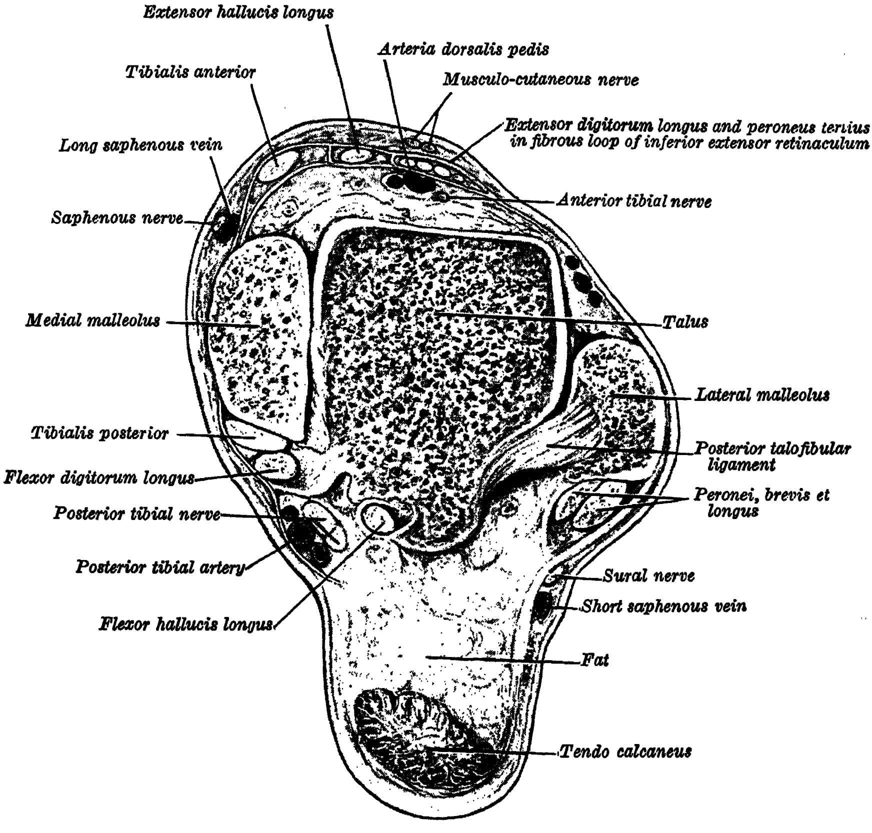
The **superior extensor retinaculum** (transverse crural ligament) (figs. 650, 657) binds down the tendons of the Tibialis anterior, Extensor hallucis longus, Extensor digitorum longus and Peroneus tertius, as they descend on the front of the ankle-joint; the anterior tibial vessels and nerve also pass under cover of it. It is attached laterally to the lower end of the anterior border of the fibula, and medially to the anterior border of the tibia; above, it is continuous with the deep fascia of the leg.

The **inferior extensor retinaculum** (cruciate crural ligament) (figs. 656, 657) is a Y-shaped band placed in front of the ankle-joint. The stem of the Y is attached to the upper surface of the calcaneum, in front of the sulcus calcanei, and passes medially, forming a strong loop which encloses the tendons of the Peroneus tertius and the Extensor digitorum longus. From the extremity of this loop two diverging bands pass medially to complete the Y. The *upper band* consists of two distinct lamellæ. The deep lamella passes behind the tendons of the Extensor hallucis longus and the Tibialis anterior, but in front of the anterior tibial vessels and nerve, to reach the tibial malleolus. The superficial lamella crosses in front of the tendon of the Extensor hallucis longus and is then firmly connected to the deep lamella; it may or may not be continued in front of the tendon of the Tibialis anterior to reach the tibia. The *lower band* extends downwards and medially to be attached to the plantar aponeurosis; it crosses the tendons of the Extensor hallucis longus and Tibialis anterior, the arteria dorsalis pedis and the terminal branches of the anterior tibial (deep peroneal) nerve. From the deep surface of the loop which encloses the tendons of the Peroneus tertius and the Extensor digitorum longus, a distinct band of fibres passes medially between the constituent layers of the interosseous talocalcanean ligament (p. 509) to gain attachment to the upper surface of the calcaneum and the under surface of the neck of the talus.*

* E. Barclay Smith, *Journal of Anatomy,* vol. xxx. 1896. T. T. Stamm, *Ibid.* vol. lxvi. 1931.

The **flexor retinaculum** (laciniate ligament) (fig. 654) extends from the tibial malleolus above to the margin of the calcaneum below; its upper border is continuous with the deep transverse fascia of the leg, its lower with the plantar aponeurosis and the fibres of origin of the Abductor hallucis muscle. It converts a series of bony grooves in this situation into canals for the passage of the tendons of the flexor muscles into the sole of the foot, and also affords protection to the posterior tibial vessels and nerve as they enter the sole of the foot. From the medial to the lateral side these structures lie in the following order: tendon of the Tibialis posterior, tendon of the Flexor digitorum longus, posterior tibial vessels and nerve, and tendon of the Flexor hallucis longus (fig. 656).

FIG. 656.—Transverse section through the lower part of the ankle-joint.



The **peroneal retinacula** are fibrous bands which retain the tendons of the Peroneus longus and brevis in position as they cross the lateral side of the ankle. The *superior retinaculum* (fig. 652) extends from the back of the lateral malleolus to the deep transverse fascia of the leg and the lateral surface of the calcaneum. The *inferior retinaculum* is continuous in front with the inferior extensor retinaculum; behind it is attached to the lateral surface of the calcaneum; some of its fibres are fixed to the peroneal tubercle of the calcaneum, forming a septum between the tendons of the Peroneus longus and brevis.

The synovial sheaths of the tendons round the ankle.—The tendons crossing the ankle-joint are enclosed in synovial sheaths. On the *front* of the ankle (fig. 657) the sheath for the Tibialis anterior extends from the upper margin of the upper extensor retinaculum to the interval between the diverging limbs of the lower retinaculum; those for the Extensor digitorum longus and Extensor hallucis longus reach upwards to just above the level of the malleoli, the former

being the higher. The sheath of the Extensor hallucis longus is prolonged on to the base of the first metatarsal bone, while that of the Extensor digitorum longus reaches only to the level of the base of the fifth metatarsal bone. On the *medial side* of the ankle (fig. 658) the sheath for the Tibialis posterior extends

FIG. 657.—The synovial sheaths of the tendons round the right ankle. Lateral aspect. (From a specimen prepared by J. C. B. Grant.)

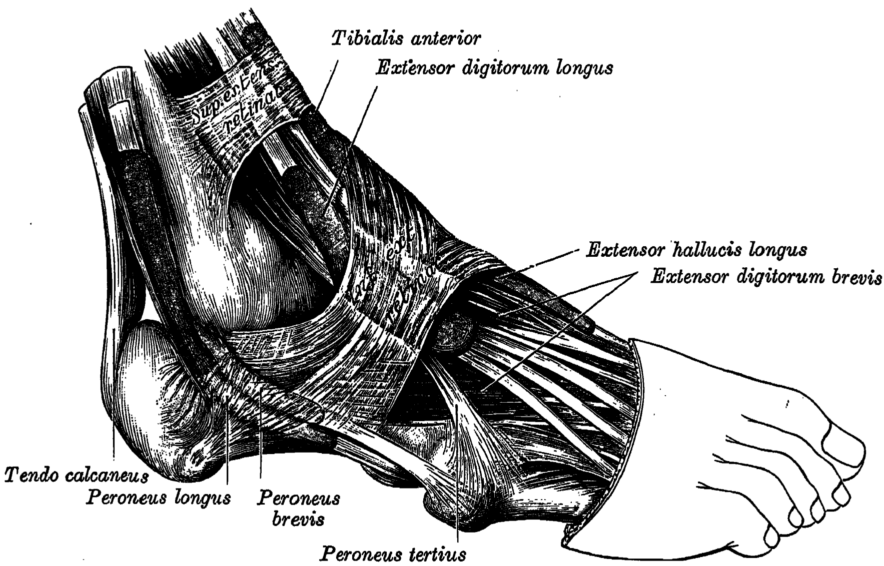


FIG. 658.—The synovial sheaths of the tendons round the right ankle. Medial aspect. (From a specimen prepared by J. C. B. Grant.)

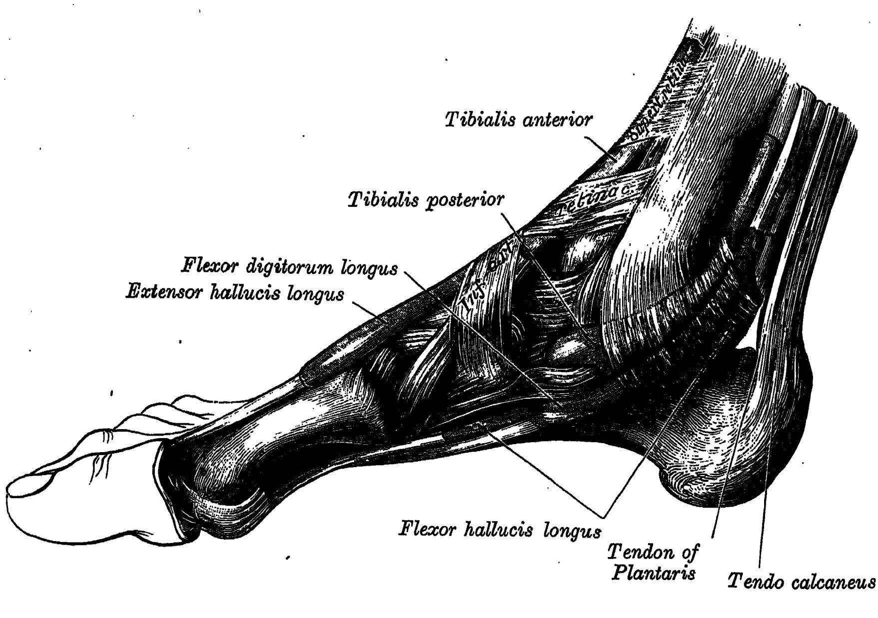


for about 4 cm. above the malleolus ; below, it ends just short of the insertion of the tendon into the tuberosity of the navicular bone. The sheath for the Flexor hallucis longus reaches up to the level of the malleolus, while that for the Flexor digitorum longus goes slightly higher ; the former is continued to the base of the first metatarsal bone, but the latter ends opposite the navicular bone. On the *lateral side* of the ankle (fig. 657) a sheath, the upper part of

which is single and the lower part double, encloses the Peroneus longus and brevis. It extends upwards for about 4 cm. above the tip of the malleolus, and downwards and forwards for about the same distance.

IV. The Muscles of the Foot

1. The Dorsal Muscle of the Foot

Extensor digitorum brevis.

The **fascia** on the dorsum of the foot (fascia dorsalis pedis) is a thin, membranous layer, continuous above with the inferior extensor retinaculum; at the sides of the foot it blends with the plantar aponeurosis; anteriorly it ensheathes the tendons on the dorsum of the foot.

The **Extensor digitorum brevis** (figs. 650, 657) is a thin muscle, which arises from the forepart of the upper and lateral surface of the calcaneum, in front of the groove for the Peroneus brevis; from the interosseous talocalcaneal ligament, and the stem of the inferior extensor retinaculum. It passes obliquely forwards and medially across the dorsum of the foot, and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip ending in a tendon which crosses the dorsalis pedis artery and is inserted into the dorsal surface of the base of the proximal phalanx of the great toe; it is sometimes described as a separate muscle—the *Extensor hallucis brevis*. The other three tendons are inserted into the lateral sides of the tendons of the Extensor digitorum longus of the second, third and fourth toes.

Nerve-supply.—The Extensor digitorum brevis is supplied by the lateral terminal branch of the anterior tibial (deep peroneal) nerve (L. 4 and 5 and S. 1).

Actions.—The Extensor digitorum brevis extends the phalanges of the four toes into which it is inserted, but, in the great toe, acts only on the first phalanx.

2. The Plantar Muscles of the Foot

The **plantar aponeurosis** (fig. 659) is of great strength, and consists of white fibres disposed, for the most part, longitudinally: it is divided into central, lateral, and medial portions.

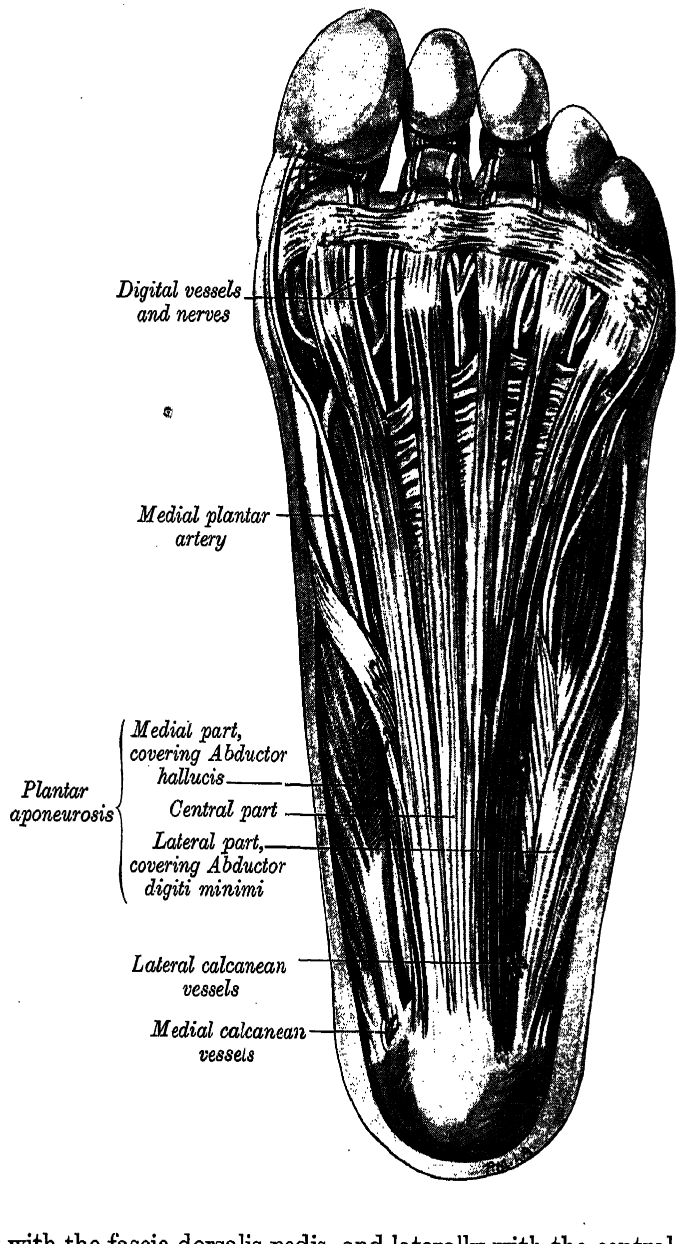
The *central portion* is the thickest: it is narrow behind, and attached to the medial tubercle of the calcaneum posterior to the origin of the Flexor digitorum brevis; it becomes broader and thinner in front, and divides near the heads of the metatarsal bones into five processes, one for each toe. Each of these processes splits opposite the metatarsophalangeal joint into a superficial and a deep stratum. The superficial stratum is inserted into the skin of the transverse sulcus which separates the toes from the sole. The deep stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the fibrous sheaths of these tendons and with the deep transverse ligaments of the sole, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. Through the intervals between the five processes the digital vessels and nerves and the tendons of the Lumbrical muscles are transmitted. At the point of division of the aponeurosis numerous transverse fasciculi bind the processes together, and connect them with the skin. The central portion of the plantar aponeurosis is continuous with the lateral and medial portions, and sends upwards, at the lines of junction, two vertical intermuscular septa, which separate the intermediate from the lateral and medial groups of plantar muscles; from these vertical septa thinner transverse septa are derived which separate the different layers of muscles. The deep surface of the central part of the aponeurosis gives origin behind to the Flexor digitorum brevis.

The *lateral portion* covers the under surface of the Abductor digiti minimi; it is thin in front and thick behind, where it forms a strong band between the

lateral tubercle of the calcaneum and the base of the fifth metatarsal bone ; it is continuous medially with the central portion, and laterally with the fascia on the dorsum of the foot.

The *medial portion* is thin, and covers the under surface of the Abductor hallucis ; it is continuous behind with the flexor retinaculum (laciniate ligament),

FIG. 659.—The plantar aponeurosis of the left foot.



medially with the fascia dorsalis pedis, and laterally with the central portion of the plantar aponeurosis.

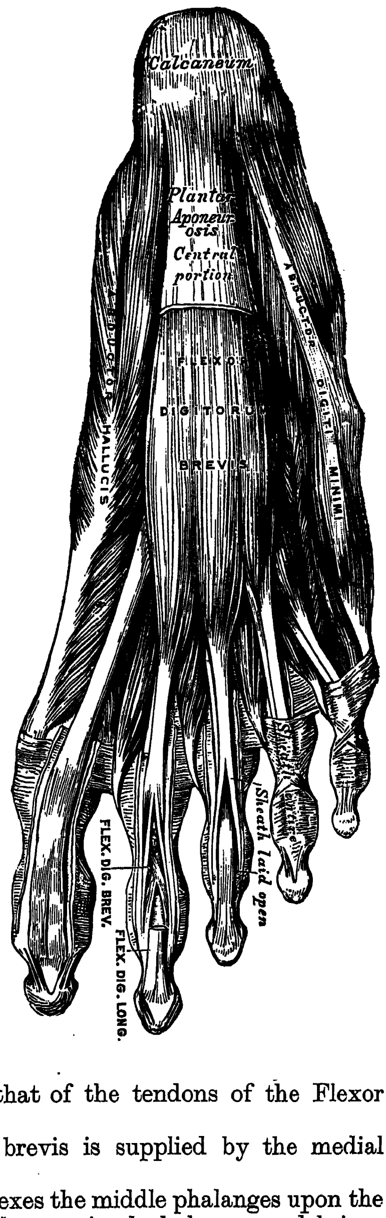
The muscles in the plantar region of the foot may be divided into medial, lateral and intermediate groups; but for descriptive purposes it is more convenient to group them in four layers, as met with in the course of dissection.

The First Layer (fig. 660)

Abductor hallucis. Flexor digitorum brevis.
Abductor digiti minimi.

All the muscles of this layer extend from the tubercles of the calcaneum to the toes, and therefore, together with the plantar aponeurosis, play a subsidiary part in maintaining the longitudinal arches of the foot.

FIG. 660.—The plantar muscles of the right foot. First layer.



The **Abductor hallucis** (fig. 660) lies along the medial border of the foot and covers the origins of the plantar vessels and nerves. It arises from the medial tubercle of the calcaneum, the flexor retinaculum (laciniate ligament), the plantar aponeurosis, and the intermuscular septum between it and the Flexor digitorum brevis. The fibres end in a tendon which is inserted, together with the medial tendon of the Flexor hallucis brevis, into the medial side of the base of the proximal phalanx of the great toe.

Nerve-supply.—The Abductor hallucis is supplied by the medial plantar nerve (L. 5 and S. 1).

Actions.—The Abductor hallucis flexes and abducts the proximal phalanx of the great toe.

The **Flexor digitorum brevis** (fig. 660) lies immediately above the central part of the plantar aponeurosis. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia. It arises by a narrow tendon from the medial tubercle of the calcaneum, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and the adjacent muscles. It divides into four tendons, one for each of the four lesser toes. Opposite the bases of the proximal phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor digitorum longus; the two slips then unite, partially decussate, and form a grooved channel for the reception of the tendon of the Flexor digitorum longus. The tendon divides again and is inserted into the sides of the middle phalanx about its middle. The mode of division of the tendons of the Flexor digitorum brevis, and of their insertion into the phalanges, is identical with that of the tendons of the Flexor digitorum sublimis in the hand.

Nerve-supply.—The Flexor digitorum brevis is supplied by the medial plantar nerve (L. 5 and S. 1 and 2).

Actions.—The Flexor digitorum brevis flexes the middle phalanges upon the proximal; continuing its action it flexes the proximal phalanges and brings the toes together.

The fibrous sheaths of the flexor tendons (fig. 660).—The terminal portions of the tendons of the long and short flexor muscles are contained in osseo-aponeurotic canals similar in their arrangement to those in the fingers. These

canals are bounded above by the phalanges, and below by fibrous bands which arch across the tendons, and are attached on either side to the margins of the phalanges. Opposite the shafts of the proximal and middle phalanges the fibrous bands (*vaginal ligaments*) are strong, and the fibres are transverse ; but opposite the joints they are much thinner, and the fibres are directed obliquely. Each canal contains a synovial sheath, which is reflected on the contained tendons ; within this sheath *vincula tendinum* are arranged similarly to those of the fingers.

The **Abductor digiti minimi** (fig. 660) lies along the lateral border of the foot, and its medial margin is in relation with the lateral plantar vessels and nerve. It arises from the lateral and medial tubercles of the calcaneum, from the under surface of the bone between the processes, from the plantar aponeurosis, and from the intermuscular septum between it and the Flexor digitorum brevis. Its tendon glides over a smooth facet on the under surface of the base of the fifth metatarsal bone and is inserted, with the Flexor digiti minimi brevis, into the lateral side of the base of the proximal phalanx of the fifth toe.

Nerve-supply.—The Abductor digiti minimi is supplied by the lateral plantar nerve (S. 1 and 2).

Actions.—The Abductor digiti minimi flexes and abducts the proximal phalanx of the little toe.

The Second Layer (figs. 661, 662)

Flexor digitorum accessorius. Lumbricales.

The **Flexor digitorum accessorius** (Quadratus plantæ) (fig. 662) arises by two heads which are separated from each other by the long plantar ligament : the medial, and larger, head is muscular, and is attached to the medial concave surface of the calcaneum below the groove for the tendon of the Flexor hallucis longus ; the lateral head, flat and tendinous, arises from the calcaneum in front of the lateral tubercle and from the long plantar ligament. The two portions join at an acute angle, and end in a flattened band which is inserted into the superior surface and lateral margin of the tendon of the Flexor digitorum longus, forming a kind of groove in which the tendon is lodged. It usually sends slips to those tendons of the Flexor digitorum longus which pass to the second, third and fourth toes.

Nerve-supply.—The Flexor digitorum accessorius is supplied by the lateral plantar nerve (S. 1).

Actions.—The Flexor digitorum accessorius assists the Flexor digitorum longus and converts the oblique pull of the tendons of that muscle into a direct backward pull on the toes.

The **Lumbricales** (fig. 662) are four small muscles, accessory to the tendons of the Flexor digitorum longus, and numbered from the medial side of the foot ; they arise from these tendons, as far back as their angles of separation, and, with the exception of the first, which arises only from the medial border of the first tendon of the Flexor digitorum longus, each springs from two tendons. The muscles end in tendons which pass forwards and upwards on the medial sides of the four lesser toes, and are inserted into the expansions of the tendons of the Extensor digitorum longus on the dorsal surfaces of the proximal phalanges.

Nerve-supply.—The first Lumbrical is supplied by the medial plantar nerve (L. 5 and S. 1) ; the others by the deep branch of the lateral plantar nerve (S. 1 and 2).

Actions.—The Lumbricals flex the proximal phalanges and, by their insertions into the tendons of the Extensor digitorum longus, extend the middle and distal phalanges.

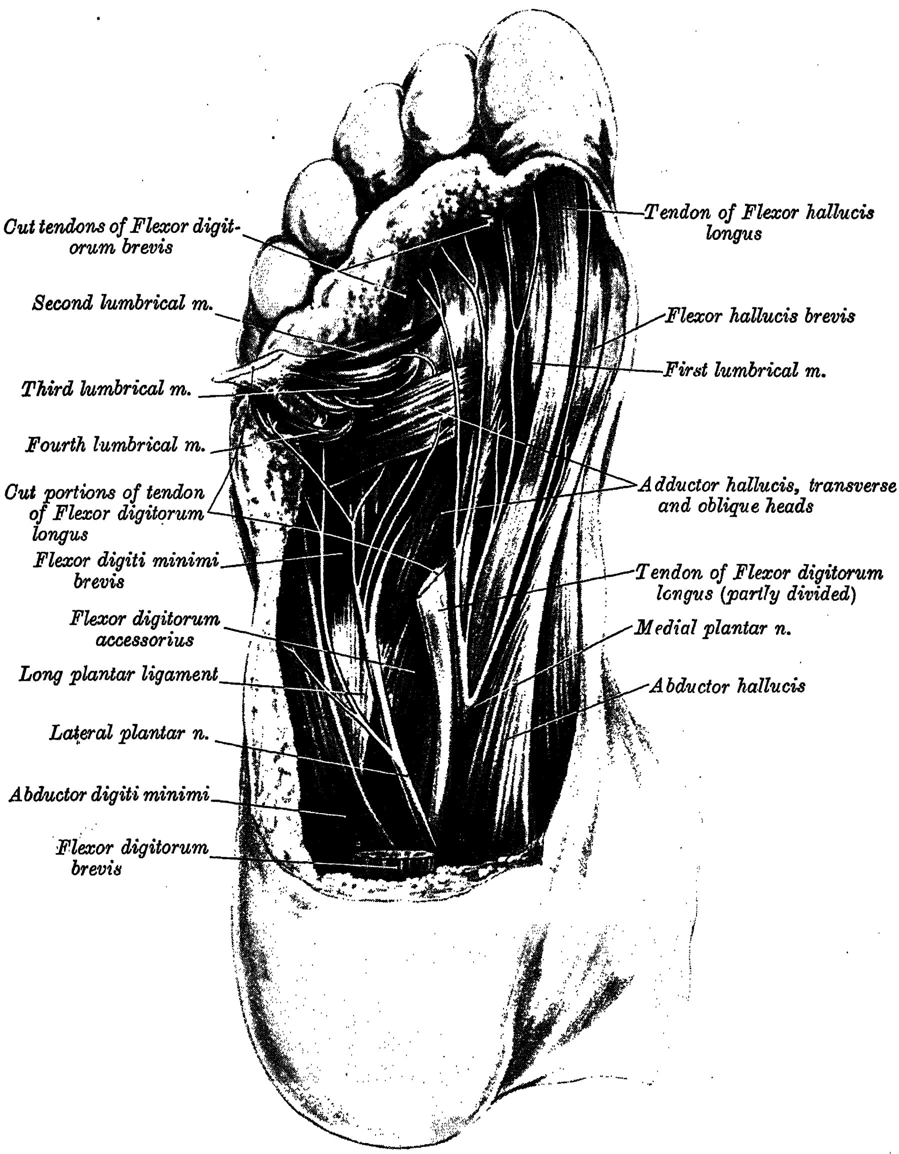
The Third Layer (figs. 661, 663)

Flexor hallucis brevis. Adductor hallucis.
Flexor digiti minimi brevis.

The **Flexor hallucis brevis** (fig. 663) arises by a pointed, tendinous process from the medial part of the under surface of the cuboid bone, behind the groove

for the Peroneus longus tendon, from the contiguous portion of the lateral cuneiform bone, and from the part of the tendon of the Tibialis posterior which is attached to that bone. It divides into a medial and a lateral portion, and the tendons of these are inserted into the corresponding sides of the base of the proximal phalanx of the great toe, a sesamoid bone being present in each

Fig. 661.—The muscles of the sole of the foot and their nerves of supply.



Most of the Flexor digitorum brevis has been removed. The Flexor digitorum longus has been divided partially, and its distal end has been turned forwards together with the second, third and fourth Lumbrical muscles.

tendon at its insertion. The medial portion is blended with the Abductor hallucis previous to its insertion ; the lateral, with the Adductor hallucis. The lateral portion of the Flexor hallucis brevis is sometimes described as the *first plantar interosseous* muscle.

Nerve-supply.—The Flexor hallucis brevis is supplied by the medial plantar nerve (L. 5 and S. 1).

Action.—The Flexor hallucis brevis flexes the proximal phalanx of the great toe.

The **Adductor hallucis** (fig. 663) arises by two heads—oblique and transverse. The *oblique head* springs from the bases of the second, third and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is inserted, together with the lateral portion of the Flexor hallucis brevis,

Fig. 662.—The plantar muscles of the right foot. Second layer.

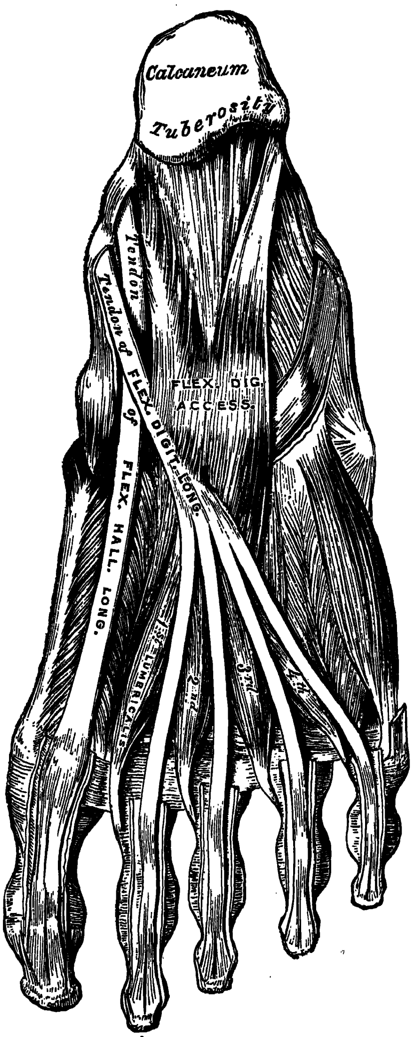


Fig. 663.—The plantar muscles of the right foot. Third layer.

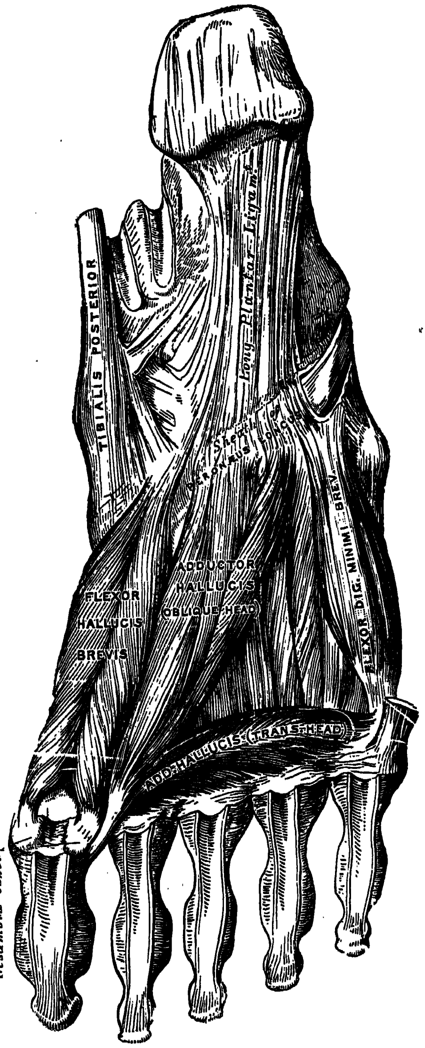

into the lateral side of the base of the proximal phalanx of the great toe. The *transverse head*, a narrow, flat fasciculus, arises from the plantar metatarsophalangeal ligaments of the third, fourth and fifth toes (sometimes only from the third and fourth), and from the deep transverse ligaments of the sole. It is inserted into the lateral side of the base of the proximal phalanx of the great toe, its tendon of insertion blending with that of the oblique head.

Nerve-supply.—The Adductor hallucis is supplied by the deep branch of the lateral plantar nerve (S. 1 and 2).

Actions.—The oblique head of the Adductor hallucis is chiefly concerned in adducting, but it also assists in flexing, the great toe; the transverse head approximates the toes and thus increases the curve of the transverse arch of the metatarsus.

The **Flexor digiti minimi brevis** (fig. 663) arises from the medial part of the plantar surface of the base of the fifth metatarsal bone, and from the sheath of the Peroneus longus ; its tendon is inserted into the lateral side of the base of the proximal phalanx of the fifth toe. Occasionally a few of the deeper fibres are inserted into the lateral part of the distal one-half of the fifth metatarsal bone ; these are described by some as a distinct muscle—the *Opponens digiti minimi.*

Nerve-supply.—The Flexor digiti minimi brevis is supplied by the superficial branch of the lateral plantar nerve (S. 1 and 2).

Action.—The Flexor digiti minimi brevis flexes the little toe.

The Fourth Layer

Interossei.

The **Interossei** in the foot are similar to those in the hand, but are grouped on each side of the middle line of the *second* digit, instead of that of the *third.* They consist of a dorsal and a plantar set.

The **Interossei dorsales** (fig. 664), four in number, are situated between the metatarsal bones. They are bipennate muscles, each arising by two heads from the adjacent sides of the metatarsal bones between which it is placed ; their tendons are inserted into the bases of the proximal phalanges, and into the aponeuroses of the tendons of the Extensor digitorum longus. The first is

FIG. 664.—The Interossei dorsales of the left foot. Dorsal aspect.

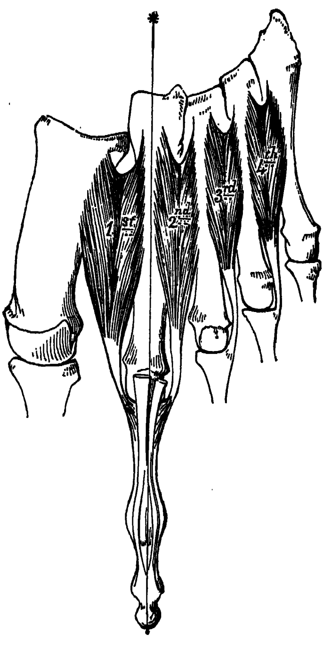

FIG. 665.—The Interossei plantares of the left foot. Plantar aspect.

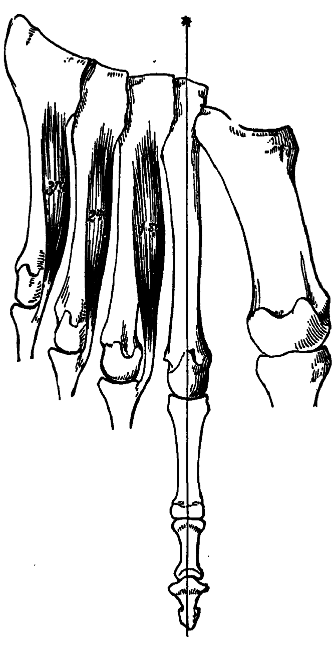


inserted into the medial side of the second toe ; the other three into the lateral sides of the second, third, and fourth toes. In the angular interval between the heads of each of the three lateral muscles, one of the perforating arteries passes to the dorsum of the foot ; through the space between the heads of the first muscle the terminal part of the dorsalis pedis artery enters the sole of the foot.

The **Interossei plantares** (fig. 665), three in number, lie below rather than between the metatarsal bones, and each is connected with but one metatarsal bone. They arise from the bases and medial sides of the shafts of the third, fourth, and fifth metatarsal bones, and are inserted into the medial sides of the

bases of the proximal phalanges of the same toes, and into the aponeuroses of the tendons of the Extensor digitorum longus.

Nerve-supply.—The Dorsal and Plantar interossei are supplied by the deep branch of the lateral plantar nerve (S. 1 and 2), except those in the fourth interosseous space, which are supplied by the superficial branch of the same nerve. The first Dorsal interosseous frequently receives an extra filament from the medial branch of the anterior tibial nerve on the dorsum of the foot, and the second Dorsal interosseous a twig from the lateral branch of the same nerve.

Actions.—The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe medially, the second muscle draws the same toe laterally, and the third and fourth draw the third and fourth toes laterally. They assist in flexing the proximal and extending the middle and distal phalanges. The Plantar interossei adduct the third, fourth and fifth toes towards the imaginary line passing through the second toe, and, by means of their insertions into the aponeuroses of the Extensor tendons, assist in flexing the proximal phalanges and extending the middle and distal phalanges.

BLOOD VASCULAR SYSTEM

THE vascular system is divided for descriptive purposes into (*a*) the *blood-vascular system*, comprising the heart and blood-vessels through which the blood circulates ; and (*b*) the *lymphatic system*, consisting of lymph-glands and lymphatic vessels, through which a colourless fluid, termed the lymph, circulates.* The two systems communicate with each other and are intimately associated developmentally.

The heart, the central organ of the blood-vascular system, is situated within the thorax. It is a hollow, muscular organ, by the contraction of which the blood is pumped to all parts of the body through a complicated series of tubes, termed *arteries*. The arteries ramify extensively in their course throughout the body, and end in minute vessels, called *arterioles*, which open into a close-meshed network of microscopic vessels, named *capillaries*. After the blood has passed through the capillaries it is collected into a series of minute vessels, called *venules*, which join with one another to form *veins* : the veins unite with one another, and ultimately two large venous trunks, named the superior and inferior venæ cavæ, are formed which return the blood to the heart. While the blood is passing through the capillaries a transudation of certain of its fluid elements takes place into the tissue-spaces. In proportions which vary according to the metabolic conditions, this fluid is taken up partly by the capillaries by a process of reabsorption, and partly by the lymph vessels, which return it to the large veins at the root of the neck. The passage of the blood through the heart and blood-vessels is termed the *circulation* of the blood, of which the following is an outline.

The heart is divided into four chambers, of which two are receiving and two are distributing chambers. The right and left *atria* receive the blood from the great veins and expel it into the right and left *ventricles*. From the ventricles the blood is pumped into the arterial system and carried to the various organs of the body. Although each atrium communicates freely with the corresponding ventricle, the right and left chambers of the heart are separated from one another by partitions or *septa*, and they do not communicate with one another after birth in normal subjects. The superior and the inferior venæ cavæ bring to the right atrium blood which has become deoxygenated and has taken up carbon dioxide during its circulation through the tissues of the body. From the right atrium the blood passes into the right ventricle, by which it is expelled into the pulmonary artery to be conveyed to the right and left lungs. As it circulates through the pulmonary capillaries the blood is brought into close relationship with the air in the lungs, and it gives off some of its carbon dioxide content and acquires a fresh supply of oxygen. Re-collected by the pulmonary veins the freshly oxygenated blood is returned to the left atrium of the heart and passes into the left ventricle. With each beat of the heart the left ventricle pumps its contents into a large artery termed the aorta, which distributes blood through its numerous branches to all the tissues and organs of the body with the exception of the lungs.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic* circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary* circulation.

It is necessary, however, to point out that the blood which circulates through the spleen, pancreas, stomach, small intestine and the greater part of the large intestine is not returned directly from these organs to the heart, but is conveyed by the *portal vein* to the liver. In the liver this vein divides like an artery, and ultimately ends in capillary-like vessels (sinusoids), from which the rootlets of the *hepatic veins* arise ; the hepatic veins carry the blood into the inferior vena cava, which conveys it to the right atrium. This constitutes the *portal circulation*, and it will be understood that the blood supplied to the

* The blood and lymph are described on pp. 28 to 31.

above-named viscera passes through two sets of minute vessels before reaching the inferior vena cava: (1) the capillaries in the spleen, pancreas, stomach, etc., draining into the portal vein, and (2) the sinusoids in the liver, draining into the hepatic veins. The passage through two sets of capillaries enables the blood to take up products of digestion from the alimentary canal and to convey them to the liver cells, where sugar is stored in the form of glycogen.

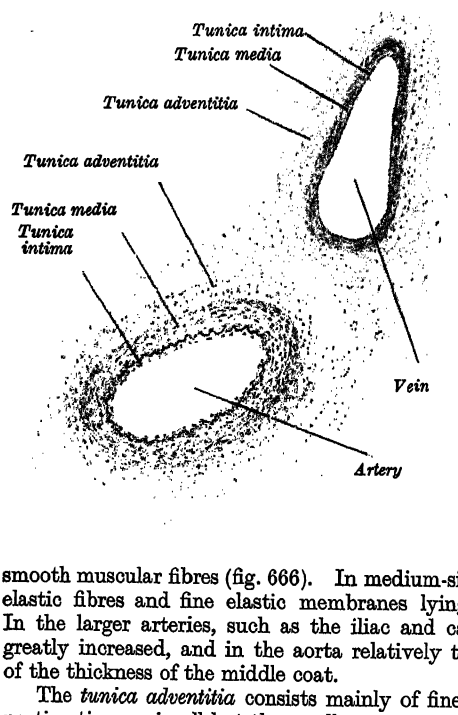
It should be stated that, in addition to the normal capillaries, communications exist between the smaller arteries and veins in the skin of the hands and feet.* These communications are of great importance in the regulation of body temperature, both local and general, as the communicating vessels are able to dilate or to become constricted and so determine the amount of flow through the capillaries at any given time.

THE STRUCTURE OF THE BLOOD-VESSELS

The arteries (figs. 666, 668).—The wall of an artery consists of three coats, viz. an internal or *tunica intima*, a middle or *tunica media*, and an external or *tunica adventitia*. The external coat is tougher than the other two, which are ruptured when a ligature is tied round the vessel, and, in virtue of their elasticity, become retracted from the site of the ligature.

The *tunica intima* consists of (*a*) an internal layer of flattened cells, (*b*) beneath these, a small quantity of loose connective tissue, and (*c*) an elastic lamina. The flattened endothelial cells are fusiform in shape with their long axes parallel to the long axes of the blood-vessels. Each cell possesses a nucleus, and is attached to adjacent cells by cement-substance which reduces silver nitrate. The connective tissue layer is very thin, and contains branched cells, and in the larger arteries, fine elastic fibres with some longitudinal unstriped muscular fibres (*musculo-elastic layer of intima*); this layer increases in thickness with increasing age. The elastic lamina is built up of longitudinally arranged elastic fibres fused together, and is usually fenestrated, having round or oval apertures at irregular intervals. In a transverse section of an artery it appears as a characteristic wavy line, owing to the contracted condition of the empty vessel.

FIG. 666.—A transverse section through an artery and a vein of a child aged 13 months. Stained with hæmatoxylin and eosin. ×20.



The *tunica media*, in the smaller and medium-sized arteries, consists principally of smooth muscular fibres arranged circularly round the vessel; the fibres have well-marked, rod-shaped nuclei. In the smallest arteries the middle coat is composed entirely of smooth muscular fibres (fig. 666). In medium-sized arteries (fig. 668) there are in addition elastic fibres and fine elastic membranes lying between the layers of muscular fibres. In the larger arteries, such as the iliac and carotid, the proportion of elastic tissue is greatly increased, and in the aorta relatively thick elastic laminæ form the greater part of the thickness of the middle coat.

The *tunica adventitia* consists mainly of fine and closely felted bundles of white connective tissue; in all but the smallest arteries it contains some elastic fibres. The elastic tissue is most abundant next the tunica media, and it is sometimes described as forming, between the adventitia and media, a special layer—the *tunica elastica externa*; this layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin. From the medium-sized to the smaller arteries it diminishes gradually in thickness; in the smallest arteries the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

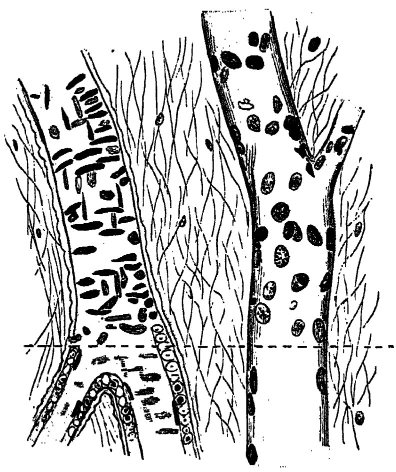
* See Hoyes, W., *Archiv f. Mikroskop. Anat.*, Bd. XIII., 1877; and R. T. Grant and E. F. Bland, *Heart*, vol. xv. 1929-31.

Some arteries have extremely thin walls in proportion to their size; this is especially the case in those situated within the cranium and vertebral canal, where the external and middle coats of the arteries are reduced in thickness.

The arteries, in their distribution throughout the body, are enclosed in thin fibro-areolar *sheaths*. An artery is loosely connected with its sheath by delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve.

The larger arteries are supplied with blood-vessels. These nutrient vessels, called the *vasa vasorum*, arise from branches of the artery itself, or of a neighbouring vessel, at some considerable distance from the points at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat; in man they do not penetrate the other coats; but in some of the larger mammals a few vessels have been traced into the middle coat. Minute veins return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymph vessels are also present in the outer coat.

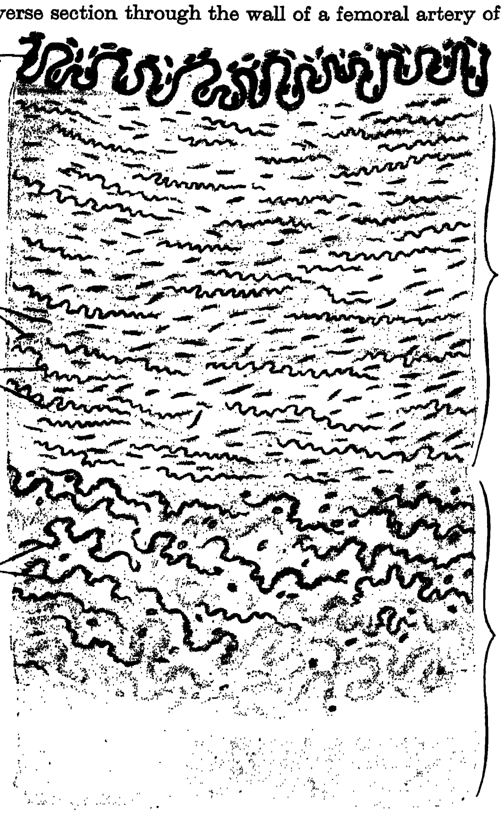
FIG. 667.—A small artery and vein, from the pia mater of a sheep. ×250.



Surface view above the interrupted line; optical section below. Artery in red; vein in blue.

Arteries are also supplied with nerves, which form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments, or bundles of filaments. Most of the nerve-fibres are non-medullated, and are derived from the

FIG. 668.—A transverse section through the wall of a femoral artery of a dog. ×250.



sympathetic system, but some are medullated. The non-medullated fibres are mostly efferent, and end in the middle coat. The medullated fibres are believed to be afferent

and are distributed to the outer and inner coats. Lamellated corpuscles (Pacinian corpuscles) are occasionally found in the outer coat of the aorta.

The capillaries.—The arterioles (excepting those of the cavernous structure of the sexual organs, of the splenic pulp, and of the placenta), subdivide into minute vessels named *capillaries* which are interposed between the arterioles and the venules, and constitute a network, the branches of which maintain the same diameter throughout.

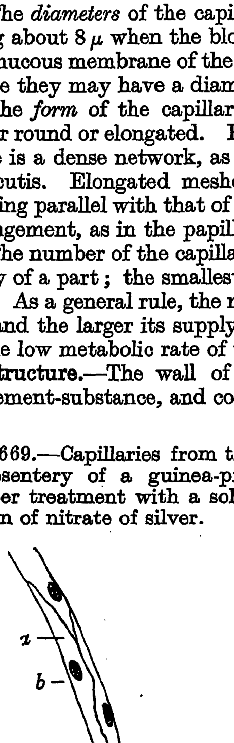
The *diameters* of the capillaries vary in the different tissues of the body, the usual size being about 8 μ when the blood is circulating. The smallest are found in the brain and in the mucous membrane of the intestines; the largest in the skin, and in the marrow of bone, where they may have a diameter of 20 μ.

The *form* of the capillary network varies in the different tissues, the meshes being either round or elongated. Round or angular meshes are most common, and prevail where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis. Elongated meshes occur in muscles and nerves, the long axis of the mesh running parallel with that of the muscle or nerve. Sometimes the capillaries have a looped arrangement, as in the papillæ of the tongue and skin.

The number of the capillaries and the size of the meshes determine the degree of vascularity of a part; the smallest meshes are found in the lungs and in the chorioid coat of the eye. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of food. Few blood-vessels are present in tendons, because of the low metabolic rate of the tissue of which they are composed.

Structure.—The wall of a capillary consists of flattened cells joined edge to edge by cement-substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver, the material which unites the edges of the epithelial cells is displayed, thus showing the outlines of the cells (fig. 669). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus, which may be displayed by staining with carmine or hæmatoxylin. Between their edges, at various points of their meeting, rounded, dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. By some they are believed to be the situations through which the colourless corpuscles of the blood, when migrating from the blood-vessels, emerge; but this view is not universally accepted.

Fig. 669.—Capillaries from the mesentery of a guinea-pig, after treatment with a solution of nitrate of silver.



a. Cells. *b*. Their nuclei.

In developing capillaries, and in the capillaries of the glomeruli of the kidneys, the intestinal villi and the chorioid coat of the eye, intercellular cement cannot be demonstrated, and the cells are believed to form a syncytium.

In many situations a delicate sheath or envelope of branched, nucleated, connective tissue cells is found around the simple capillary tubes, particularly the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

Rouget (1873) * described a special variety of unstriped muscle cell placed at intervals along certain capillaries. The cells are almost transparent and have long, branching thread-like processes which run round the circumference of the capillary tube and by their contraction cause a local constriction of the vessel (fig. 670). '*Rouget cells*' have been described (*a*) on some capillaries in certain situations in amphibia and (*b*) in some capillaries of the mammal, during certain stages of development. Indisputable evidence has not been adduced to enable one to accept their presence anywhere on a vessel less than about 10 μ in diameter, or on fully formed mammalian capillaries.†

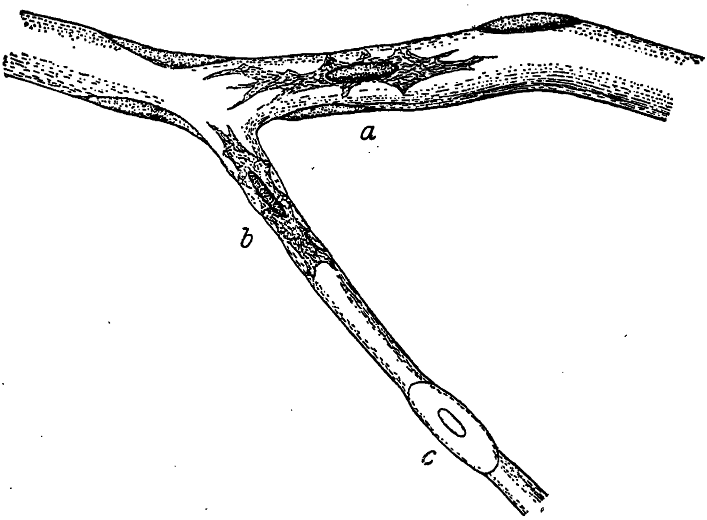
The sinusoids.—In the heart, the liver, the suprarenal and parathyroid glands, and in the carotid and coccygeal bodies, the smallest blood-vessels differ from true capillaries. They are wider, with an irregular lumen, and have no connective tissue covering, their endothelial cells being in direct contact with the cells of the organ. Moreover, their walls are often incomplete. These vessels have been called *sinusoids* by Minot. They are formed by columns of cells or trabeculæ pushing their way into a large blood-vessel or blood-space and carrying its endothelium before them; at the same time the wall of the vessel or space grows out between the columns of cells.

* *A. Physiol. norm. et path.* p. 601.

† Consult *The Anatomy and Physiology of Capillaries*, by August Krogh, 1924.

The veins.—The walls of the veins, like those of the arteries, are composed of three coats—internal, middle, and external; and these are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective tissue or areolar (fig. 666). The main difference between the veins and the arteries is in the comparative weakness of the middle coat in the former.

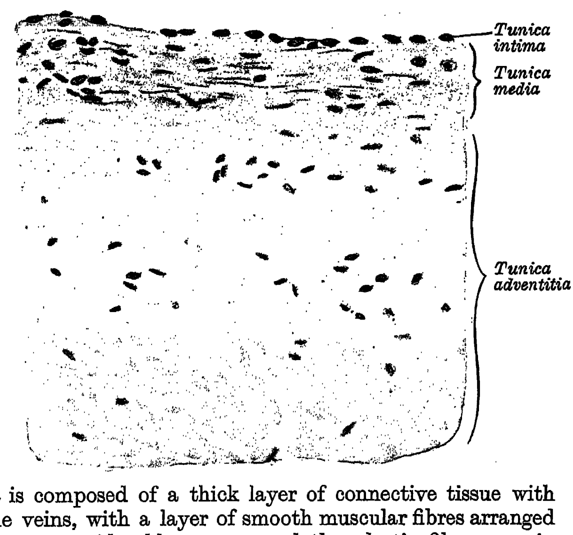
Fig. 670.—Contractile cells of Rouget on the wall of a capillary of the tail of a salamander tadpole (Vimtrup). From *The Endocrine Organs*, by permission of Sir E. Sharpey-Schafer.



a, an expanded cell; *b*, a partially contracted cell which is causing the wall of its capillary to be diminished; *c*, an erythrocyte.

In the smallest veins the three coats are difficult to distinguish (fig. 667). The endothelium is supported on a membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (tunica adventitia), while the inner is composed of a network of longitudinal elastic fibres (tunica media). In the veins next above these in size (0·4 mm. in diameter), a connective tissue layer containing numerous smooth muscular fibres circularly disposed forms the middle coat, while the elastic and connective tissue elements of the outer coat are more distinctly perceptible. In the middle-sized veins (fig. 666) the endothelium is of the same character as in the arteries, but its cells are shorter and broader. It is supported by a connective tissue layer, consisting of a delicate network of branched cells, and external to this there is a layer of elastic fibres disposed in the form of a network in place of the definite fenestrated membrane seen in arteries. This constitutes the *tunica intima*. The *tunica media* is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a layer of smooth muscular fibres arranged circularly. The white fibres are in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *tunica adventitia* consists, as in the arteries, of areolar tissue with longitudinal elastic fibres. In the largest veins it is very much thicker than the tunica media, and contains a large number of

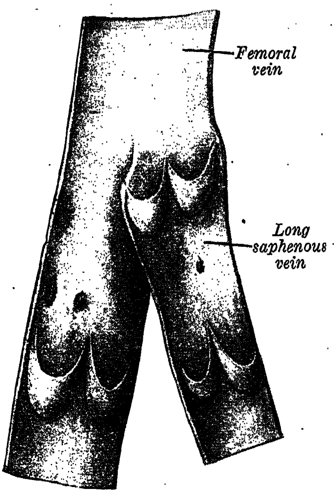
Fig. 671.—A transverse section through the wall of a femoral vein of a dog. ×250. The elastic tissue is not differentiated in this preparation.



longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal and azygos veins. In the inferior vena cava, renal and portal veins they extend through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. The large veins which open into the heart are covered for a short distance with a layer of cardiac muscle continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater; (3) in the veins of the retina; (4) in the veins of the spongy substance of bones; (5) in the venous spaces of the corpora cavernosa and corpus spongiosum. The veins of the above-mentioned parts consist of an endothelial lining supported on areolar tissue.

Most veins are provided with *valves* which serve to prevent the reflux of the blood (fig. 672). Each valve is formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and is covered on both surfaces by endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three, and sometimes only one. The valves are semilunar. They are attached by their convex edges to the wall of the vein; the concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. The wall of the vein on the cardiac side of the attachment of each valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially in the veins of the lower extremities, these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins, i.e. those less than 2 mm. in diameter, also in the venæ cavæ, hepatic, renal, uterine and ovarian veins. The cerebral and spinal veins, the veins of the spongy tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. A few valves are found in each testicular vein, and one also at its termination. A few valves are occasionally found in the azygos and intercostal veins. Valves are present in the tributaries of the portal vein in the fœtus and for a short time after birth; as a rule they soon atrophy and disappear, but sometimes they persist in a degenerate form.

Fig. 672.—The upper portions of the femoral and long saphenous veins laid open to show valves. About two-thirds of natural size.



The larger veins, like the arteries, are supplied with nutrient vessels, termed *vasa vasorum*. Nerves also are distributed to the veins in the same manner as to the arteries, but in much fewer numbers.

The Thoracic Cavity

The shape and the skeletal walls of the thoracic cavity are described on pp. 238, 239. Its chief contents are the heart and the two lungs.

The inlet of the thorax.—The parts which pass through the upper opening of the thorax are, from before backwards, in or near the median plane, the Sternohyoid and Sternothyroid muscles, the remains of the thymus, the inferior thyroid veins, the trachea, œsophagus, thoracic duct and the Longus cervicis (Longus colli) muscles; laterally the innominate veins, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary arteries and the superior intercostal arteries, the vagus, cardiac, phrenic, and sympathetic nerves, the greater parts of the anterior primary rami of the first

thoracic nerves, and the left recurrent laryngeal nerve. The apices of the lungs, covered by the pleuræ, project through the inlet into the root of the neck.

The **outlet of the thorax** is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the thoracic cavity is much longer behind than in front. The Diaphragm (p. 555) closes the opening and forms the convex floor of the thorax. The floor is flatter at the centre than at the periphery, and higher on the right side than on the left; in the dead body the right side of the floor reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on each side the floor slopes suddenly downwards to the costal and vertebral attachments of the Diaphragm; this slope is more marked and longer behind than in front, so that only a narrow space is left between the Diaphragm and the posterior wall of the thorax.

The **thoracic cavity**.—The capacity of the thoracic cavity does not correspond with its apparent size, because the lower part of the space enclosed by the ribs is occupied by some of the abdominal viscera. On the other hand, the fact that the thoracic cavity extends for a short distance into the neck above the anterior parts of the first ribs compensates for this difference to a slight extent. During life the size of the thoracic cavity is constantly varying with the movements of the ribs and Diaphragm.

The thoracic cavity is divided into right and left halves by a septum, termed the *mediastinum*, which stretches from the back of the sternum to the vertebral column, and extends from the thoracic inlet above to the Diaphragm below. The heart lies in the mediastinum, enclosed within a fibroserous sac, termed the *pericardium*; the lungs occupy the right and left halves of the thoracic cavity. Each lung is covered with a serous membrane, called the *pleura*, which also lines the wall of the corresponding half of the chest, and forms the lateral boundary of the mediastinum (fig. 682).

For purposes of description the mediastinum is divided into a superior and an inferior part. The *superior part* extends downwards from the thoracic inlet as far as an oblique plane passing through the lower edge of the manubrium sterni in front and the lower border of the fourth thoracic vertebra behind. The *inferior part*, below this plane, is subdivided into three portions, viz. an *anterior* in front of the pericardium, a *posterior* behind the pericardium and Diaphragm, and a *middle*, which contains the pericardium, the heart and the large vessels entering or leaving the latter (fig. 684). Details of the contents of the different parts of the mediastinum are given with the description of the respiratory organs.

The Pericardium

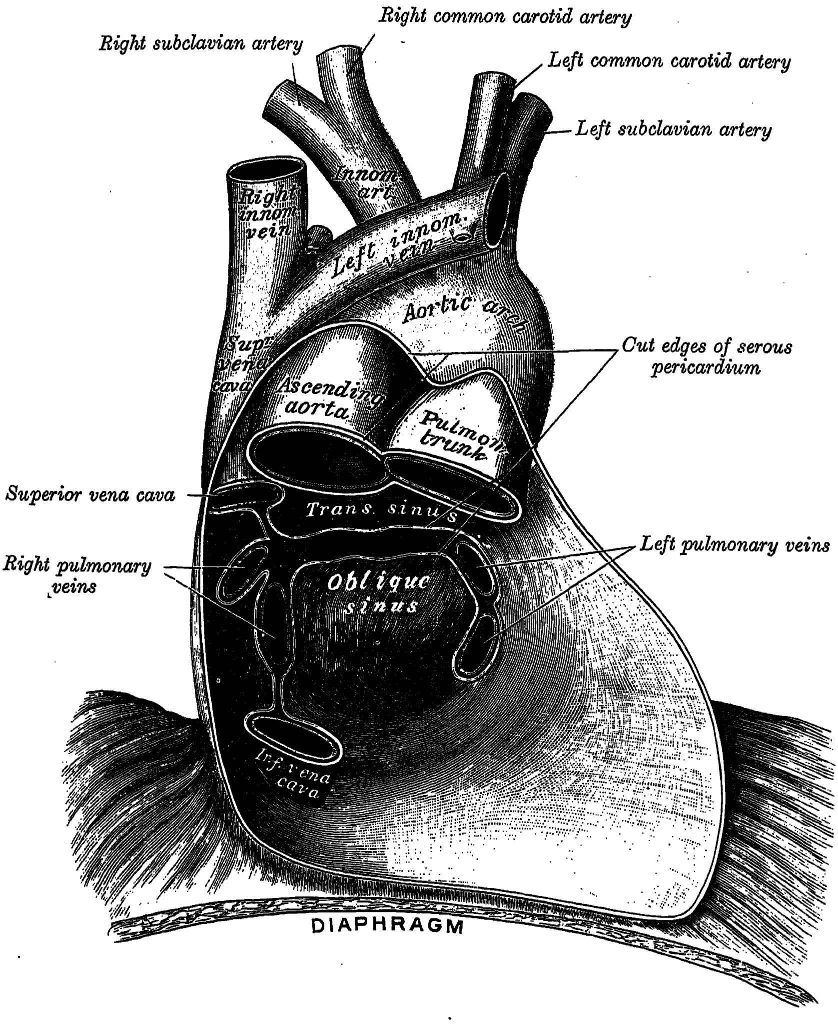
The **pericardium** (fig. 673) is a conical, fibroserous sac, which contains the heart and the roots of the great vessels. It is placed in the mediastinum behind the body of the sternum and the cartilages of the ribs from the second to the sixth inclusive, and in front of the thoracic vertebræ, from the fifth to the eighth inclusive.

The **structure of the pericardium**.—Although the pericardium is usually described as a single sac, an examination of its structure shows that it consists essentially of two sacs intimately connected with one another, but different in structure. The outer sac, known as the *fibrous pericardium*, consists of fibrous tissue. The inner sac, or *serous pericardium*, is a delicate membrane which lines the fibrous sac and covers the heart; it is composed of a single layer of flattened cells resting on loose areolar tissue. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being a potential one.

The *fibrous pericardium* is a cone-shaped bag, the apex of which is truncated and continuous with the external coats of the great vessels, while its base is attached to the central tendon and to a small part of the muscular substance of the left half of the Diaphragm. In some of the lower mammals the base is either completely separated from the Diaphragm or joined to it by some loose

fibrous tissue ; in man much of its diaphragmatic attachment consists of loose fibrous tissue which can be readily broken down, but over a small area the central tendon of the Diaphragm and the pericardium are fused. Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal fascia (p. 538). The fibrous pericardium is also attached to the posterior surface of the sternum by a *superior* and an *inferior sternopericardial ligament* ; the superior passing to the upper end of the body, and the inferior to the lower end. By means of all these connexions it is securely anchored within the thoracic cavity.

FIG. 673.—The posterior wall of the pericardial sac, showing the lines of reflection of the serous pericardium on to the great vessels.



The vessels receiving prolongations from the fibrous pericardium are : the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. The inferior vena cava, which enters the pericardium through the central tendon of the Diaphragm, receives no covering from the fibrous layer.

The *serous pericardium* is, as already stated, a closed sac which lines the fibrous pericardium and is invaginated by the heart ; it therefore consists of a *visceral* and a *parietal* portion. The visceral portion, or *epicardium*, covers the heart and the great vessels, and from the latter is continuous with the parietal layer, which lines the fibrous pericardium. The portion which covers

the vessels is arranged in the form of two tubes. The aorta and pulmonary trunk are enclosed in one tube ; the superior and inferior venæ cavæ and the four pulmonary veins are enclosed in a second tube, the attachment of which to the parietal layer is ∩-shaped. The cul-de-sac between the limbs of the ∩ lies behind the left atrium and is known as the *oblique sinus*, while the passage between the aorta and pulmonary trunk, in front, and the atria, behind, is named the *transverse sinus* (fig. 673).

Anteriorly, the pericardium is separated from the front wall of the thorax, in the greater part of its extent, by the lungs and pleuræ ; but a small area, usually corresponding with the left half of the lower part of the body of the sternum and the sternal ends of the cartilages of the fourth and fifth ribs of the left side, is in direct relationship with the chest-wall. Until puberty or adolescence the lower end of the thymus is in contact with the front of the upper part of the pericardium. *Posteriorly*, it rests upon the bronchi, the œsophagus, the œsophageal plexus of nerves, the descending thoracic aorta and the posterior part of the mediastinal surface of each lung. *Laterally*, it is covered by the pleuræ, and is in relation with the mediastinal surfaces of the lungs ; the phrenic nerve, with its accompanying vessels, descends between the pericardium and the mediastinal pleura on each side. *Inferiorly*, it is separated from the liver and the fundus of the stomach by the Diaphragm.

The ligament of the left vena cava.—Between the left pulmonary artery and subjacent pulmonary vein is a triangular fold of the serous pericardium, known as the *ligament of the left vena cava.* It is formed by the folding of the serous layer over the remnant of the left duct of Cuvier (left superior vena cava) (p. 158). The lumen of this duct is obliterated during fœtal life, but its wall persists as a fibrous band stretching from the upper part of the left superior intercostal vein to the back of the left atrium, where it is continuous with a small vein, termed the *oblique vein of the left atrium*, which opens into the coronary sinus (fig. 676).

The *arteries* of the pericardium are derived from the internal mammary arteries and their musculophrenic branches, and from the descending thoracic aorta ; its *nerves* are derived from the vagus and phrenic nerves, and the sympathetic trunks.

Applied Anatomy.—Fluid effusions into the pericardial sac may cause serious embarrassment of the heart's action, and paracentesis of the pericardium, and withdrawal of the fluid may be necessary. The puncture may be made in the fifth or sixth left intercostal space near the sternum, with care to avoid wounding the internal mammary artery that usually runs 1·25 cm. lateral to the sternal edge. Alternatively the exploring needle may be entered at the left costoxiphoid angle, and passed upwards and backwards into the pericardial sac. Curschmann recommends paracentesis in or lateral to the left mammary line in the fifth or sixth left interspace, in view of the fact that the fluid tends to collect at the sides of, and below, the heart rather than in front of it.

The Heart (Cor)

The heart is a hollow, muscular organ of a somewhat conical form ; it lies between the lungs in the middle mediastinum (fig. 674), and is enclosed in the pericardium. It is placed obliquely in the chest behind the body of the sternum and adjoining parts of the rib cartilages, and projects farther into the left than into the right half of the thoracic cavity, so that about one-third of it is situated on the right of the median plane and two-thirds on the left (Plate XIII, fig. 1).

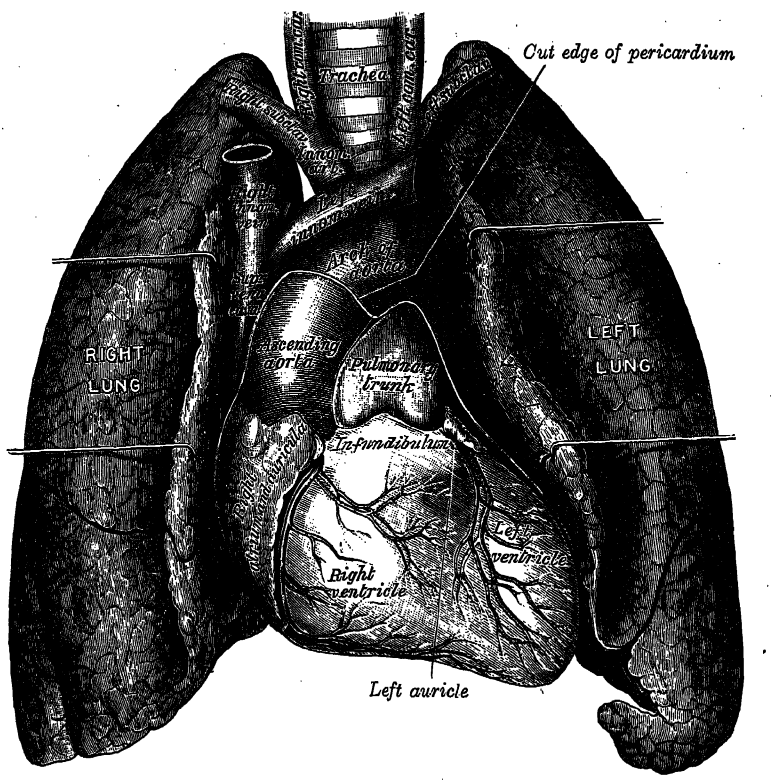
Size.—The heart of the adult measures about 12 cm. from base to apex, 8 to 9 cm. transversely at the broadest part, and 6 cm. anteroposteriorly. Its weight, in the male, varies from 280 to 340 grammes ; in the female, from 230 to 280 grammes. It continues to increase in weight and size up to an advanced period of life, and this increase is more marked in men than in women.

Component parts.—As already stated (p. 661) the heart is divided into four chambers, viz. right and left atria, and right and left ventricles : the division is indicated on the surface of the heart by grooves or sulci. The atria are separated from the ventricles by the *atrioventricular groove* (coronary sulcus) ; this groove contains the trunks of the coronary vessels of the heart, and is

deficient in front, where it is crossed by the root of the pulmonary trunk. The *interatrial groove,* separating the two atria, is scarcely marked on the posterior surface, while anteriorly it is hidden by the pulmonary trunk and aorta. The ventricles are separated by two grooves, termed the *anterior* and *inferior interventricular grooves* (longitudinal sulci); the former is situated on the sternocostal surface of the heart, near its left margin, the latter on the diaphragmatic surface near the right margin; these grooves extend from the base of the ventricular portion to a notch, termed the *incisura apicis cordis,* situated a little to the right of the apex of the heart.

The *base* (fig. 676) is somewhat quadrilateral in form; it faces backwards and to the right, and is separated from the fifth, sixth, seventh and eighth

FIG. 674.—The heart and lungs. Anterior aspect.

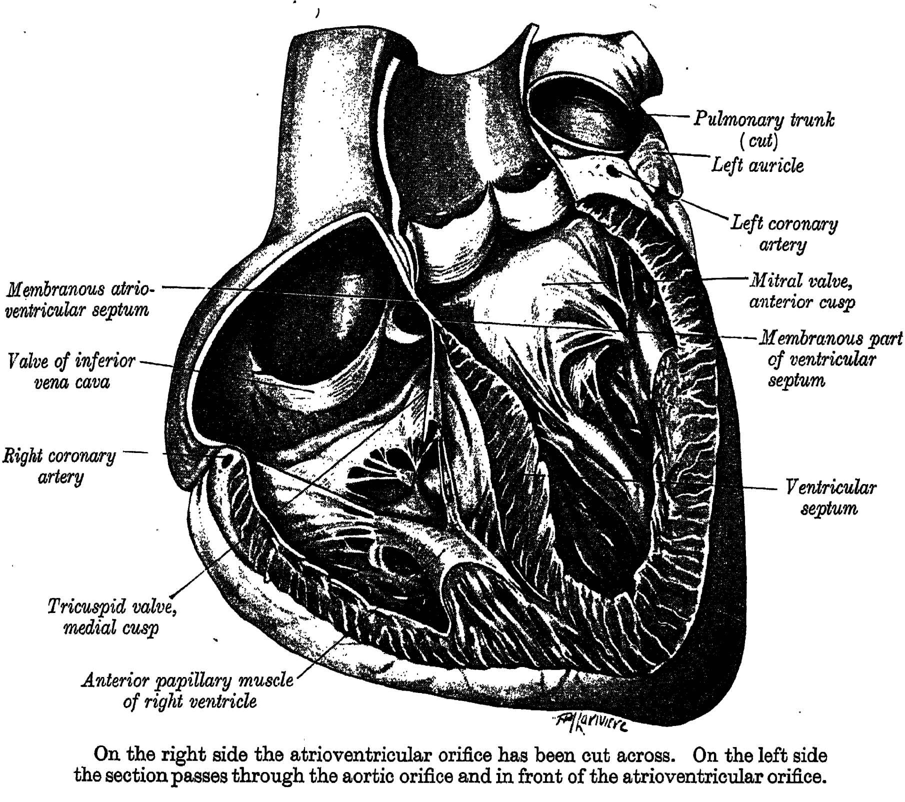


thoracic vertebræ by the pericardium, right pulmonary veins, œsophagus and aorta. It is formed mainly by the left atrium, and, to a small extent, by the posterior part of the right atrium. It is in relation above with the bifurcation of the pulmonary trunk, and is bounded below by the posterior part of the atrioventricular groove, containing the coronary sinus. On the right it is limited by the rounded right border of the right atrium, and on the left by the rounded left border of the left atrium. The four pulmonary veins, two on each side, open into the left atrium, whilst the superior vena cava opens into the upper part, and the inferior vena cava into the lower part, of the right atrium. The portion of the left atrium between the openings of the right and left pulmonary veins constitutes the anterior wall of the oblique sinus of the pericardium (p. 669).

The *apex,* formed by the left ventricle, is directed downwards, forwards and to the left, and is overlapped by the left lung and pleura: it lies behind the left fifth intercostal space, about 8 cm. from the mid-sternal line, or, in the male, about 4 cm. below and 2 cm. to the medial side of the left nipple.

The *sternocostal surface* (fig. 677) is directed forwards, upwards and to the left. It consists of an atrial and a ventricular portion, the former being above and to the right, the latter below and to the left, of the anterior part of the atrioventricular groove. The atrial portion is almost entirely formed by the right atrium ; the greater part of the left atrium is hidden by the ascending aorta and pulmonary trunk (fig. 677), and only a small part of its auricle projects forwards on the left side of the pulmonary trunk. Of the ventricular portion, about one-third is formed by the left, and two-thirds by the right ventricle, the line of separation between the ventricles being marked by the anterior interventricular groove. The sternocostal surface is separated by the pericardium from the body of the sternum, the Sternocostalis (Transversus thoracis) muscles and the cartilages of the third, fourth, fifth and sixth ribs ; owing to

FIG. 675.—A section through the heart, showing the ventricular septum.



On the right side the atrioventricular orifice has been cut across. On the left side the section passes through the aortic orifice and in front of the atrioventricular orifice.

the bulging of the heart towards the left side a much larger part of the surface lies behind the left than the right rib-cartilages. The sternocostal surface is also covered by the pleuræ and the thin, anterior parts of the lungs, with the exception of a small, triangular area corresponding with the cardiac notch in the left lung. The base of this area is represented by a line in the median plane from the level of the fourth costal cartilages to the junction of the body of the sternum with the xiphoid process, and the sides by lines from a point ·4 cm. medial to the apex of the heart to the upper and lower ends of the base line.

The *diaphragmatic surface* (fig. 676), directed downwards and slightly backwards, is formed by the ventricles (chiefly by the left ventricle), and rests upon the central tendon and a small part of the left muscular portion of the Diaphragm. It is separated from the base by the posterior part of the atrioventricular groove, and is traversed obliquely by the inferior interventricular groove.

The *left surface* is directed upwards, backwards and to the left. It is formed almost entirely by the left ventricle, but a small part of the left atrium and the left auricle contribute to its formation superiorly. Convex from before back-

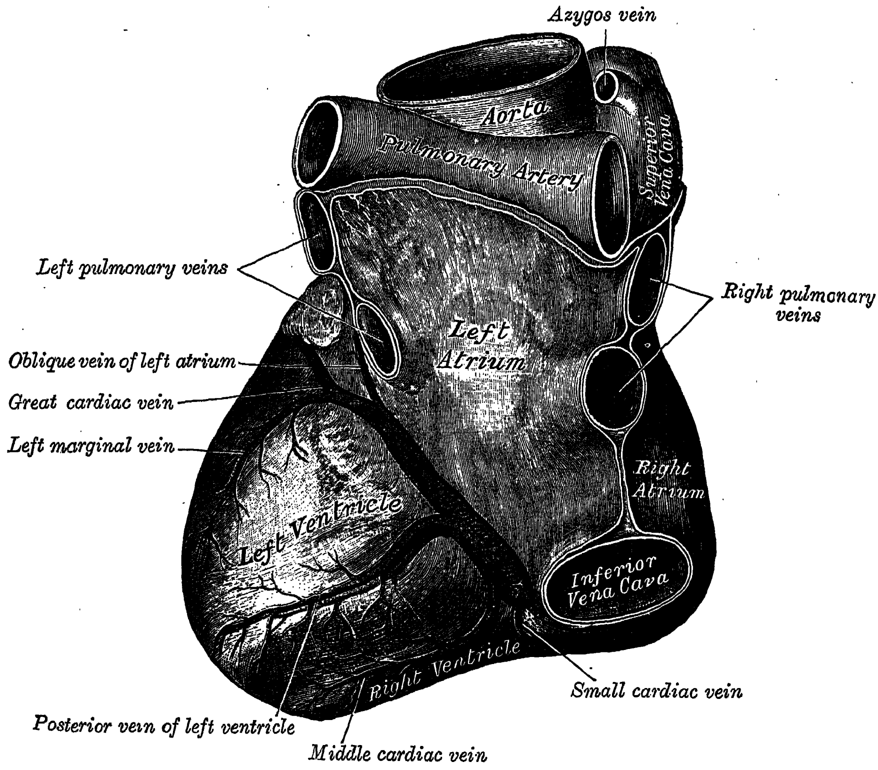
wards and from above downwards, it is widest above, where it is crossed by the atrioventricular groove, and narrowest at the apex. It is separated by the pericardium from the left phrenic nerve and its accompanying vessels, and by the left pleura from the deep hollow on the mediastinal surface of the left lung, below and in front of the hilum.

The *right margin* of the heart, formed by the right atrium, is rounded and almost vertical; it is situated behind the third, fourth and fifth right costal cartilages 1·25 cm. from the margin of the sternum.

The *inferior* or *acute margin*, formed almost entirely by the right ventricle, is nearly horizontal, and extends from the lower limit of the right border to the apex of the heart.

The *left* or *obtuse margin* is rounded, and is formed mainly by the left ventricle, but to a slight extent, above, by the left auricle. It extends from the

Fig. 676.—The base and the diaphragmatic surface of the heart.



left auricle, obliquely downwards, with a convexity to the left, to the apex of the heart, and separates the sternocostal from the left surface.

The **atrial septum**.—A partition, named the *atrial septum* (figs. 678, 682), intervenes between the right and left atria, and is placed so obliquely that the right atrium lies in front and slightly to the right of the left atrium.

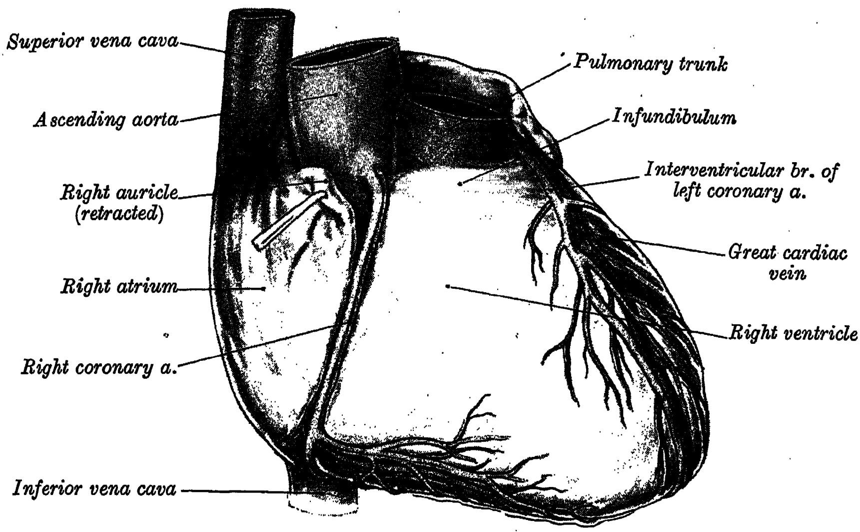
The **right atrium** (figs 677, 678) is a somewhat quadrangular chamber which forms the right surface of the heart. The superior vena cava opens into its upper and posterior part and the inferior vena cava into its lower and posterior part. A small, conical, muscular pouch, termed the *auricle*, projects towards the left from its upper and anterior part and overlaps the right side of the root of the aorta. The margins of the auricle are notched, and its interior is encroached on by an irregular, muscular reticulum.

In well fixed hearts the outer surface of the lateral wall of the atrium is marked by a shallow groove, termed the *sulcus terminalis*, which extends between the right sides of the orifices of the superior and inferior venæ cavæ. It

corresponds in position with the crista terminalis on the inner surface and indicates the line of union of the atrium and the right horn of the sinus venosus, which is incorporated within the right atrium in the adult heart.

Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung and is separated from it by the pleura and the pericardium. *Laterally*, it is related to the mediastinal surface of the right lung in front of the hilum but is separated from it by the pleura, the right phrenic nerve and pericardiacophrenic vessels and the pericardium. *Posteriorly* and to the left, the right atrium is related to the left atrium and is separated from it by the atrial septum, which forms the posterior wall of the chamber ; posteriorly and to the right, it is related to the right pulmonary veins. *Medially*, it is

FIG. 677.—The sternocostal surface of the heart.



related to the commencement of the ascending aorta and, to a lesser extent, to the root of the pulmonary trunk.

The *interior of the right atrium* (fig. 678) presents the following parts for examination :

Orifices:
- Superior vena cava.
- Inferior vena cava.
- Coronary sinus.
- Foramina venarum minimarum.
- Right atrioventricular.

Valves:
- Valve of the inferior vena cava.
- Valve of the coronary sinus.

Fossa ovalis.
Annulus ovalis.
Intervenous tubercle.
Musculi pectinati.
Crista terminalis.

The *superior vena cava* (figs. 677, 678) returns the blood from the upper half of the body, and opens into the upper and posterior part of the atrium. Its orifice is directed downwards and forwards, and has no valve.

The *inferior vena cava* (fig. 678), larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the atrium near the atrial septum ; its orifice is guarded by a rudimentary valve, termed the *valve of the inferior vena cava*.

The *coronary sinus* (fig. 676) returns the greater part of the blood from the substance of the heart. Its opening is placed between the orifice of the inferior

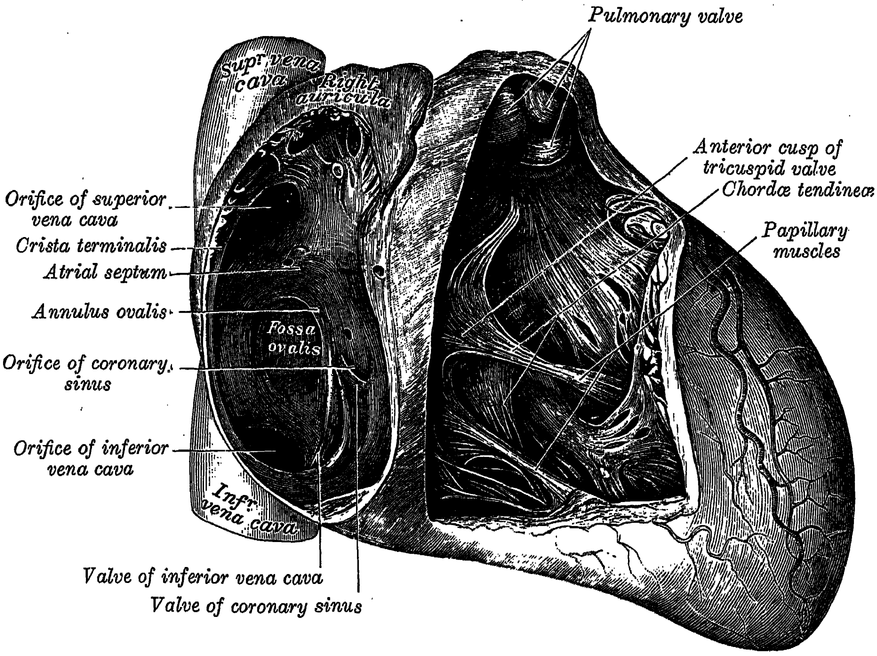
vena cava and the atrioventricular opening, and is protected by a thin, semicircular valve, which is termed the *valve of the coronary sinus.*

The *foramina venarum minimarum* are the orifices of minute veins (*venæ cordis minimæ*), which return a small quantity of blood directly from the substance of the heart. They are more numerous on the septal wall than elsewhere.

The *right atrioventricular orifice* is the large opening between the right atrium and ventricle; it is described with the right ventricle (p. 676).

The *valve of the inferior vena cava* is situated in front of the orifice of the inferior vena cava. It is semilunar in form, its convex margin being attached to the anterior margin of the orifice; its concave margin, which is free, ends in two cornua, of which the left is continuous with the anterior edge of the annulus ovalis (limbus fossæ ovalis), while the right is lost on the wall of

Fig. 678.—The interior of the right side of the heart.



the atrium. The valve is formed by a duplication of the lining membrane of the atrium, enclosing a few muscular fibres. During fœtal life this valve is of large size, and serves to direct the blood from the inferior vena cava into the left atrium, through an opening, named the foramen ovale, in the atrial septum. It varies considerably in size and it sometimes presents a cribriform or filamentous appearance; occasionally it is absent.

The *valve of the coronary sinus* (fig. 678) is a semicircular fold of the lining membrane of the atrium, which covers the lower part of the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the atrium. This valve may be double or it may be cribriform.

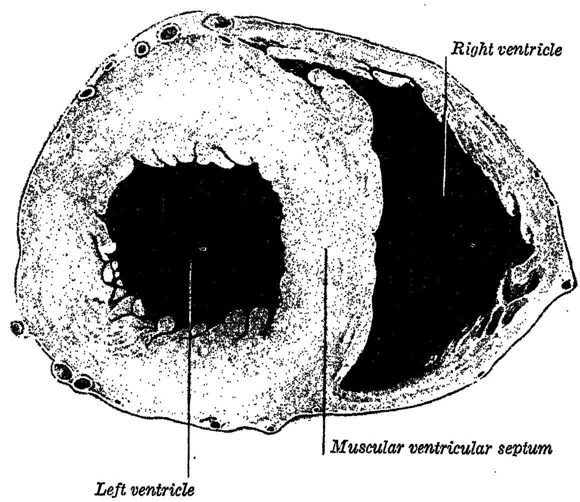
The *fossa ovalis* (fig. 678) is an oval depression on the lower part of the septal wall of the atrium, above and to the left of the orifice of the inferior vena cava. It is formed by the septum primum of the fœtal heart (p. 140).

The *annulus ovalis* (limbus fossæ ovalis) (fig. 678) is the prominent margin of the fossa ovalis. It is most distinct above and at the sides of the fossa; below, it is deficient. Its anterior edge is continuous with the left horn of the valve of the inferior vena cava. A small, slit-like, valvular opening is occa-

sionally found, at the upper margin of the fossa, leading upwards, beneath the limbus, into the left atrium ; it is the remains of the foramen ovale between the two atria.

The *intervenous tubercle* is a small projection on the posterior wall of the atrium, just below the orifice of the superior vena cava. It is distinct in the hearts of quadrupeds, but in man is scarcely visible. During fœtal life it may direct the blood from the superior vena cava towards the right atrioventricular opening.

Fig. 679.—A transverse section through the ventricles of the heart.



The *crista terminalis* is a smooth, muscular ridge, which is placed in the lateral wall of the right atrium and extends from the right side of the orifice of the superior vena cava to the right side of the orifice of the inferior vena cava, where it is connected to the right end of the valve of the latter vessel. It occupies the site of the right venous valve of the embryo (p. 137) and demarcates in the interior of the heart the atrium proper from the smooth-walled *sinus venarum*, into which the great veins open.

The *musculi pectinati* are nearly parallel muscular ridges which run forwards from the crista terminalis across the lateral and anterior walls of the right atrium, inclining towards the atrioventricular orifice. In the auricle they are connected to one another so as to form a muscular network.

The **right ventricle** (figs. 678, 681, 682) extends from the right atrium nearly to the apex of the heart. Its *anterosuperior surface* is convex, and forms a large part of the sternocostal surface of the heart. In the greater part of its extent it is separated from the chest wall only by the pericardium, but the left pleura and, to a lesser extent, the anterior margin of the left lung are interposed both above and to the left side. Its *inferior surface* is flattened and is related to the central tendon and the adjoining part of the Diaphragm, but is separated from it by the pericardium. Its *left*, or *posterior*, *wall* is formed by the ventricular septum, which bulges into the right ventricle, so that a transverse section of the cavity presents a crescentic outline (fig. 679). Its upper left angle forms a conical pouch termed the *infundibulum* (conus arteriosus), from which the pulmonary trunk arises. A tendinous band, which is named the *tendon of the infundibulum*, connects the posterior surface of the infundibulum to the aorta ; this tendon is continuous with the membranous part of the ventricular septum (p. 681). A prominent muscular ridge passes downwards and to the right from the posterior wall of the infundibulum, and intervenes between the atrioventricular and the pulmonary orifices (fig. 681). It is termed the *infundibuloventricular crest*, and it marks the lower limit of the bulbar part of the right ventricle (p. 145). The wall of the right ventricle is thinner than that of the left, the proportion between them being as 1 to 3 ; it is thickest at the base, and gradually becomes thinner towards the apex of the ventricle.

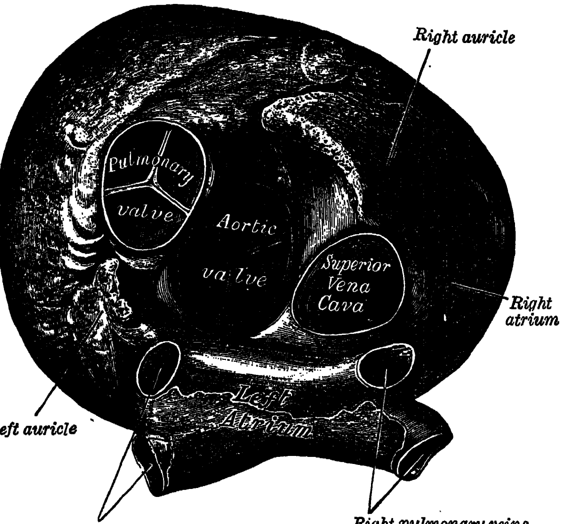
The interior of the right ventricle (fig. 681) presents the following parts for examination :

Orifices { Right atrioventricular. Pulmonary trunk.	Valves { Right atrioventricular or tricuspid. Pulmonary.
Trabeculæ carneæ.	Chordæ tendineæ.

The *right atrioventricular* or *tricuspid orifice* is the large, oval aperture between the right atrium and the right ventricle. Situated at the base of the ventricle, it is encircled by a fibrous ring, covered with the lining membrane of the heart; it is considerably larger than the left atrioventricular orifice, being sufficient to admit the tips of three or four fingers; its circumference measures from 12 to 13 cm. It is guarded by the right atrioventricular (tricuspid) valve.

The *orifice of the pulmonary trunk* is situated at the summit of the infundibulum, close to the ventricular septum; it is circular in form, and has a diameter of about 3 cm. It is placed above and to the left of the atrioventricular opening, and is guarded by the pulmonary valve.

Fig. 680.—The heart. Superior aspect.



The red lines indicate the lines along which the parietal layer of the serous pericardium becomes continuous with the epicardium.

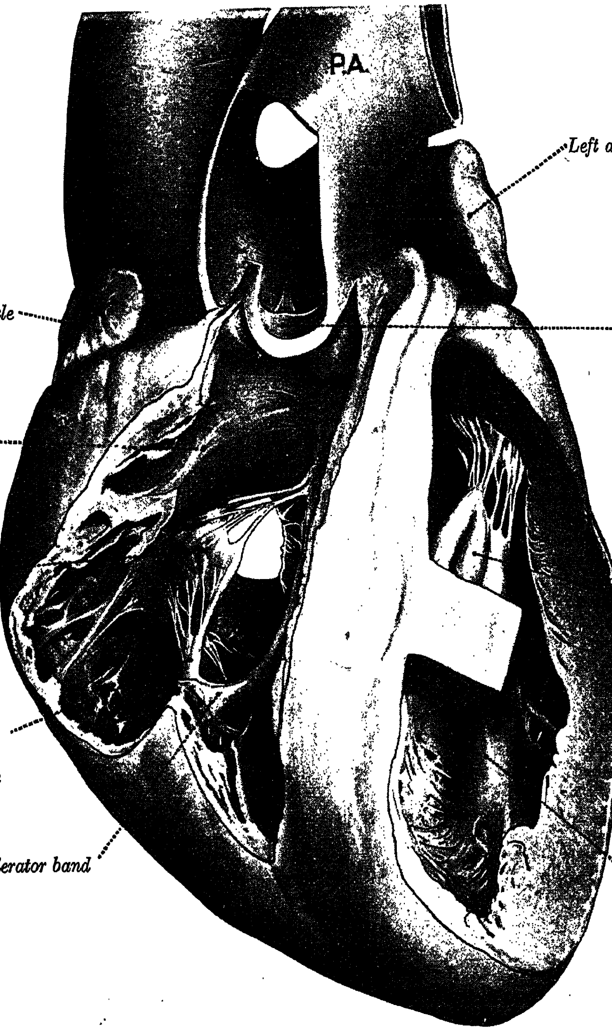
The *right atrioventricular (tricuspid) valve* (figs. 678, 681) guards the right atrioventricular orifice, and consists of three somewhat triangular cusps, named, *anterior*, *inferior* and *medial*; in the angles between the cusps small intermediate segments are sometimes seen. The anterior cusp, the largest, is interposed between the atrioventricular orifice and the infundibulum (conus arteriosus), while the medial cusp is in relation with the ventricular septum. Each cusp is formed by a duplicature of the lining membrane of the heart, strengthened by intervening layers of fibrous tissue. The central parts of the cusps are comparatively thick and strong, their marginal portions thin and translucent. Their bases are attached to the fibrous ring surrounding the atrioventricular orifice and are also joined to each other so as to form a continuous annular membrane, while their apices project into the ventricular cavity. Their atrial surfaces, directed towards the blood-current from the atrium, are smooth; their ventricular surfaces, directed towards the wall of the ventricle, are rough and irregular and, together with the apices and margins of the cusps, give attachment to a number of delicate, tendinous cords, which are termed the *chordæ tendineæ*.

The *trabeculæ carneæ* are round or irregular muscular columns which project from the whole of the inner surface of the ventricle, with the exception of the infundibulum (conus arteriosus), the wall of which is smooth. They are of three kinds: some are mere ridges, others are fixed at their ends but free in the middle, while a third set (*musculi papillares*) are continuous by their bases with the wall of the ventricle, while their apices project into the cavity, and give origin to the chordæ tendineæ, which pass to be attached to the segments of the tricuspid valve. There are two papillary muscles, anterior and inferior (posterior); the anterior is the larger, and its chordæ tendineæ are connected with the anterior and inferior cusps of the valve; the inferior papillary muscle sometimes consists of two or three parts, and its chordæ tendineæ are connected with the inferior and medial cusps. Some chordæ tendineæ also spring directly from the ventricular septum, or from small septal papillary muscles, and pass to the anterior and medial cusps. A muscular band, well-marked in sheep and some other animals, frequently extends from the ventricular septum to the base of the anterior papillary muscle and serves to convey the right fasciculus of the atrioventricular bundle (p. 684). From its attachments it may assist

in preventing over-distension of the ventricle, and so has been named the *moderator band* (fig. 681).

The *pulmonary valve* (figs. 678, 680) consists of three semilunar segments or cusps, which are attached, by their convex margins, to the wall of the pulmonary trunk at its junction with the ventricle, their free borders being directed

FIG. 681.—A dissection of the ventricles, viewed from in front. (A. K. Maxwell.) From Quain's *Elements of Anatomy*, 11th edition, vol. iv., part iii. *The Heart*, by Professor Thomas Walmsley, 1929.



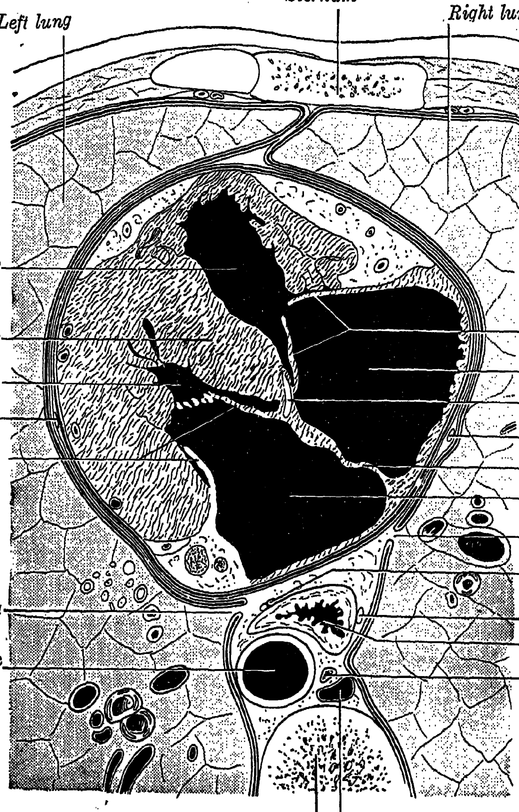
upwards into the lumen of the vessel. Two of the cusps are situated anteriorly (right and left) and the third is posterior. Each consists of a duplicature of the lining membrane, with a little fibrous tissue interposed between the two endothelial layers. The free and attached margins are strengthened by tendinous fibres, and at the middle of the free margin there is a thickened *nodule*. From this nodule tendinous fibres radiate through the cusp to its attached margin, but are absent from two narrow crescentic portions, which are termed the *lunulæ*. These are placed one on each side of the nodule, and immediately adjoining the free margin. Opposite to the semilunar cusps the pulmonary trunk presents three slight dilatations or sinuses.

The left atrium is rather smaller than the right, but its walls are thicker,

measuring about 3 mm. A small somewhat conical pouch, termed the *auricle*, projects forwards from its upper left corner.

The cavity of the left atrium is formed to a large extent by the proximal parts of the pulmonary veins, which are incorporated during its development (p. 141). It is cuboidal in form, and extends to the right behind the right atrium, from which it is separated by the atrial septum. Anteriorly, and to the left, it is concealed by the roots of the pulmonary trunk and aorta. Its posterior aspect forms most of the base of the heart (p. 670) and lies in the

FIG. 682.—A transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra.



anterior wall of the oblique sinus of the pericardium. The two pulmonary veins open into it on each side.

The *auricle* is somewhat constricted at its junction with the principal cavity; it is longer, narrower and more curved than that of the right atrium, and its margins are more deeply indented. It is directed forwards on the left side of the pulmonary trunk, and overlaps the root of this vessel.

The interior of the left atrium (fig. 685) presents the following parts for examination:

Orifices of the four pulmonary veins.
Left atrioventricular orifice.
Foramina venarum minimarum.
Musculi pectinati.

The *pulmonary veins*, four in number, open into the upper part of the posterior surface of the left atrium—two on each side of its middle line; their

orifices are not provided with valves. The two left veins frequently end by a common opening.

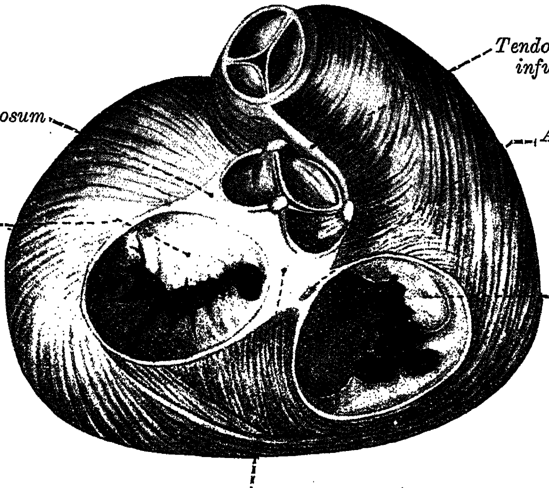
The *left atrioventricular orifice* is the aperture between the left atrium and ventricle ; it is described below.

The *foramina venarum minimarum* are the orifices of minute veins (venæ cordis minimæ) which return a small quantity of blood from the muscular substance of the heart.

The *musculi pectinati*, fewer and smaller than those in the right atrium, are confined to the inner surface of the auricle.

On the atrial septum a lunate impression may be seen, bounded below by a crescentic ridge, the concavity of which is directed upwards. The depression is just above the fossa ovalis of the right atrium.

FIG. 683.—The base of the ventricles, after removal of the atria and the pericardium. From Quain's *Elements of Anatomy*, vol. iv., part iii. *The Heart*, by Professor Thomas Walmsley, 1929.



The **left ventricle** is longer and more conical in shape than the right, and on transverse section its cavity presents an oval or nearly circular outline (fig. 679). It takes part in the formation of the sternocostal and left surfaces of the heart and is related to the mediastinal surface of the left lung, but the pericardium, the left phrenic nerve and pericardiacophrenic vessels, and the left pleura intervene between them. Inferiorly, it forms a large part of the diaphragmatic surface of the heart, and, anteriorly, it is separated from the right ventricle by the ventricular septum. It also forms the apex of the heart. Its walls are about three times as thick as those of the right ventricle.

Its interior (figs. 681, 685) presents the following parts for examination :

Orifices { Left atrioventricular. Aortic — Valves { Left atrioventricular or mitral. Aortic.

Trabeculæ carneæ. — Chordæ tendineæ.

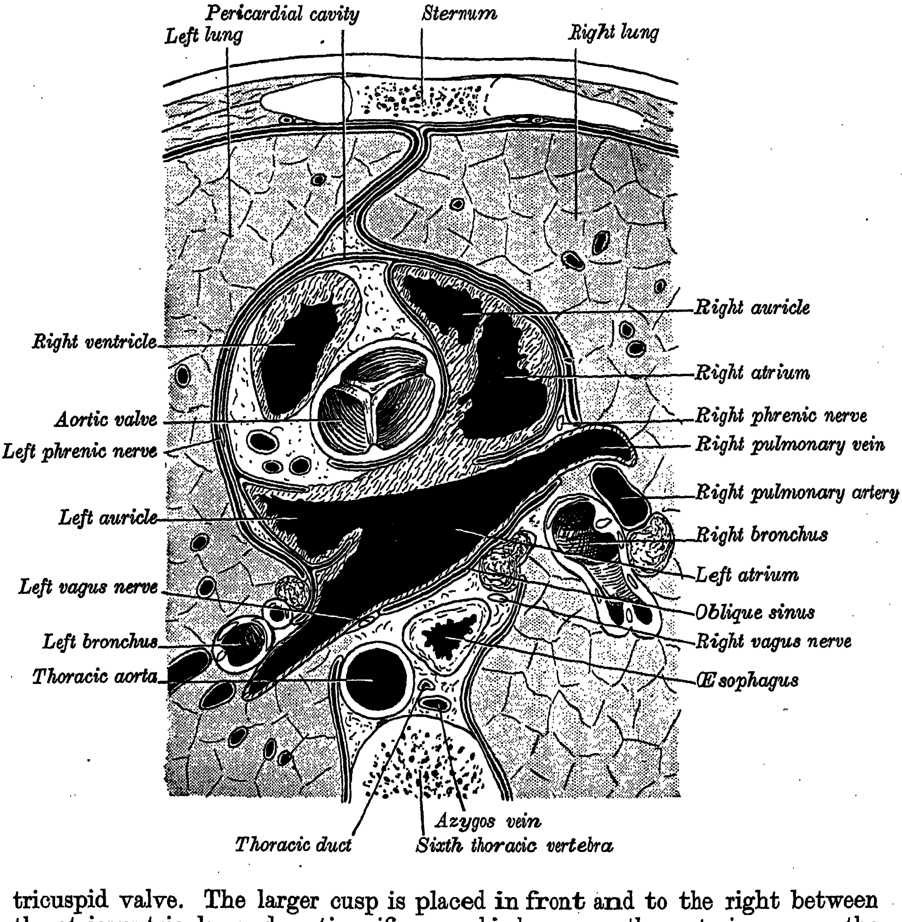
The *left atrioventricular* or *mitral orifice* is placed below and to the left of the aortic orifice. It is smaller than the right atrioventricular orifice, admitting the tips of two or three fingers ; its circumference measures a little over 10 cm. It is surrounded by a dense, fibrous ring and is guarded by the left atrioventricular or mitral valve.

The *aortic orifice* is a circular aperture in front and to the right of the left atrioventricular orifice, from which it is separated by the anterior cusp of the mitral valve. Its orifice has a diameter of a little over 2·5 cm., and is guarded by the aortic valve. The portion of the ventricle immediately below the aortic

orifice is termed the *aortic vestibule,* and possesses fibrous instead of muscular walls.

The *left atrioventricular* or *mitral valve* (figs. 683, 685) is attached to the fibrous ring which encircles the left atrioventricular orifice in the same way as the tricuspid valve is attached around the right atrioventricular orifice. It consists of two triangular cusps, formed by duplications of the lining membrane, strengthened by fibrous tissue and containing a few muscular fibres. The cusps are of unequal size, and are larger, thicker and stronger than those of the

FIG. 684.—A transverse section through the mediastinum at the level of the lower part of the body of the sixth thoracic vertebra.



tricuspid valve. The larger cusp is placed in front and to the right between the atrioventricular and aortic orifices, and is known as the *anterior cusp* ; the smaller or *posterior cusp* is placed behind and to the left of the opening. Two small cusps are usually found in the angles between the larger cusps. The cusps of the mitral valve are furnished with chordæ tendineæ, which are attached in a manner similar to those on the right side of the heart ; they are, however, thicker, stronger and less numerous.

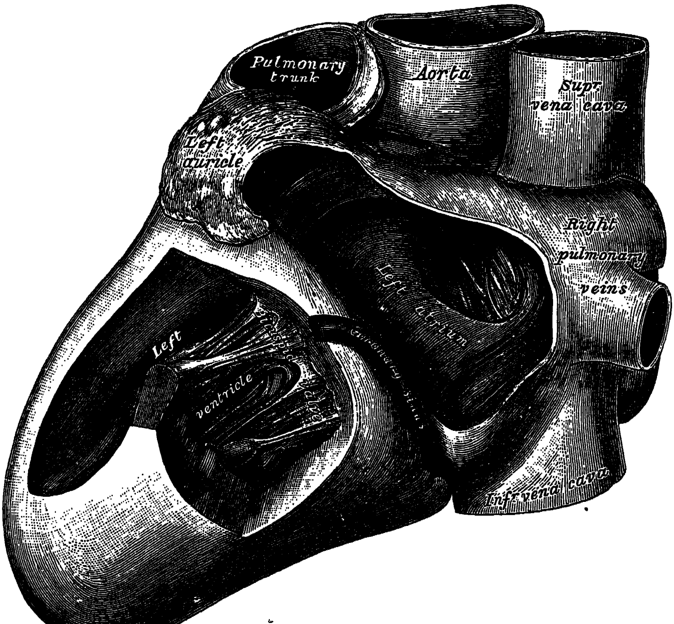
The *aortic valve* (figs. 680, 686) consists of three semilunar segments or cusps which surround the orifice of the aorta ; two are posterior (right and left), and one anterior. They are similar in structure, and in their mode of attachment, to the cusps of the pulmonary valve, but are larger, thicker and stronger ; the lunulæ are more distinct, and the nodules thicker and more prominent (fig. 686). Opposite the cusps the aorta presents three slight dilatations, termed the *aortic sinuses,* which are larger than those at the origin of the pulmonary trunk.

The *trabeculæ carneæ* are of three kinds, like those in the right ventricle, but they are more numerous, and present a dense interlacement, especially at the

apex and upon the posterior wall of the ventricle. The *papillary muscles* are two in number, one [superior] springing from the sternocostal, the other [inferior] from the diaphragmatic wall ; they are of large size, and end in rounded extremities, from which the chordæ tendineæ arise. Chordæ tendineæ from each papillary muscle are attached to both cusps of the mitral valve.

The **ventricular septum.**—The right ventricle is separated from the left by the *ventricular septum* (figs. 675, 690), which slopes obliquely from before backwards and towards the right, and is curved with the convexity towards the right ventricle (fig. 679) : its margins correspond with the anterior and inferior interventricular grooves on the surface of the heart. The greater portion of the septum is thick and muscular ; in its upper part, just below the junction of the anterior and right cusps of the aortic valve, there is a thin, fibrous area,

FIG. 685.—The interior of the left side of the heart.



which is termed the *membranous part of the ventricular septum* (fig. 690). This part of the septum is small in extent and oval in outline. On its right side it is crossed near its centre by the upper part of the attached border of the medial (septal) cusp of the tricuspid valve, which divides it into anterior and posterior portions. The anterior part separates the two ventricles from each other and may occasionally be congenitally defective (p. 146) ; the posterior part (atrioventricular septum) intervenes between the aortic vestibule of the left ventricle and the right atrium near the anterior horn of the annulus ovalis (limbus fossæ ovalis) (p. 146). Superiorly, the membranous part of the ventricular septum can be traced into the tendon of the infundibulum (conus arteriosus).

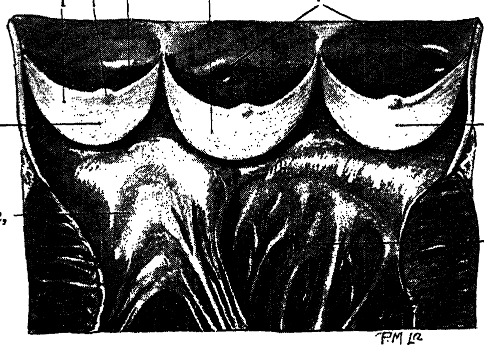
Structure.—The heart consists of muscular fibres (*myocardium*), and of fibrous rings which serve partly for their attachment. It is covered with the visceral layer of the serous pericardium (*epicardium*), and lined with the *endocardium*.

The *endocardium* is a thin, smooth, glistening membrane which lines the chambers of the heart, and is continuous with the lining membrane of the large blood-vessels ; by its reduplications it assists in forming the valves. It consists of a layer of endothelial cells placed on a stratum of connective tissue and elastic fibres.

The *fibrous rings* surround the atrioventricular and arterial orifices, and are stronger on the left than on the right side of the heart. The atrioventricular

rings serve for the attachment of the muscular fibres of the atria and ventricles, and for the attachment of the atrioventricular valves. The interval between the aortic arterial ring, in front, and the atrioventricular rings, behind (fig. 683), is occupied by a tough mass of fibrous tissue, which represents the *os cordis* of some of the larger mammals and is termed the *trigonum fibrosum dextrum.* A similar, but smaller, mass of fibrous tissue, termed the *trigonum fibrosum*

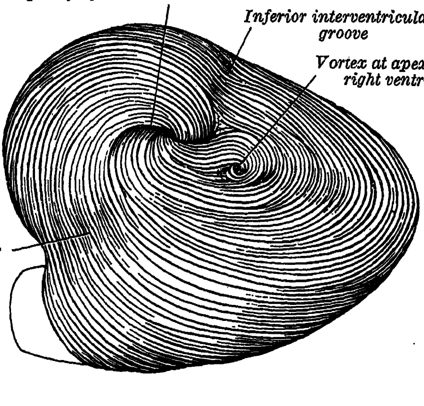
FIG. 686.—The aortic orifice laid open to show the aortic valve.



sinistrum, lies between the left side of the aortic arterial ring and the front of the left atrioventricular ring. The tendon of the infundibulum (conus arteriosus) has already been mentioned (p. 675).

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and their valves. Each ring receives, by its ventricular margin, the attachment of some of the muscular fibres of the ventricles; its opposite margin presents three deep, semicircular notches, to which the middle coat of the artery is firmly fixed. The attachment of an artery to its fibrous ring is strengthened by the external coat of the artery and the epicardium externally, and by the endocardium internally. From the margins of the semicircular notches the fibrous structure of the ring is continued into the segments of the valves. The middle coat of the artery in this situation is thin, and the vessel is dilated to form the sinuses of the aorta and pulmonary trunk.

FIG. 687.—The two vortices at the apex of the heart. (Mall.)



The *muscular structure of the heart* consists of fibres which are transversely and longitudinally striated (p. 35), and present an exceedingly intricate interlacement. They comprise (*a*) the fibres of the atria, (*b*) the fibres of the ventricles and (*c*) the atrioventricular bundle.

The *fibres of the atria* are arranged in two layers—a superficial, common to both atria, and a deep, proper to each. The *superficial fibres* are most distinct on the front of the atria, across the bases of which they run in a transverse direction, forming a thin and incomplete layer; some of them pass into the atrial septum. The *deep fibres* consist of looped and annular fibres. The *looped fibres* pass upwards over each atrium, and are attached by their extremities to the corresponding atrioventricular ring, in front and behind; the *annular fibres* surround the auricles, and form annular bands around the terminations of the veins and around the fossa ovalis.

The *fibres of the ventricles* are arranged in a complex manner, and various accounts have been given of their course and connexions; the following description is based on that given by MacCallum.* They consist of superficial and deep layers, all of which, with the exception of two, are inserted into the papillary muscles of the ventricles. The *superficial layers* comprise the following: (*a*) Fibres which spring from the tendon of the infundibulum (p. 675) and sweep downwards and towards the left across the anterior interventricular groove and around the apex of the heart, where they form a vortex (fig. 687) and pass upwards and inwards to terminate in the papillary muscles of the left ventricle; those arising from the upper (anterior) half of the tendon of the infundibulum pass to the inferior and septal papillary muscles, those from the lower (posterior) half to the superior papillary muscle. (*b*) Fibres which arise from the right atrioventricular ring and run diagonally across the diaphragmatic surface of the right ventricle and round its right border on to its sternocostal surface. There they dip beneath the fibres just described, and, crossing the anterior interventricular groove, wind around the apex of the heart and end in the inferior papillary muscle of the left ventricle. (*c*) Fibres which spring from the left atrioventricular ring, and, crossing the inferior interventricular groove, pass successively into the right ventricle and end in its papillary muscles. The *deep layers* are three in number; they arise in the papillary muscles of one ventricle and, curving in an S-shaped manner, turn in at the interventricular groove and end in the papillary muscles of the other ventricle (fig. 689). The layer which is most superficial in the right ventricle lies next the lumen of the left, and vice versa. Those of the first layer almost encircle the right ventricle and, crossing in the septum to the left ventricle, unite with the superficial fibres from the right atrioventricular ring to form the inferior papillary muscle. Those of the second layer have a less extensive course in the wall of the right ventricle and a correspondingly greater course in the left, where they join with the superficial fibres from the upper half of the tendon of the infundibulum (conus arteriosus) to form the papillary muscles of the septum. Those of the third layer pass almost entirely round the left ventricle and unite with the superficial fibres from the lower half of the tendon of the infundibulum (conus arteriosus) to form the superior papillary muscle. The arrangement of these three layers ensures the synchronisation of ventricular systole and the closure of the atrioventricular valves. Besides the layers just described there are two bands which do not end in papillary muscles. One springs from the right atrioventricular ring, crosses in the atrioventricular septum, encircles the deep layers of the left ventricle and ends in the left atrioventricular ring. The second band is apparently confined to the left ventricle; it is attached to the left atrioventricular ring and encircles the portion of the ventricle adjacent to the aortic orifice.†

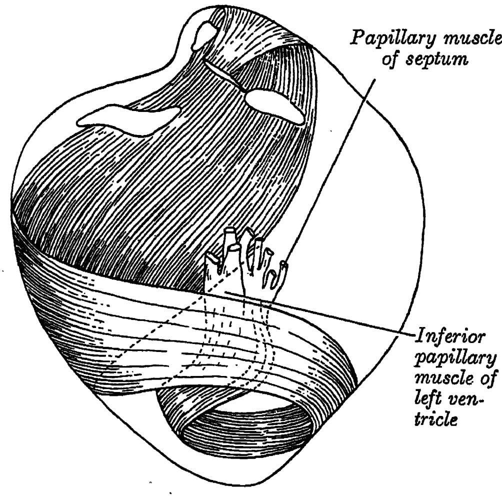

FIG. 689.—A diagram of the arrangement of the deep layers of the muscular fibres of the ventricles, as seen in a cross-section of the ventricles. (Based on MacCallum's description.)

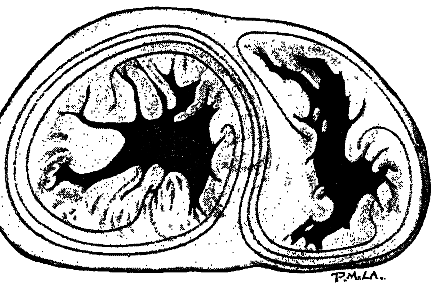

A. Blackhall-Morison ‡ draws attention to the existence of a set of fibres belonging to the left ventricular musculature and to the lower segment of the left atrium, and which

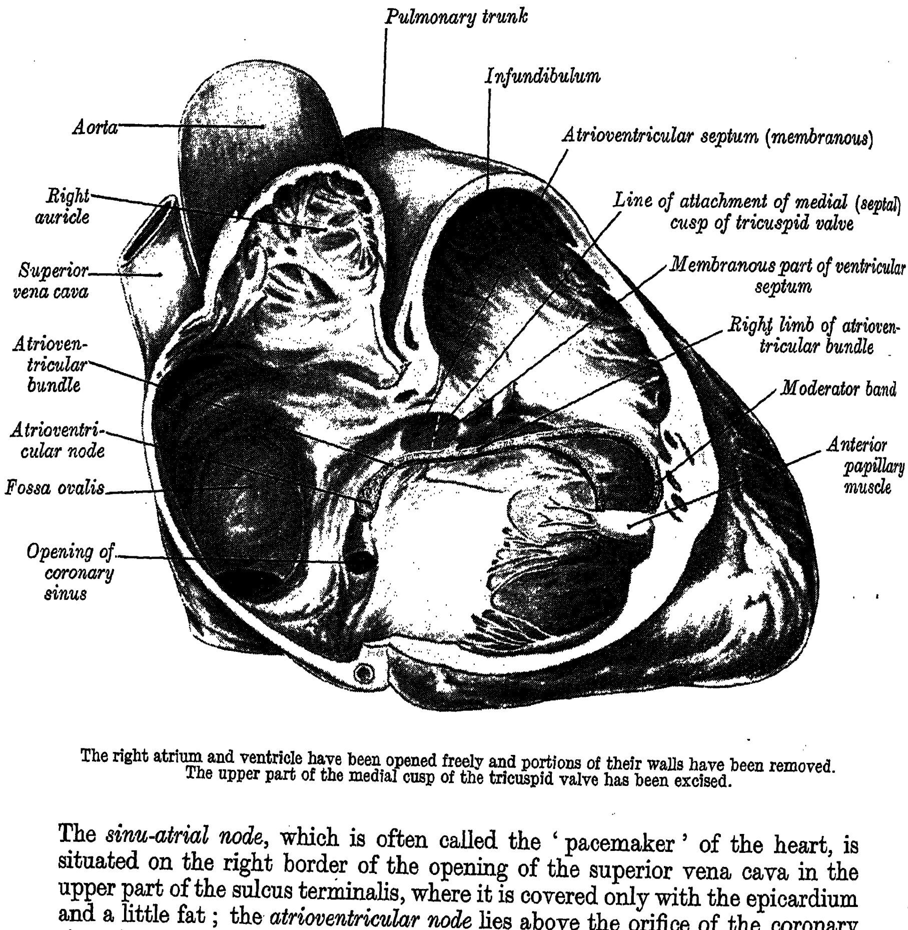
† Franklin P. Mall gives an account of his researches "On the Muscular Architecture of the Ventricles of the Human Heart" in the *American Journal of Anatomy*, vols. 11 and 13.

‡ *Edinburgh Medical Journal*, New Series, vol. xxx. No. 9, September 1923.

have a triple insertion into the base of the aorta, close to the cusps of the aortic valve. The effect of the contraction of these fibres " is to rotate the base of the aorta in the direction of the general ventricular twist in systole."

The *atrioventricular bundle* (fig. 690) is a direct, muscular connexion between the atria and the ventricles. It arises in association with two branching networks of fine, striated muscle fibres, which differ from the cardiac muscle fibres in several features and are termed the sinu-atrial and atrioventricular nodes.

FIG. 690.—A schematic representation of the atrioventricular bundle. The course of the bundle is represented in red.



The right atrium and ventricle have been opened freely and portions of their walls have been removed. The upper part of the medial cusp of the tricuspid valve has been excised.

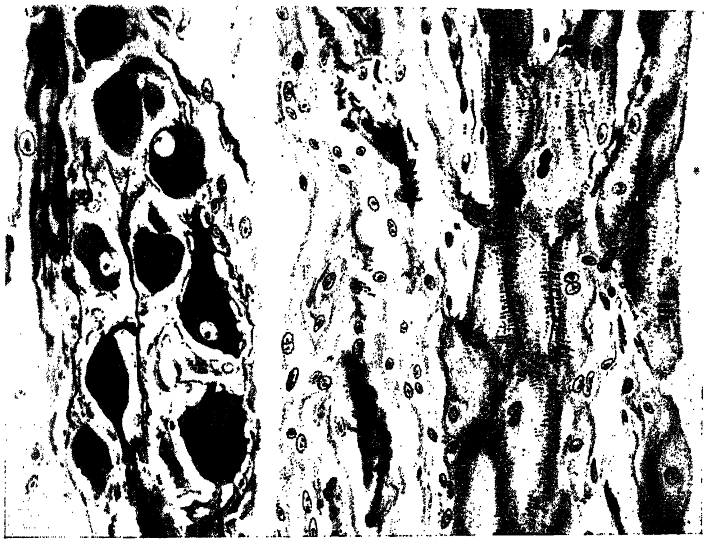
The *sinu-atrial node*, which is often called the 'pacemaker' of the heart, is situated on the right border of the opening of the superior vena cava in the upper part of the sulcus terminalis, where it is covered only with the epicardium and a little fat; the *atrioventricular node* lies above the orifice of the coronary sinus in the annular and septal fibres of the right atrium. From the atrioventricular node the atrioventricular bundle passes upwards in the trigonum fibrosum dextrum until it reaches the posterior margin of the membranous part of the ventricular septum, and then turns forwards below it. In this situation it divides into right and left fasciculi which straddle the muscular septum. These run down in the right and left ventricles, one on each side of the ventricular septum, covered with endocardium. The right fasciculus passes into the moderator band, and breaks up into numerous strands, which end in an intricate network on the papillary muscles and on the wall of the right ventricle. The left fasciculus consists of two main strands, an anterior and a posterior, which are distributed to the papillary muscles and the wall of the left ventricle. In the ox the atrioventricular bundle and its divisions are enveloped in a sheath of connective tissue; by injecting this sheath with Indian ink the ramifications of the bundle can be demonstrated. In the human heart the sheath is not well developed; it surrounds the bundle but not the fasciculi. The nodes and greater portion of the bundle consist of narrow, somewhat

fusiform fibres, but the terminal strands of the bundle are composed of modified Purkinje's fibres (fig. 691). No direct connexion between the two nodes has been proved to exist.

Kent has described a second atrioventricular bundle in the right lateral wall of the heart, containing cardiac muscle-fibres, fine nerve-fibres, and fibres resembling those of Purkinje.

A. Blackhall-Morison * has shown that in the sheep and pig the atrioventricular bundle " is a great avenue for the transmission of nerves from the auricular to the ventricular heart " ; large and numerous nerve-trunks enter the bundle and course with it. Branches

FIG. 691.—Longitudinal section of the left fasciculus of the atrioventricular bundle from the heart of a cow. ×260. Note the incomplete striation of the cells of the fasciculus. Drawn from a microphotograph kindly lent by Professor D. M. Blair and Dr. Francis Davies.



arise from these nerve-trunks and form plexuses around groups of Purkinje cells, and from these plexuses fine fibrils go to innervate individual cells.

The sinu-atrial and atrioventricular nodes, the atrioventricular bundle and its right fasciculus, are supplied by the right coronary artery ; the left fasciculus of the bundle is supplied by both coronary arteries.

Applied Anatomy.—Clinical and experimental evidence goes to prove that this bundle conveys impulses from the atrial septum to the ventricles, and much attention has been paid to it, because it may become fibrosed and lose much of its conducting power (heart-block). The condition is characterised by a slow pulse, a tendency to syncopal or epileptiform seizures, and the fact that while the cardiac atria beat at a normal rate, the ventricles contract much less frequently.

Vessels and Nerves.—The *arteries* supplying the heart are the right and left coronary branches of the aorta (p. 693) ; the majority of the *veins* are drained by the coronary sinus into the right atrium.

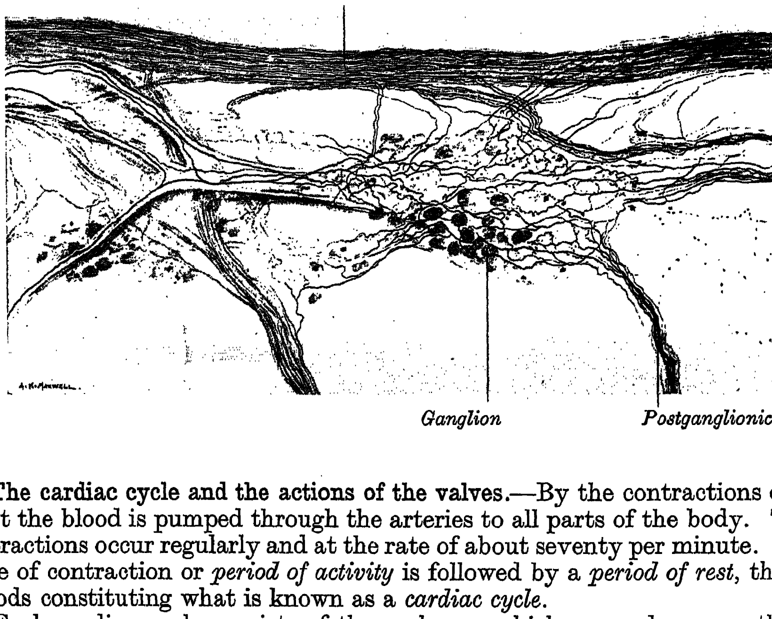
The *lymph vessels* are described on p. 878.

The *nerves* are derived from the cardiac plexus (p. 1149), which is formed by branches from the vagi and sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate nerve-filaments being furnished with small ganglia. The atrioventricular bundle receives nerve-fibres from ganglia in the atrial septum. Other ganglia are found in relation with the sinu-atrial node, and supply it with nerve-filaments.

* *Journal of Anatomy and Physiology*, vol. xlvi.

H. H. Woollard (*Journal of Anatomy*, vol. lx. 1926) has investigated, by the methylene blue method, the distribution of the cardiac nerves in the dog, cat, rabbit and guinea-pig. His chief conclusions are: 1. In the intracardiac ganglia the types of cell, though varying in the disposition of the dendrites and in the mode of the ending of the preganglionic fibres, all belong to the parasympathetic (fig. 692). 2. There is some evidence to show that the atria and the atrioventricular bundle are supplied by parasympathetic and sympathetic fibres, while the ventricular muscle is supplied by sympathetic fibres only. 3. The fibres spin a plexus about the muscle-cell, and ultimately enter the protoplasm of the muscle and run in the protoplasmic connexions of the muscle; small endings, often perinuclear in position, are given off inside the muscle-cell. 4. The valves, the subendocardial and the subepicardial tissues are innervated by a very fine plexus of nerves which, for the most part, belongs to the sympathetic system. 5. The larger branches of the coronary arteries are predominantly innervated by sympathetic, the finer branches by parasympathetic, fibres.

FIG. 692.—Nerves and ganglia from the posterior surface of the left atrium of a dog. Methylene blue preparation. ×55. H. H. Woollard.



The cardiac cycle and the actions of the valves.—By the contractions of the heart the blood is pumped through the arteries to all parts of the body. These contractions occur regularly and at the rate of about seventy per minute. Each wave of contraction or *period of activity* is followed by a *period of rest*, the two periods constituting what is known as a *cardiac cycle*.

Each cardiac cycle consists of three phases, which succeed one another as follows: (1) a short, simultaneous contraction of both atria, termed the *atrial systole*, followed, after a slight pause, by (2) a simultaneous, but more prolonged, contraction of both ventricles, named the *ventricular systole*, and (3) a *period of rest*, or *diastole*, during which the whole heart is relaxed. The atrial contraction commences at the sinu-atrial node, and sweeping over the atria forces their contents through the atrioventricular openings into the ventricles, regurgitation into the veins being prevented by the contraction of their muscular coats. When the ventricles contract, the atrioventricular valves are closed, and prevent the passage of the blood back into the atria; the papillary muscles at the same time are shortened, and, pulling on the chordæ tendineæ, prevent the inversion of the valves into the atria. As soon as the pressure in the ventricles exceeds that in the pulmonary trunk and aorta, the valves guarding the orifices of these vessels are opened, and the blood is driven from the right ventricle into the pulmonary trunk, and from the left ventricle into the aorta. The moment the systole of the ventricles ceases, the pressure of the blood in the pulmonary trunk and aorta closes the pulmonary and aortic valves, thus preventing regurgitation of blood into the ventricles, and the valves remain shut until re-opened by the next ventricular systole. During the period of rest the tension of the atrioventricular valves is relaxed, and blood flows from the veins through the atria into the ventricles. The filling of the ventricles is

completed by the systole of the atria. The average duration of a cardiac cycle is about $\frac{8}{10}$ of a second, made up as follows :

Atrial systole, $\frac{1}{10}$.	Atrial diastole, $\frac{7}{10}$.
Ventricular systole, $\frac{3}{10}$.	Ventricular diastole, $\frac{5}{10}$.
Total systole, $\frac{4}{10}$.	*Complete diastole*, $\frac{4}{10}$.

The rhythmical action of the heart is *muscular* in origin—that is to say, the heart-muscle possesses the inherent property of contraction apart from any nervous stimulation. The more embryonic the muscle the better is it able to initiate the contraction wave, and the normal systole of the heart starts at the sinu-atrial node, where the muscle is most embryonic in nature : for this reason the sinu-atrial node has been called the 'pacemaker' of the heart. A slight pause occurs between the systole of the atria and that of the ventricles. This is due to the fact that the contraction of the ventricles is excited by an impulse conveyed by the atrioventricular bundle, conduction along the fibres of which is relatively slow. The nerves, although not concerned in originating the contractions of the heart-muscle, play an important rôle in regulating their force and frequency in order to subserve the physiological needs of the organism.

Applied Anatomy.—Wounds of the heart are often immediately fatal, because, when blood is effused into the pericardial sac, it presses on the thin-walled atria and mechanically hampers the cardiac muscle. Such penetrating wounds, however, are not necessarily fatal, as many cases have been recorded in which the wound has been sutured successfully. On the other hand, non-penetrating wounds may prove fatal, if one of the coronary arteries has been divided or if pericarditis supervenes.

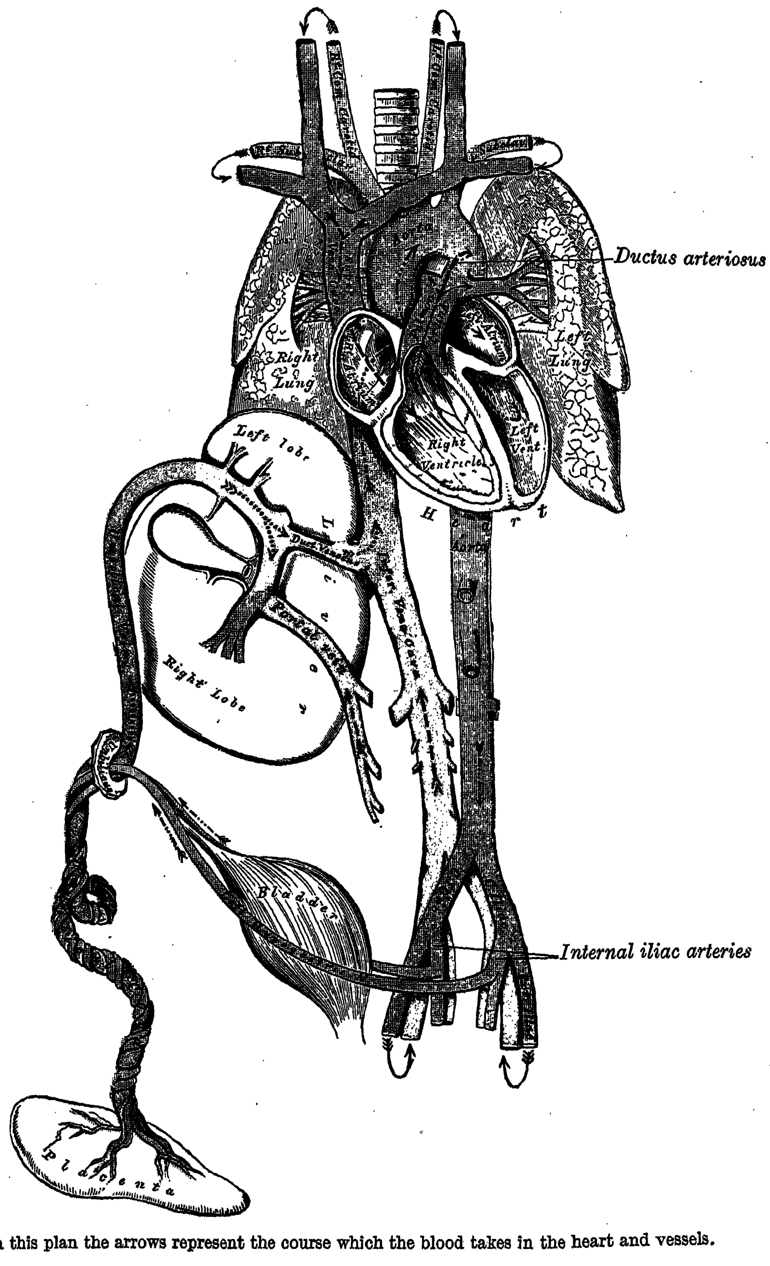
The Fœtal Circulation (fig. 693)

The fœtal blood is carried to the placenta by the umbilical arteries, and returned from the placenta to the fœtus by the two umbilical veins. These veins unite in the umbilical cord to form a single vein (vena umbilicalis impar) which enters the abdomen at the umbilicus, and passes in the free margin of the falciform ligament to the visceral surface of the liver, where it gives off two or three branches to the left lobe, and others to the lobus quadratus. At the porta hepatis it joins the left branch of the portal vein, from which, opposite this point, a large vessel arises and ascends on the posterior aspect of the liver to join the left hepatic vein immediately before that vessel opens into the inferior vena cava. This vessel is termed the *ductus venosus*. During fœtal life the portal vein is small compared with the umbilical vein, and the proximal and distal parts of its left branch actually function as branches of the latter vessel (fig. 693). It will be seen therefore that the blood conveyed by the left umbilical vein passes to the inferior vena cava in three different ways. Some enters the liver directly and is carried to the inferior vena cava by the hepatic veins ; a considerable quantity circulates through the liver with the portal venous blood, before entering the inferior vena cava by the hepatic veins ; the remainder passes into the inferior vena cava through the ductus venosus.

In the inferior vena cava, the blood carried by the ductus venosus and hepatic veins mixes with that returning from the lower limbs and from the abdominal wall It enters the right atrium, and, guided by the valve of the inferior vena cava, passes through the foramen ovale into the left atrium, where it mingles with a small quantity of blood returned from the lungs by the pulmonary veins. From the left atrium it passes into the left ventricle, and from that cavity into the aorta, through the branches of which it is probably distributed almost entirely to the head and the upper limbs, only a small quantity being carried into the descending aorta. The blood from the head and the upper limbs is returned by the superior vena cava to the right atrium, where it mixes with a small portion of that returned by the inferior vena cava. From the right atrium the blood passes into the right ventricle, and thence into the pulmonary trunk. The lungs of the fœtus being inactive, only a small quantity of the blood conveyed by the pulmonary trunk is distributed to them by the

right and left pulmonary arteries, and returned by the pulmonary veins to the left atrium: the greater part passes through the ductus arteriosus into the aorta, where it mixes with the small quantity of blood transmitted by the left ventricle into this part of the aorta. It descends through the aorta and

FIG. 693.—A plan of the fœtal circulation.



In this plan the arrows represent the course which the blood takes in the heart and vessels.

is in part distributed to the lower limbs and to the viscera of the abdomen and pelvis, but most of it is conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fœtus the following facts will be inferred: 1. The placenta serves the purposes of nutrition and excretion, receiving the impure blood from the fœtus, and returning it purified and charged with nutritive material. 2. Some of the blood of the left

Note that the lower part of the œsophagus inclines forwards away from the vertebral column.

umbilical vein traverses the liver before entering the inferior vena cava; this is correlated with the relatively large size of the liver, especially at an early period of fœtal life. 3. Only the pulmonary veins open directly into the left atrium, and the volume of blood which enters it from this source is very small. On the other hand, the volume of the blood entering the right atrium is much greater, and the pressure within that chamber is much higher than the pressure in the left atrium. As a result, the flap-like septum primum (p. 141) is thrust over to the left (fig. 184, *D*) and the passage of blood from the right to the left side of the heart is effected easily. The valve of the inferior vena cava is placed so as to enable it to direct the current of blood which issues from that vessel to the foramen ovale and so to the left atrium, whereas the blood entering the right atrium from the superior vena cava passes directly into the right ventricle. At an early period of fœtal life it is probable that these two streams are quite distinct, for the inferior vena cava opens almost directly into the left atrium, and the valve of the inferior vena cava would exclude the current from the right ventricle. At a later period, as the separation between the two atria becomes more marked, it is probable that some mixture of the two streams takes place. 4. The pure blood carried from the placenta to the fœtus, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and the upper limbs. 5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and the upper limbs, together with a small quantity from the left ventricle, is distributed to the abdomen and the lower limbs.

The Changes in the Vascular System at Birth

At birth, when respiration is established, an increased amount of blood from the pulmonary trunk passes through the pulmonary arteries to the lungs, and a correspondingly increased amount returns by the pulmonary veins to the left atrium. The pressures within the two atria become equalised, and the foramen ovale, which is valve-like in character, is closed by the apposition, and later by the fusion, of the septum primum to the septum secundum (fig. 184). Not infrequently the fusion is incomplete and a small communication between the two atria may persist throughout life. Such a communication has no functional significance as, owing to the equality of the intra-atrial pressures and the valve-like arrangement of the opening, no blood can pass from one side to the other.

When the umbilical cord is ligatured and the placental circulation is cut off, the umbilical vein becomes thrombosed and is gradually converted into a fibrous cord which constitutes the *ligamentum teres* of the liver. The ductus venosus also becomes obliterated, but the reasons for its obliteration are not so obvious and may possibly be associated with the alteration in the position of the liver brought about by the establishment of the respiratory movements. Its fibrous remnant is found in the adult as the *ligamentum venosum* of the liver.

The closure of the ductus arteriosus is an essential but, probably, a gradual process, taking some months to complete. Before birth the vessel is the direct continuation of the pulmonary trunk, but when the right and left pulmonary arteries dilate to carry additional blood to the lungs, it becomes a ‘ backwater ’ and its direction is altered by the rotation of the heart to the left (p. 146). Ultimately it forms an impervious cord which connects the left pulmonary artery near its origin to the arch of the aorta and is termed the *ligamentum arteriosum*. Following ligature of the umbilical cord, the umbilical or hypogastric arteries become thrombosed from the point at which they give off their last branches—the superior vesical arteries—to the umbilicus, and are subsequently converted into fibrous cords, which lie in the extraperitoneal fatty tissue of the lower part of the anterior abdominal wall and produce the *lateral umbilical folds* of peritoneum.

THE ARTERIES

The distribution of the systemic arteries is like a highly branched tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the viscera and to the peripheral parts of the body. Arteries are found in all parts of the body, except in the hairs, nails, epidermis, cartilages and corneæ ; the larger trunks usually occupy protected situations, running, in the limbs, along the flexor surfaces, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as in the cœliac artery and the thyrocervical trunk ; more usually the vessel gives off several branches in succession, and still continues as the main trunk, as in the arteries of the limbs.

A branch of an artery is smaller than the trunk from which it arises ; but if an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk ; and the combined sectional area of all the arterial branches greatly exceeds that of the aorta.

Arteries do not always end in capillaries ; in many cases they unite with one another, forming what are called *anastomoses*. Anastomosis between trunks of nearly equal size is found in the brain, where the two vertebral arteries unite to form the basilar artery, and the two anterior cerebral arteries are connected by the anterior communicating artery ; and in the abdomen, where the intestinal arteries have free anastomoses between their larger branches. In the limbs, the anastomoses are largest and most numerous around the joints ; the branches arising from an artery above a joint uniting with branches from the vessels below it. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to a main artery. From the practical point of view, the importance of any individual arterial anastomosis depends on the distance which separates the points of origin of the anastomosing vessels. The smaller branches of arteries anastomose more frequently than the larger ; and between the smallest twigs these anastomoses may be so numerous that they constitute a close network. In certain regions of the body, for example, the spleen, the kidney and certain parts of the brain, there are arteries which have no anastomoses with their neighbours except through the agency of the capillaries, and are therefore called *end-arteries*. If an artery of this type be occluded, serious nutritional disturbances resulting in death (necrosis) will occur in the tissues supplied by the vessel.

The Pulmonary Trunk

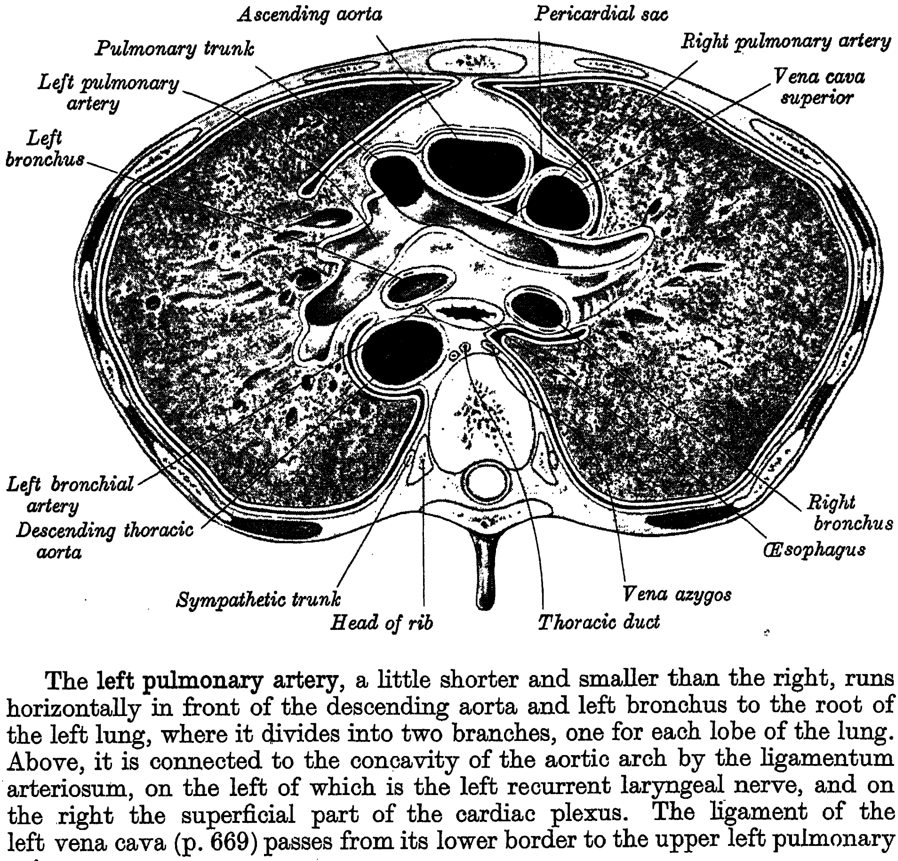
The **pulmonary trunk** (figs. 695, 697) conveys deoxygenated blood from the right ventricle of the heart to the lungs. It is about 5 cm. in length and 3 cm. in diameter, and arises from the infundibulum (conus arteriosus) of the right ventricle. It runs upwards and backwards, at first in front of the ascending aorta, and then to its left side. In the concavity of the aortic arch it divides, at the level of the fifth thoracic vertebra, into right and left pulmonary arteries, which are of nearly equal size.

Relations.—The whole of the pulmonary trunk is contained within the pericardium. It and the ascending aorta are enclosed in a common tube of the visceral layer of the serous pericardium. The fibrous layer of the pericardium is gradually lost upon the external coats of the two pulmonary arteries. *In front*, the pulmonary trunk is separated from the sternal end of the left second intercostal space by the pleura, the left lung and the pericardium. *Behind*, it rests at first upon the ascending aorta and the left coronary artery ; at a higher level it lies in front of the left atrium, and the ascending aorta is on its right side. The auricle of the corresponding atrium and a coronary

artery lie on each side of its origin. The superficial part of the cardiac plexus lies between the division of the pulmonary trunk and the arch of the aorta.

The **right pulmonary artery**, slightly longer and larger than the left, runs horizontally to the right, behind the ascending aorta, superior vena cava and upper right pulmonary vein, and in front of the œsophagus and the right bronchus, to the root of the right lung, where it divides into two branches. The lower and larger of these is distributed to the middle and lower lobes of the lung; the upper and smaller accompanies the eparterial bronchus to the upper lobe.

FIG. 694.—A transverse section through the thorax, showing the relations of the pulmonary trunk, etc.



The **left pulmonary artery**, a little shorter and smaller than the right, runs horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches, one for each lobe of the lung. Above, it is connected to the concavity of the aortic arch by the ligamentum arteriosum, on the left of which is the left recurrent laryngeal nerve, and on the right the superficial part of the cardiac plexus. The ligament of the left vena cava (p. 669) passes from its lower border to the upper left pulmonary vein.

The terminal branches of the pulmonary arteries are described with the anatomy of the lungs.

Applied Anatomy.—Embolism of the pulmonary trunk by a clot of blood coming from the right side of the heart in patients with heart-disease, or from a thrombosed vein in cases, for example, of influenza, enteric fever, puerperal sepsis, or fractured limbs, is a common cause of sudden or rapid death.

THE AORTA

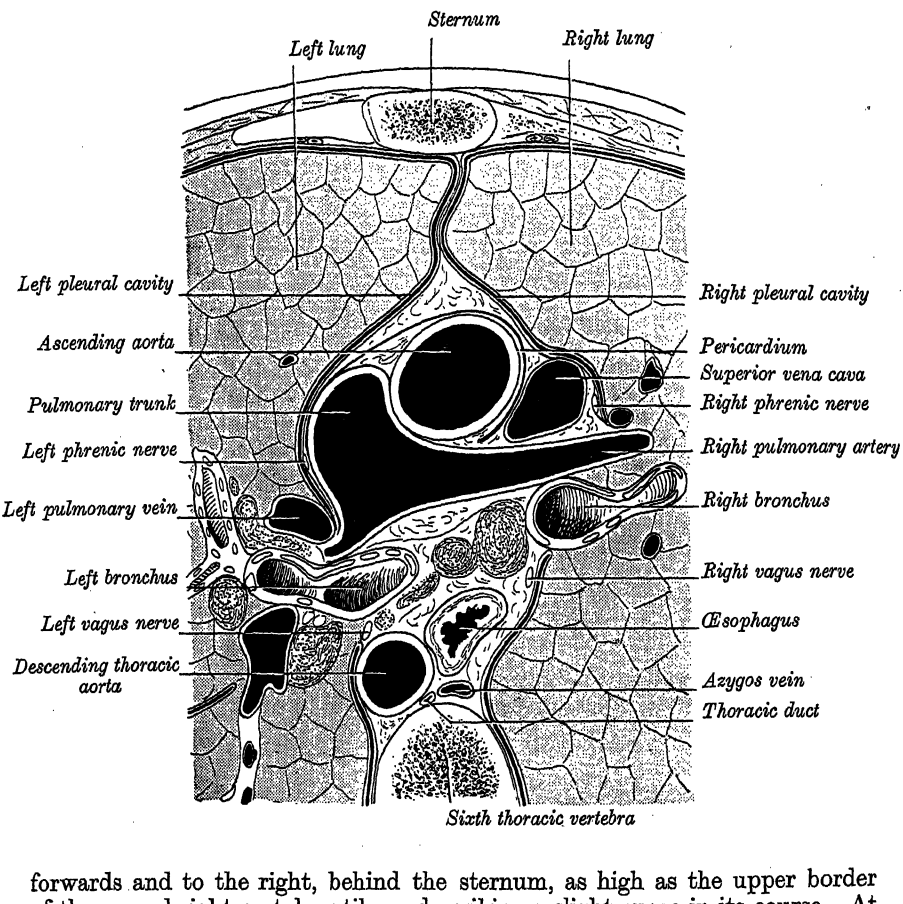
The **aorta** is the main trunk of the series of vessels which convey the oxygenated blood to the tissues of the body. It begins at the upper part of the left ventricle, where it is about 3 cm. in diameter, and after ascending for a short distance, arches backwards and to the left, over the root of the left lung; it then descends within the thorax on the left side of the vertebral column,

and enters the abdominal cavity through the aortic opening in the diaphragm. Considerably diminished in size (about 1·75 cm. in diameter), it ends, a little to the left of the median plane, at the level of the lower border of the fourth lumbar vertebra, by dividing into the right and left common iliac arteries. Hence it is described in several portions, viz. the *ascending aorta*, the *arch of the aorta*, and the *descending aorta*, the last being divided into the *descending thoracic* and *abdominal aortæ*.

The Ascending Aorta

The **ascending aorta** (figs. 674, 697) is about 5 cm. long. It begins at the base of the left ventricle, on a level with the lower border of the third costal cartilage, behind the left half of the sternum; it passes obliquely upwards,

Fig. 695.—A transverse section through the mediastinum at the level of the upper part of the body of the sixth thoracic vertebra.



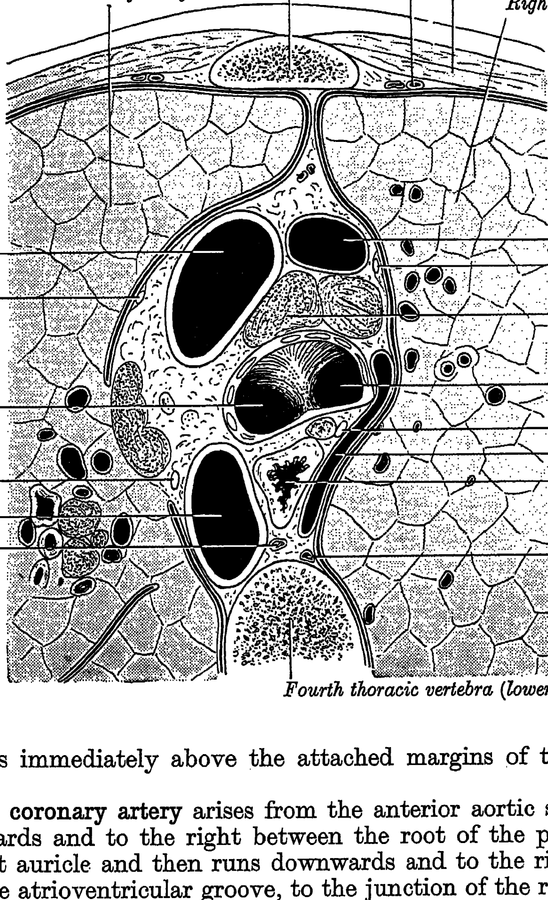
forwards and to the right, behind the sternum, as high as the upper border of the second right costal cartilage, describing a slight curve in its course. At its origin, opposite the cusps of the aortic valve, there are three small dilatations called the aortic sinuses. At the union of the ascending aorta with the aortic arch the calibre of the vessel is slightly increased, owing to a bulging of its right wall. This dilatation is termed the *bulb of the aorta*, and, on transverse section at this level, the vessel presents a somewhat oval outline.

Relations.—The ascending aorta is contained within the fibrous pericardium, and is enclosed in a tube of the serous pericardium, common to it and the pulmonary trunk. *Anteriorly* its lower part is related to the infundibulum (conus arteriosus) of the right ventricle, the commencement of the pulmonary

trunk and the auricle of the right atrium ; higher up, it is separated from the sternum by the pericardium, the right pleura, the anterior margin of the right lung, some loose areolar tissue and the remains of the thymus ; *posteriorly*, it is related successively to the left atrium, the right pulmonary artery and the right bronchus ; on its *right side*, to the superior vena cava and right atrium, the former lying partly behind it ; on its *left side*, to the left atrium and the pulmonary trunk.

Branches.—The branches of the ascending aorta are the right and left coronary arteries (figs. 677, 698), which supply the heart ; they arise from the

Fig. 696.—A transverse section through the mediastinum at the level of the lower part of the body of the fourth thoracic vertebra.



aortic sinuses immediately above the attached margins of the cusps of the aortic valve.

The **right coronary artery** arises from the anterior aortic sinus. It passes at first forwards and to the right between the root of the pulmonary trunk and the right auricle and then runs downwards and to the right in the right portion of the atrioventricular groove, to the junction of the right and inferior margins of the heart. Here it turns to the left and runs on the back of the heart, as far as the inferior interventricular groove, where it anastomoses with the left coronary artery. The right coronary artery supplies branches to the right atrium and, by means of a marginal branch (fig. 698), to both surfaces of the right ventricle. Near its termination it gives off an *interventricular branch*, which runs forwards in the inferior interventricular groove, supplies branches to both ventricles and anastomoses near the apex of the heart with the interventricular branch of the left coronary artery.

The **left coronary artery**, larger than the right, arises from the left posterior aortic sinus and, after a short course forwards between the pulmonary trunk and the left auricle, turns to the left in the atrioventricular groove. It then passes backwards round the left margin of the heart and accompanies the

coronary sinus as far as the interventricular groove, where it anastomoses with the right coronary artery. It supplies branches to the left atrium and the base of the left ventricle. At the point where it turns to the left, the left coronary artery gives off a large *interventricular branch*, which descends in the anterior interventricular groove, to the incisura apicis cordis. This branch supplies both ventricles and anastomoses with the interventricular branch of the right coronary artery. In many subjects it turns round the apex of the heart and runs backwards for a variable distance in the inferior interventricular groove (fig. 698).

There is a very free anastomosis between the minute branches and between the capillaries of the two coronary arteries in the substance of the heart.*

Peculiarities.—Very rarely the coronary arteries arise by a common trunk; or their number may be increased to three or four. The areas of distribution of the two arteries on the diaphragmatic surface of the heart are subject to considerable variation.

Applied Anatomy.—The sudden blocking of a coronary artery by an embolus, or its more gradual obstruction by arterial disease or thrombosis, is a common cause of sudden death in persons past middle age. If the obstruction to the passage of blood is incomplete, the patient may suffer from *angina pectoris*, a condition associated with agonising pain in the precordial region and down the left arm.

The Arch of the Aorta

The **arch of the aorta** (figs. 697, 699) connects the ascending with the descending aorta; it begins behind the manubrium sterni at the level of the upper border of the second right sternocostal articulation, and runs at first upwards, backwards and to the left in front of the trachea; it is then directed backwards on the left side of the trachea, and finally passes downwards on the left side of the body of the fourth thoracic vertebra, at the lower border of which it is continuous with the descending aorta. It thus forms two curvatures: one with its convexity upwards, the other with its convexity forwards and to the left. Its upper border is usually about the level of the middle of the manubrium sterni.

Relations.—The arch of the aorta is covered *anteriorly* by the pleuræ and anterior margins of the lungs. As the vessel runs backwards, its *left* side is in contact with the left lung and pleura. Passing downwards on the left side of this part of the arch there are four nerves; in order from before backwards these are: the left phrenic, the lower of the cervical cardiac branches of the left vagus, the superior cervical cardiac branch of the left sympathetic, and the trunk of the left vagus. As the left vagus crosses the arch it gives off its recurrent laryngeal branch, which hooks round below the vessel to the left of the ligamentum arteriosum and then passes upwards on its right side. The left superior intercostal vein runs obliquely upwards and forwards on the left side of the arch, crossing superficial to the vagus but deep to the phrenic nerve (fig. 697). On the *right* are the deep part of the cardiac plexus, the left recurrent laryngeal nerve, and the œsophagus; the trachea lies behind and to the right of the vessel. *Above*, the innominate, left common carotid and left subclavian arteries arise from the convexity of the arch and are crossed close to their origins by the left innominate vein. *Below*, the arch is related to the bifurcation of the pulmonary artery, the left bronchus, the ligamentum arteriosum, the superficial part of the cardiac plexus and the left recurrent laryngeal nerve. As already stated (p. 691), the ligamentum arteriosum connects the commencement of the left pulmonary artery to the inferior aspect of the aortic arch.

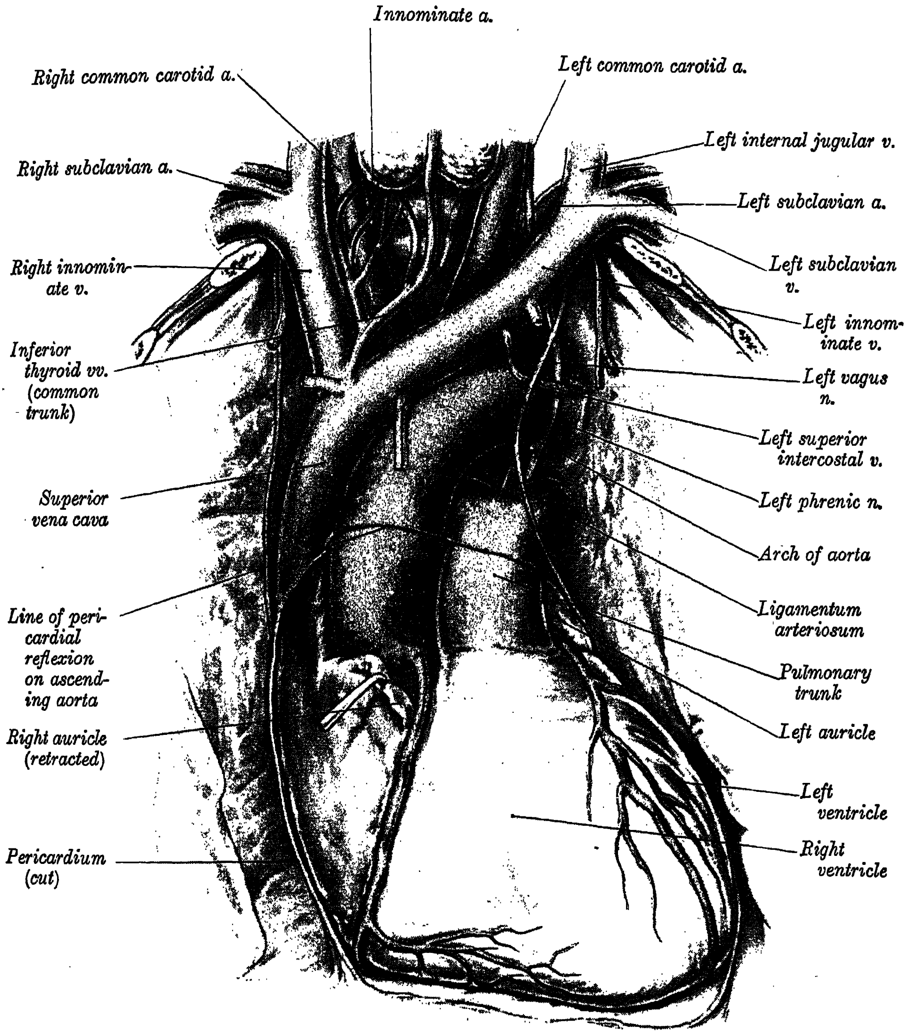
In the fœtus the lumen of the aorta is considerably narrowed between the origin of the left subclavian artery and the attachment of the ductus arteriosus, forming what is termed the *aortic isthmus*, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which His named the *aortic spindle*—the point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent,

* Consult in this connexion *The Blood Supply of the Heart*, by Louis Gross, 1921.

in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm.

Peculiarities.—The summit of the arch of the aorta is usually about 2·5 cm. below the upper border of the sternum ; but it may reach nearly to the top of the bone. Occasionally it is found 4 cm., more rarely from 5 to 8 cm., below this point. Sometimes the aorta arches over the root of the right lung (right aortic arch) instead of over that of the left, and passes down on the right side of the vertebral column, a condition which is normal

FIG. 697.—The heart and great vessels.



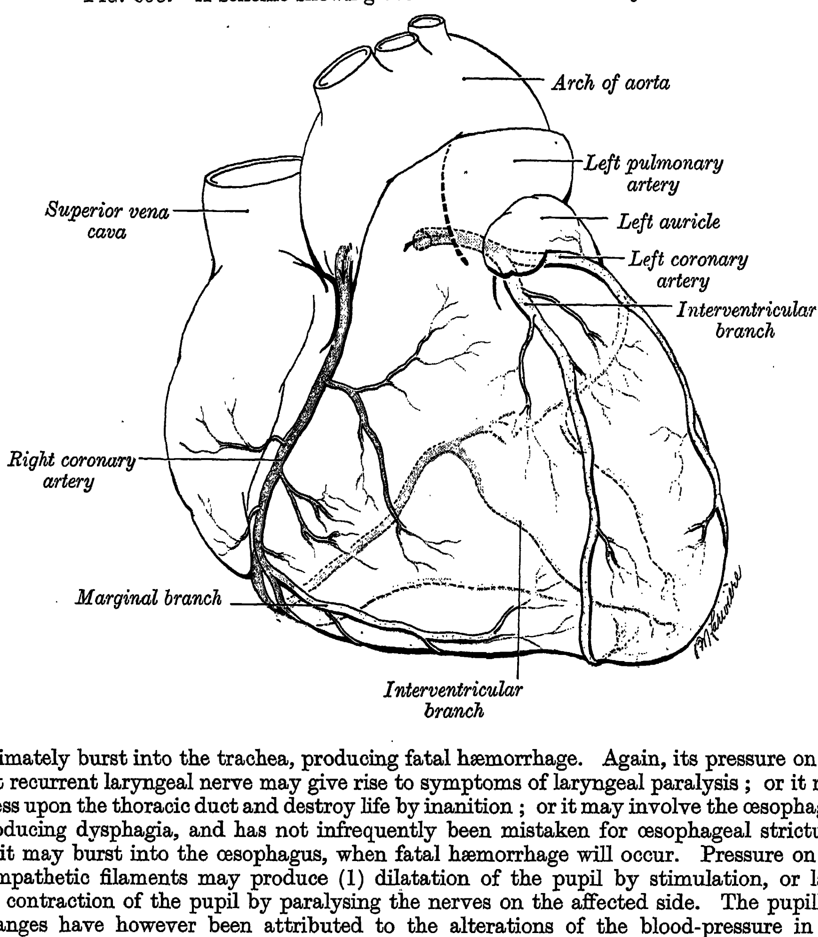
in birds. In such cases there is usually a transposition of the thoracic and of the abdominal viscera. Less frequently the aorta, after arching over the root of the right lung, passes behind the œsophagus to gain its usual position on the left side of the vertebral column ; this peculiarity is not accompanied by transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upwards, and subdivides into three branches, to supply the head and upper limbs. Sometimes the aorta subdivides near its origin into two branches, which soon reunite ; in these cases the œsophagus and trachea usually pass through the interval between the two branches ; this is the normal condition of the vessel in the reptilia and is due to persistence of a part of the right dorsal aorta which usually disappears (fig. 190).

Applied Anatomy.—The ascending aorta and the arch of the aorta are frequent sites of aneurysm.

Aneurysm of the ascending aorta in a majority of cases affects the anterior sinus, owing to the fact that the reflux of blood which follows the closing of the aortic valve is directed chiefly against the anterior wall of the vessel. If the aneurysmal sac projects forwards it may destroy part of the sternum and the costal cartilages, usually on the right side, and appear as a pulsating tumour on the front of the chest. In other cases it may compress or open into the right lung, bronchi, or trachea; it may burst into the pericardium (a common cause of death in these aneurysms), or may compress the right atrium, the pulmonary trunk and the adjoining part of the right ventricle, and open into one or other of these structures. It may press upon the superior vena cava or the innominate veins, causing great venous engorgement in their tributaries; an aneurysm has occasionally perforated into the superior vena cava, setting up an arteriovenous aneurysm.

Aneurysm of the aortic arch usually involves the posterior part of the vessel. It may press upon the trachea and give rise to the sign known as 'tracheal tugging,' impede the breathing, or produce cough, dyspnœa, stridor, bronchiectasis, or hæmoptysis, or it may

FIG. 698.—A scheme showing the course of the coronary arteries.



ultimately burst into the trachea, producing fatal hæmorrhage. Again, its pressure on the left recurrent laryngeal nerve may give rise to symptoms of laryngeal paralysis; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the œsophagus, producing dysphagia, and has not infrequently been mistaken for œsophageal stricture; or it may burst into the œsophagus, when fatal hæmorrhage will occur. Pressure on the sympathetic filaments may produce (1) dilatation of the pupil by stimulation, or later (2) contraction of the pupil by paralysing the nerves on the affected side. The pupillary changes have however been attributed to the alterations of the blood-pressure in the carotid artery on the affected side—lowering of pressure leading to partial collapse of the tortuous vessels of the iris and dilatation of the pupil, increase of pressure tending to straighten out these vessels and diminish the pupillary aperture. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce weakness, or even a disappearance, of the pulse in one or the other wrist, or in the left superficial temporal artery; or the tumour may present itself at or above the manubrium, generally either in the median line, or the right of the sternum, and may simulate an aneurysm of one of the arteries of the neck.

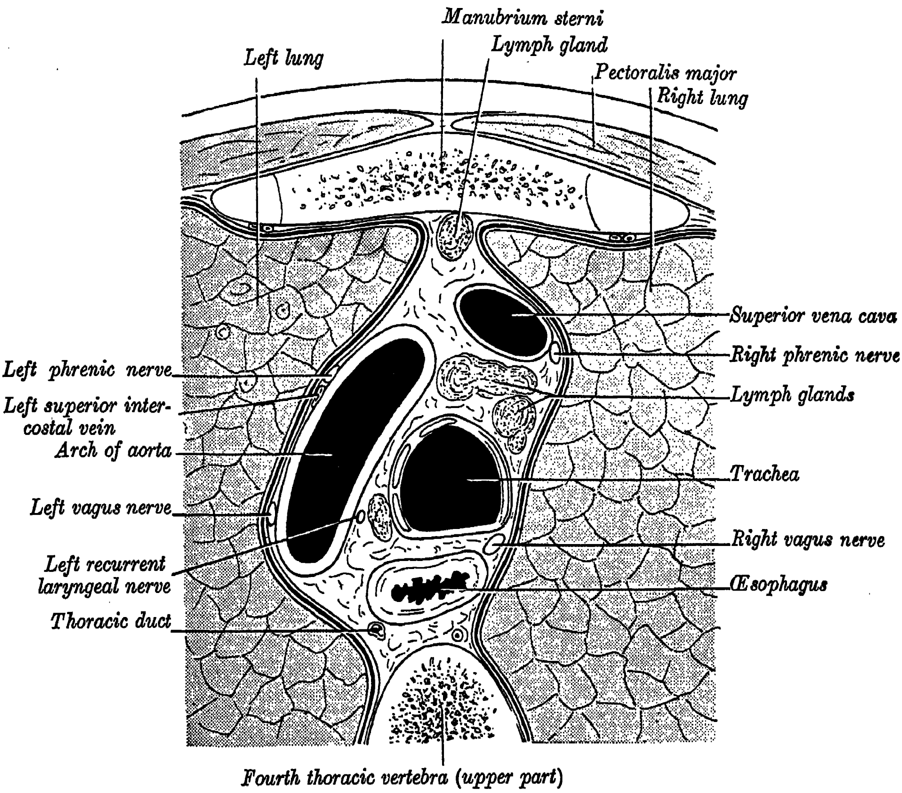
Many of the physical signs of an aortic aneurysm may be simulated with extraordinary fidelity by the pulsation or throbbing of a distended and elastic aorta. This condition may be met with in young persons with aortic regurgitation and greatly hypertrophied hearts, in patients who are of a neurotic or hysterical temperament, and in cases of Graves's disease or of marked anæmia. The condition is known as dynamic dilatation of the aorta, and in no way threatens life.

Branches (figs. 697, 700).—Three branches are given off from the upper aspect of the arch of the aorta, viz.: the innominate, the left common carotid and the left subclavian.

Peculiarities.—The branches may spring from the commencement of the arch or upper part of the ascending aorta; or the distance between them at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid to the innominate artery.

The number of the primary branches may be reduced to one; more commonly there are two, the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the

FIG. 699.—A transverse section through the mediastinum at the level of the upper part of the body of the fourth thoracic vertebra.



number may be increased to four, through the right carotid and subclavian arteries arising directly from the aorta; in most of these cases the right subclavian arises from the left end of the arch and passes to the right behind the œsophagus (see also p. 149). Another common variation in which there are four primary branches is that where the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks may be increased to five or six; very rarely, the external and internal carotid arteries arise separately, the common carotid being absent on one or both sides. In some few cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

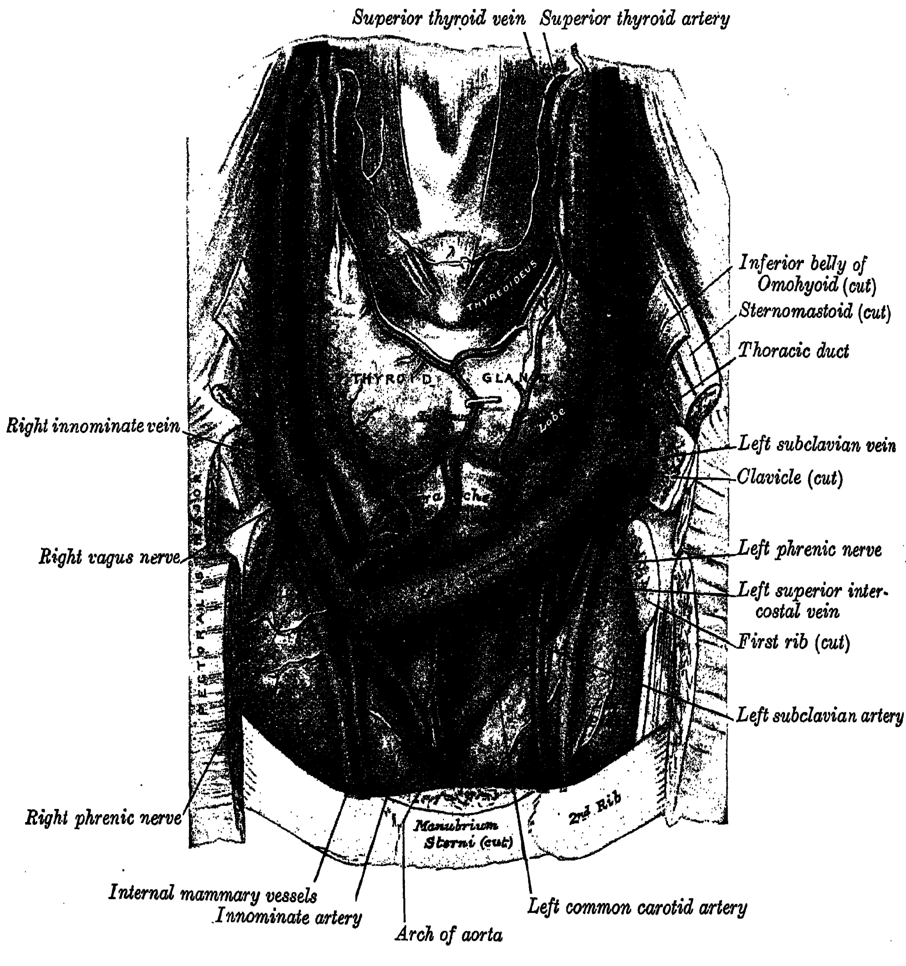
When the aorta arches over to the right side, the arrangement of the three branches is reversed: there is a left innominate artery, and the right carotid and right subclavian arise separately. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

Other arteries may spring from the arch of the aorta. Of these the most common are the bronchial (one or both), and the thyroidea ima; the internal mammary and the inferior thyroid have been seen to arise from it.

The Innominate Artery (figs. 697, 700, 701, 703)

The **innominate artery** is the largest branch of the arch of the aorta, and is from 4 to 5 cm. in length. It arises from the convexity of the arch of the aorta, posterior to the centre of the manubrium sterni ; it passes obliquely upwards, backwards and to the right, lying at first in front of the trachea and

Fig. 700.—Dissection of the lower part of the neck, and the upper part of the thorax. Anterior aspect.



then on its right side. At the level of the upper border of the right sterno-clavicular joint it divides into the right common carotid and right subclavian arteries.

Relations.—*Anteriorly* it is separated from the manubrium sterni by the Sternohyoid and Sternothyroid, the remains of the thymus, the left innominate and right inferior thyroid veins, which cross its root, and sometimes the cardiac branches of the right vagus nerve. *Posteriorly* it is related to the trachea below, and the right pleura above ; on the *right side*, to the right innominate vein, the upper part of the superior vena cava, and the pleura ; and on the *left side*, the remains of the thymus, the origin of the left common carotid artery, the inferior thyroid veins, and at a higher level the trachea.

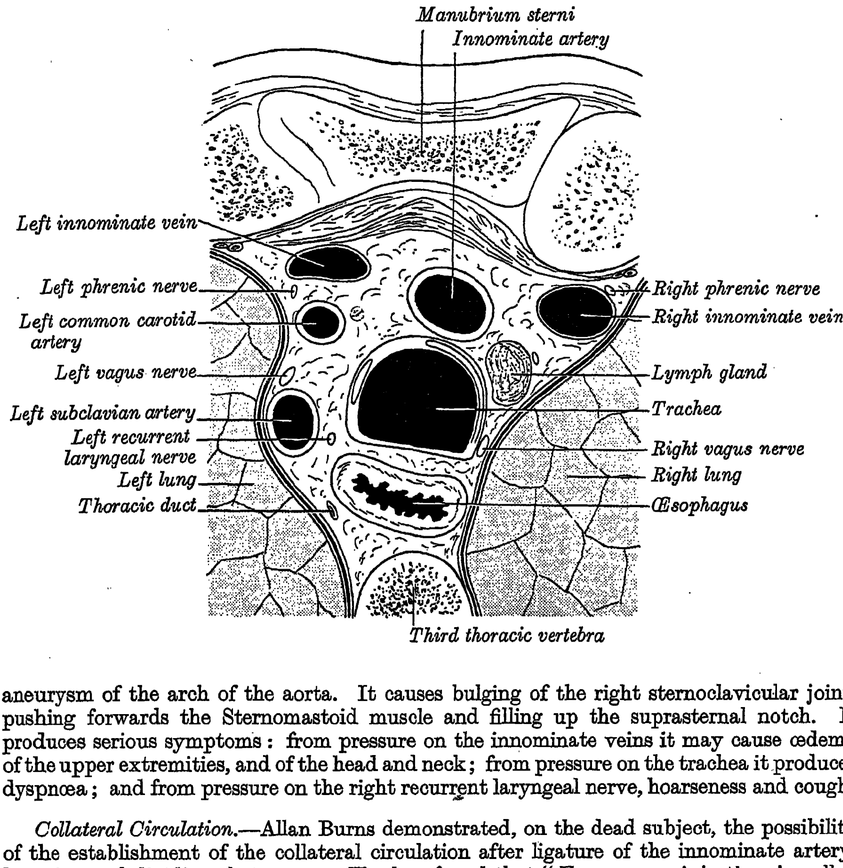
Branches.—The innominate artery is usually devoid of branches other than its terminal ones, but occasionally the *thyroidea ima* arises from it, and sometimes it gives off a *thymic* or a *bronchial branch.*

The **thyroidea ima**, small and inconstant, ascends, in front of the trachea to the isthmus of the thyroid gland, in which it ends. It occasionally arises from the aorta, or from the right common carotid, subclavian or internal mammary arteries.

Peculiarities.—The innominate artery sometimes projects above the upper border of the manubrium sterni. It may divide above the level of the sternoclavicular joint, less frequently below it. When the aortic arch is on the right side, the innominate artery is directed to the left side of the neck.

Applied Anatomy.—The innominate artery may be wounded in performing the operation of low tracheotomy, or a badly placed tracheotomy tube may ulcerate into the vessel. Aneurysm of the innominate artery not infrequently occurs as an accompaniment of

Fig. 701.—A transverse section through the mediastinum at the level of the body of the third thoracic vertebra.



aneurysm of the arch of the aorta. It causes bulging of the right sternoclavicular joint, pushing forwards the Sternomastoid muscle and filling up the suprasternal notch. It produces serious symptoms: from pressure on the innominate veins it may cause œdema of the upper extremities, and of the head and neck; from pressure on the trachea it produces dyspnœa; and from pressure on the right recurrent laryngeal nerve, hoarseness and cough.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery. He then found that " Even coarse injection, impelled into the aorta, passed freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely." * The branches by which this circulation is carried on are numerous; thus, all the communications across the median plane between the branches of the carotid arteries of opposite sides are available for the supply of blood to the right side of the head and neck; the anastomosis between the costocervical of the subclavian and the third posterior intercostal (see *infra* on the collateral circulation after obliteration of the descending thoracic aorta) brings the blood, by a free and direct course, into the right subclavian; the numerous connexions between the posterior intercostal arteries and the branches of the axillary and internal mammary arteries assist in the supply of blood to the right arm, while the inferior epigastric from the external iliac, by means of its anastomosis with the internal mammary, compensates for any deficiency in the vascularity of the wall of the chest.

* *Surgical Anatomy of the Head and Neck*, p. 62.

THE ARTERIES OF THE HEAD AND NECK

The principal arteries of the head and neck are the two common carotids; they ascend in the neck and each divides into two branches, viz. (1) the external carotid, supplying the exterior of the head, the face and the greater part of the neck; (2) the internal carotid, supplying to a great extent the parts within the cranial and orbital cavities.

These arteries, together with the veins and nerves which accompany them, are situated in a cleft on each side of the neck. This cleft may be said to possess three walls; a posterior formed mainly by the cervical vertebræ with their attached muscles; a medial consisting of the trachea, œsophagus, thyroid gland, larynx and the constrictor muscles of the pharynx; and an antero-lateral made up of the Sternomastoid with, at different levels, the Omohyoid, and the Digastric and Stylohyoid muscles.

The Common Carotid Arteries

The **common carotid arteries** differ in length and in their mode of origin. The *right* artery begins at the bifurcation of the innominate artery behind the right sternoclavicular joint and is confined to the neck. The *left* artery springs from the highest part of the arch of the aorta immediately behind and to the left of the innominate artery, and therefore consists of a thoracic and a cervical portion.

The **thoracic portion of the left common carotid artery** (figs. 700, 701) ascends from the arch of the aorta to the level of the left sternoclavicular joint, where it is continuous with the cervical portion. It lies at first in front of the trachea, but later inclines to its left side.

Relations.—*In front*, it is separated from the manubrium sterni by the Sternohyoid and Sternothyroid, the anterior portions of the left pleura and lung, the left innominate vein and the remains of the thymus; *behind*, it is related to the trachea, the left subclavian artery, the left edge of the œsophagus, the left recurrent laryngeal nerve and the thoracic duct. On its *right side* it is related below to the innominate artery, and above to the trachea, the inferior thyroid veins and the remains of the thymus; at its *left side* are the left vagus and phrenic nerves, the left pleura and lung.

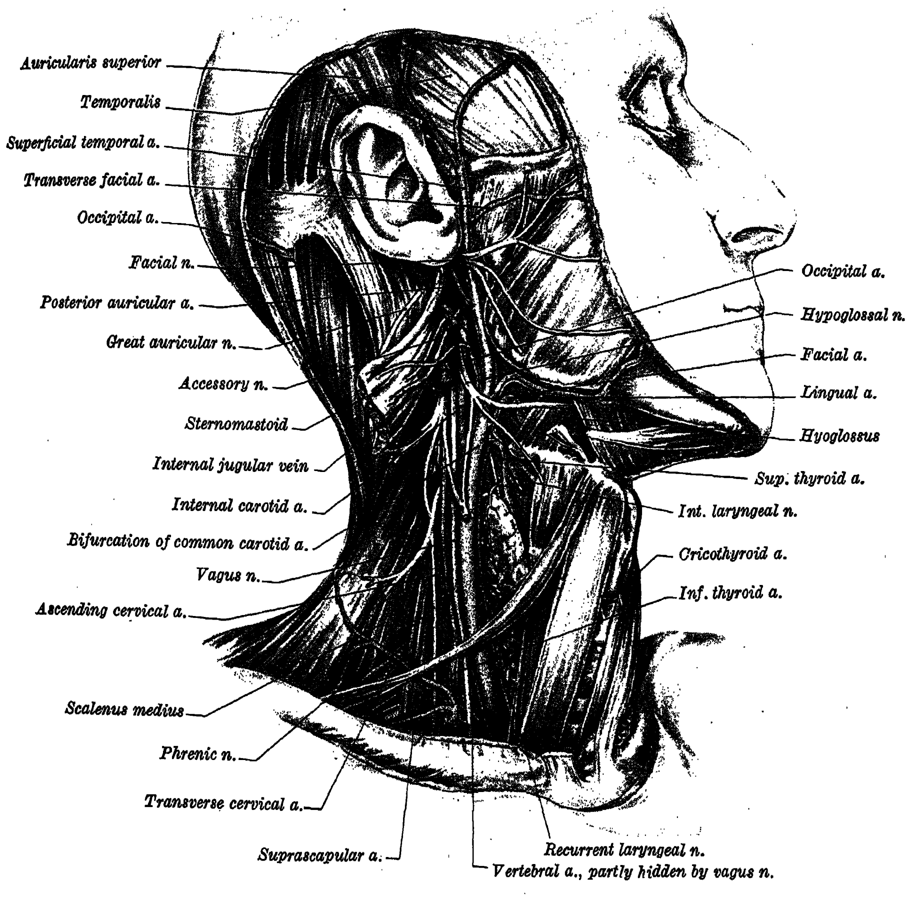
The **cervical portions** of the common carotid arteries resemble each other so closely that one description will apply to both (figs. 702, 704). Each passes obliquely upwards, from behind the sternoclavicular joint, to the level of the upper border of the thyroid cartilage, where it divides into the external and internal carotid arteries. At its point of division the vessel shows a dilatation, termed the *carotid sinus*, which usually involves, and may be restricted to, the proximal part of the internal carotid artery. In this situation the tunica media is thinner than elsewhere and the tunica adventitia contains a large number of sensory nerve-endings, which are derived from the glossopharyngeal (p. 1069) and probably also from the vagus nerves. The *carotid body*, which lies behind the point of division of the common carotid artery, is a small, reddish-brown structure; it is intimately related to the carotid sinus, both topographically and functionally.

At the lower part of the neck the two arteries are separated from each other by a narrow interval which contains the trachea; but at the upper part, the thyroid gland, the larynx, and the pharynx project forwards between the two vessels. The common carotid artery is contained in the carotid sheath (p. 537), which is derived from the deep cervical fascia, and is composed of loose cellular tissue, but the part surrounding the artery is thicker and denser than the rest. This sheath encloses also the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve between the artery and vein, on a plane posterior to both. The descending branch of the hypoglossal nerve is embedded in its anterior wall (fig. 583).

Relations.—The common carotid artery is crossed superficially, at the level of the cricoid cartilage, by the superior belly of the Omohyoid. Below the

level of this muscle the artery is very deeply seated, being covered with the skin, superficial fascia, Platysma, deep cervical fascia, Sternomastoid, Sternohyoid and Sternothyroid. Above the level of the Omohyoid it is more superficial, being covered merely by the skin, the superficial fascia, Platysma, deep cervical fascia and the medial margin of the Sternomastoid. When the latter muscle is drawn backwards, the artery is seen to be contained in the *carotid triangle* (p. 716); this part of the artery is crossed obliquely, from its medial to its lateral side, by the sternomastoid branch of the superior thyroid

FIG. 702.—A dissection of the right side of the neck, showing the carotid and subclavian arteries and their branches.

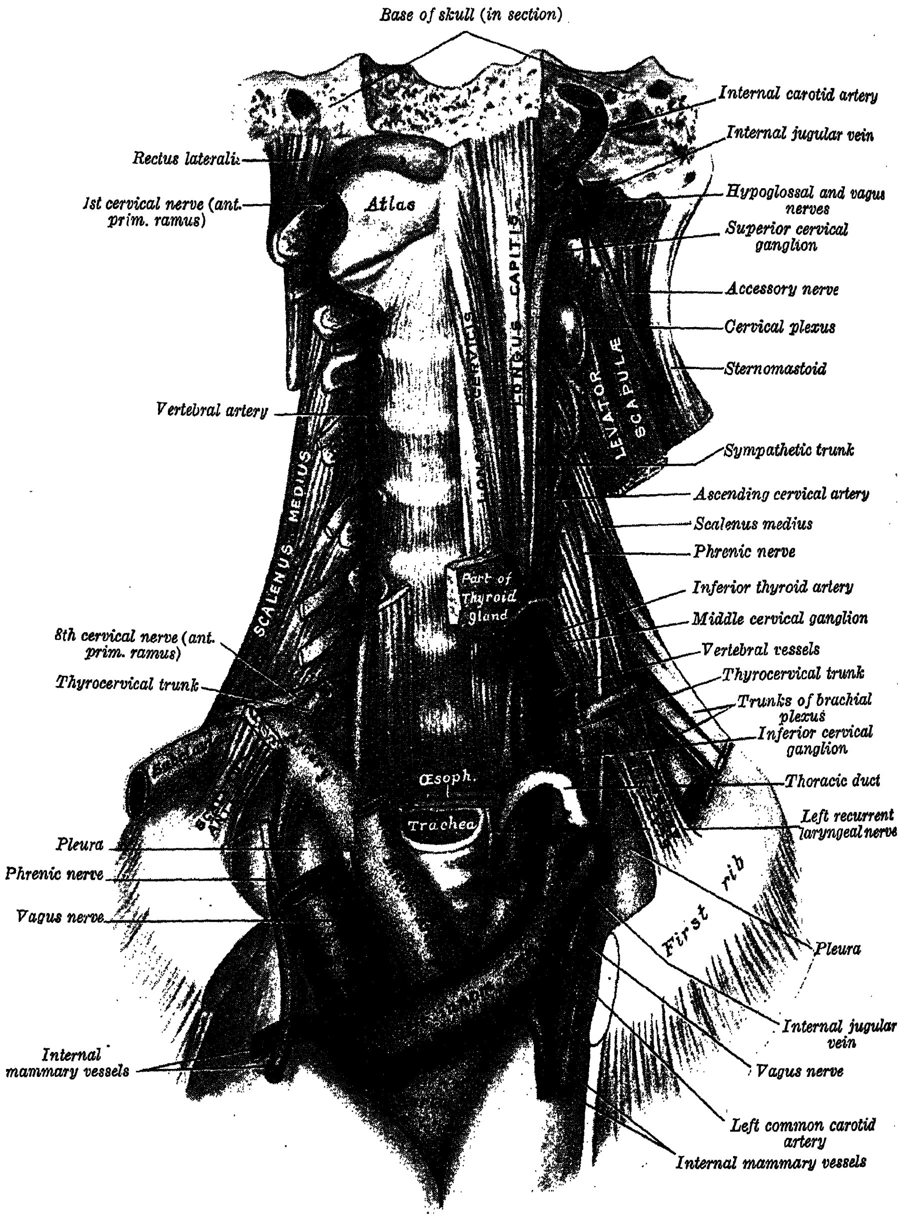


The parotid and submandibular glands and the posterior belly of the digastric have been removed together with the lower part of the internal jugular vein, the upper part of the stylohyoid and the lower part of the sternomastoid, muscle. The upper part of the sternomastoid muscle has been retracted to expose the structures under cover of it.

artery. In front of or within its sheath is the descending branch of the hypoglossal nerve, this branch being joined by the descendens cervicalis nerve, which springs from the second and third cervical nerves and crosses the vessel obliquely. The superior thyroid vein crosses the artery near its termination, and the middle thyroid vein a little below the level of the cricoid cartilage; the anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the Sternohyoid and Sternothyroid muscles. *Behind,* the artery is separated from the transverse processes of the fourth, fifth and sixth cervical vertebræ by the Longus cervicis (Longus colli) and Longus capitis muscles and the origin of the Scalenus anterior, the sympathetic trunk and the ascending cervical artery being interposed between the artery and the muscles. Below the level of the sixth cervical vertebra the common carotid artery lies in the angle between

the Scalenus anterior and the Longus cervicis, anterior to the vertebral vessels, the inferior thyroid and subclavian arteries, and, on the left side, the thoracic duct. *Medial* to it are the œsophagus, trachea, and the lobe of the thyroid

FIG. 703.—A drawing of a dissection of the prevertebral and upper thoracic regions showing the vessels, etc., near the root of the neck, the cervical course of the vertebral artery, and the structures which lie posterior to the left internal jugular vein.



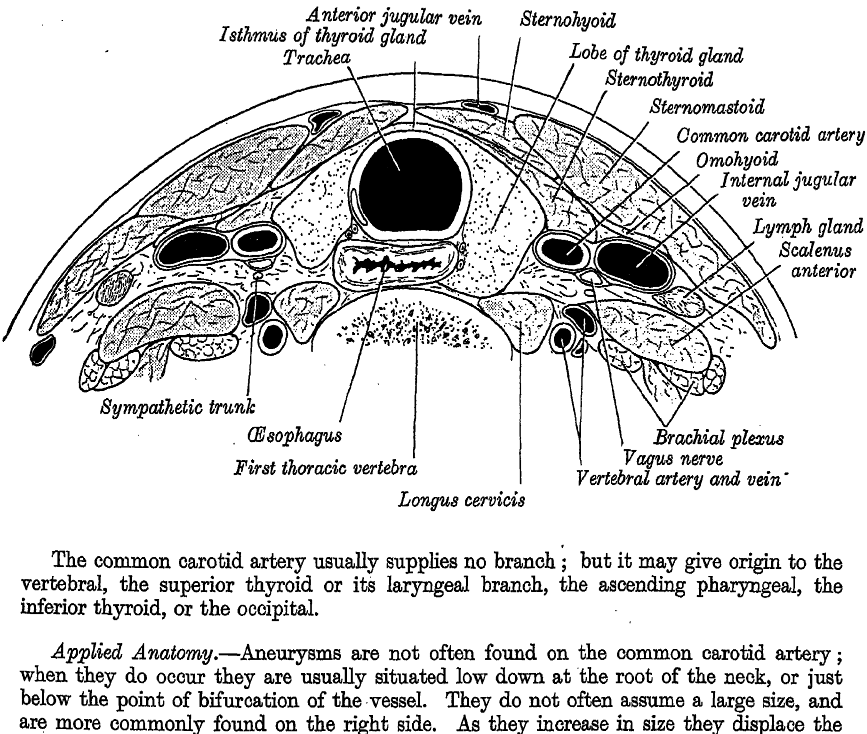
gland (which overlaps it), the inferior thyroid artery and recurrent laryngeal nerve being interposed; higher up, the larynx and pharnyx are medial to the artery. *Lateral* to the artery are the internal jugular vein and vagus nerve.

On the right side, at the lower part of the neck, the recurrent laryngeal nerve crosses obliquely behind the artery; the right internal jugular vein diverges from the artery, but the left vein approaches and often overlaps the lower part of the vessel.

Peculiarities.—In about 12 per cent. of subjects the *right* common carotid artery arises above the level of the upper border of the sternoclavicular joint. It may arise as a separate branch from the arch of the aorta, or in conjunction with the left carotid. The *left* common carotid artery varies in its origin more frequently than the right. In the majority of abnormal cases it arises with the innominate artery; if that artery be absent, the two carotids arise usually by a single trunk. It is rarely joined with the left subclavian, except in cases of transposition of the aortic arch.

Division of the common carotid artery may occur at or about the level of the hyoid bone; more rarely it occurs below the usual level, opposite the middle of the larynx, or the lower border of the cricoid cartilage; one case is described by Morgagni, where the artery was only 4 cm. in length and divided at the root of the neck. Very rarely the artery ascends in the neck without undergoing subdivision, either the external or the internal carotid being wanting. In a few cases the artery has been found absent, the external and internal carotid arteries arising directly from the arch of the aorta; this peculiarity existed on both sides in some instances, on one side only in others.

Fig. 704.—A transverse section through the anterior part of the neck at the level of the body of the first thoracic vertebra.



The common carotid artery usually supplies no branch; but it may give origin to the vertebral, the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or the occipital.

Applied Anatomy.—Aneurysms are not often found on the common carotid artery; when they do occur they are usually situated low down at the root of the neck, or just below the point of bifurcation of the vessel. They do not often assume a large size, and are more commonly found on the right side. As they increase in size they displace the trachea and larynx, and therefore dyspnœa becomes a prominent symptom. Dysphagia also may be present from pressure on the œsophagus, especially if the aneurysm is on the left side; and pressure on the recurrent laryngeal nerve may produce hoarseness and laryngeal cough. Pressure on the sympathetic will cause pupillary changes—dilatation of the pupil when the sympathetic is irritated or the arterial blood-supply to the eye is lessened, contraction when the sympathetic has become paralysed; sympathetic irritation may also cause unilateral sweating of the head and neck. Pressure on the superficial branches of the cervical plexus may give rise to pain in the head, face and neck; pressure on the vagus to irregular action of the heart and to asthmatic attacks. It is important to bear in mind that an enlarged lymph gland in the carotid triangle, receiving a transmitted pulsation from the carotid artery, may simulate aneurysm of that vessel, but may be distinguished from it by the character of the pulsation, which is not expansile.

Embolism of the left common carotid artery, or the thrombosis that may follow injury to the wall of the vessel by penetrating gunshot wounds of the neck, have been known to produce aphasia by interference with the blood-supply of the brain.

Digital compression of the common carotid artery is sometimes required, and is best effected by pressing the vessel with the thumb against the anterior tubercle of the transverse process of the sixth cervical vertebra (p. 208).

The upper part of the common carotid artery should be selected as the spot upon which to place a ligature, for the lower part is placed very deeply; moreover, on the left side, the internal jugular vein, in most cases, passes obliquely in front of it. The part of the vessel which is most favourable for the operation is that opposite the level of the cricoid cartilage.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation can be perfectly established by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and between the deep cervical and descending branch of the occipital; the vertebral takes the place of the internal carotid within the cranium.

Wounds of the common carotid should be treated by suture whenever possible, because, after ligature of the vessel, hemiplegia or other symptom of cerebral disturbance supervenes in about twenty-five per cent. of cases.

The External Carotid Artery

The **external carotid artery** (fig. 702) begins opposite the upper border of the thyroid cartilage, at the level of the disc between the third and fourth cervical vertebræ, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to a point behind the neck of the mandible, where, in the substance of the parotid gland, it divides into the superficial temporal and maxillary (internal maxillary) arteries. It diminishes rapidly in size, owing to the number and large size of its branches. In the child, it is a little smaller than the internal carotid artery; but in the adult, the two vessels are of nearly equal size. At its origin, it is contained within the carotid triangle (p. 716), and lies superficial to and nearer the median plane than the internal carotid artery; higher up it is situated lateral to this artery.

Relations.—Within the carotid triangle the external carotid artery is covered by the skin, the superficial fascia, the loop between the cervical branch of the facial nerve and the anterior cutaneous nerve of the neck, the deep fascia, and the anterior margin of the Sternomastoid; it is crossed by the hypoglossal nerve and its vena comitans, by the lingual and common facial veins and sometimes by the superior thyroid vein. Leaving the carotid triangle it is crossed by the posterior belly of the Digastric and the Stylohyoid, and then ascends between the latter muscle and the posteromedial surface of the parotid gland. Finally, it enters the gland, where it lies deep to the facial nerve and the junction of the superficial temporal and maxillary veins. Medially, it is related to the wall of the pharynx, the superior laryngeal nerve, and the ascending pharyngeal artery. At a higher level the internal carotid artery is medial to it, but is separated from it by the styloid process, the Styloglossus and Stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve and a part of the parotid gland (fig. 705).

Applied Anatomy.—Ligature of the external carotid may be required in cases of wound of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumours of the scalp or face. It is also done as a preliminary measure to excision of the maxilla or tongue. The seat of election for ligature is between the origins of its superior thyroid and lingual branches, just below the tip of the greater cornu of the hyoid bone.

Collateral Circulation.—The circulation is re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid artery, and of the occipital artery with branches of the subclavian, etc.

The Branches of the External Carotid Artery (figs. 702, 706)

The branches of the external carotid artery are:

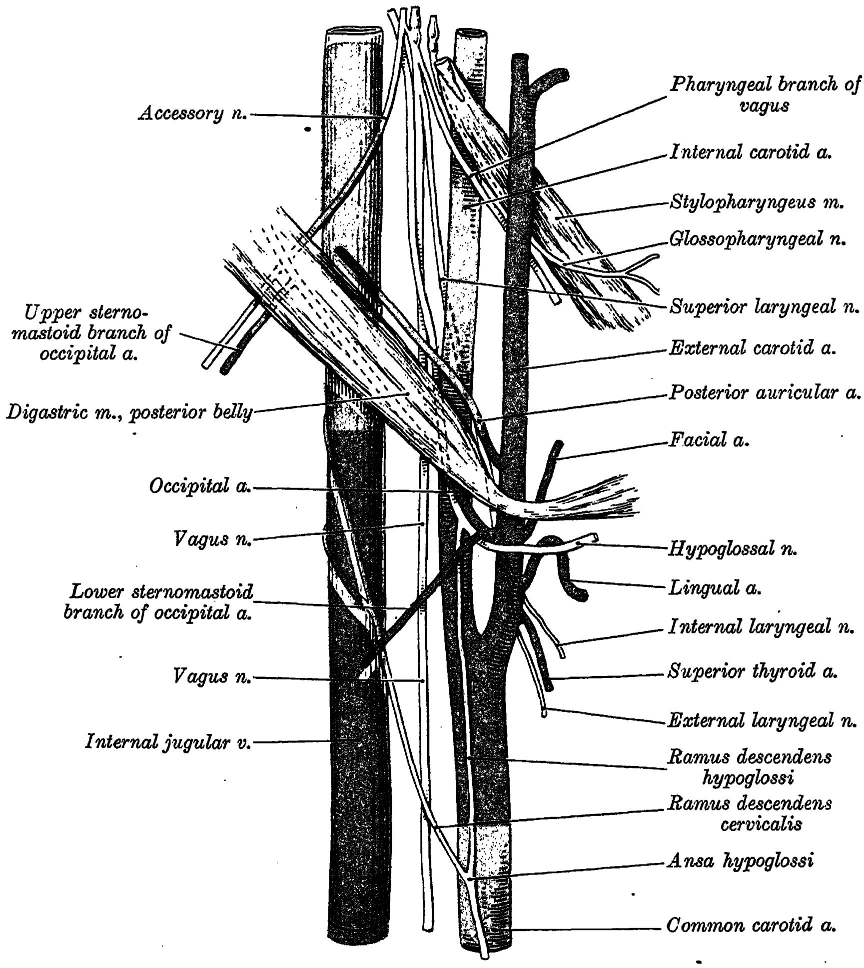
1. Superior thyroid.	4. Facial.	7. Superficial temporal.
2. Ascending pharyngeal.	5. Occipital.	8. Maxillary.
3. Lingual.	6. Posterior auricular.	

1. **The superior thyroid artery** (fig. 702) arises from the front of the external carotid artery just below the level of the greater cornu of the hyoid bone and,

divides into its terminal branches at the apex of the corresponding lobe of the thyroid gland.

Relations.—From its origin beneath the anterior border of the Sternomastoid it runs downwards and forwards in the carotid triangle along the lateral border of the Thyrohyoid, and is covered by the skin, Platysma and fasciæ; it then passes under cover of the Omohyoid, Sternohyoid and Sternothyroid.

FIG. 705.—A diagram showing the structures crossing the internal jugular vein and carotid arteries, and those intervening between the external and internal carotid arteries. Modified from a figure in R. B. Green's *Human Anatomy for Dental Students*, 1923.



o its medial side are the Constrictor pharyngis inferior and the external branch ᶠ the superior laryngeal nerve, but the nerve frequently lies on a more posterior plane.

Branches.—It distributes twigs to the adjacent muscles, and branches to the thyroid gland; it anastomoses with its fellow of the opposite side, and with the inferior thyroid arteries. The branches to the gland are generally two in number, an anterior and a posterior; the anterior branch follows the medial border of the upper pole of the lobe and supplies principally the anterior surface; it sends a branch across the upper border of the isthmus to anastomose with the corresponding artery of the opposite side; the posterior branch descends on the posterior border of the gland, supplying its medial and lateral surfaces, and anastomoses with the inferior thyroid artery. Sometimes a lateral branch is distributed to the lateral surface of the gland.

Besides the arteries distributed to the muscles and to the thyroid gland, the superior thyroid artery supplies the following branches:

Infrahyoid.	Superior laryngeal.
Sternomastoid.	Cricothyroid.

The **infrahyoid artery** is small and runs along the lower border of the hyoid bone deep to the Thyrohyoid, and anastomoses with the vessel of the opposite side.

The **sternomastoid branch** frequently arises from the external carotid artery; it runs downwards and laterally across the sheath of the common carotid artery, and enters the Sternomastoid.

The **superior laryngeal artery**, larger than either of the preceding, is frequently a separate branch of the external carotid artery; it accompanies the internal laryngeal nerve and passes deep to the Thyrohyoid; it pierces the lower part of the thyrohyoid membrane, and supplies the muscles, mucous membrane and glands of the larynx, anastomosing with the artery of the opposite side, and with the inferior laryngeal branch of the inferior thyroid artery.

The **cricothyroid branch** is small and runs transversely across the upper part of the cricothyroid ligament, communicating with the artery of the opposite side.

Applied Anatomy.—The superior thyroid artery, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hæmorrhage. The superior thyroid is ligatured in cases of goitre where the removal of a lobe of the thyroid gland may present special dangers.

The position of the sternomastoid branch is of importance in connexion with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel and may chance to be wounded in opening the sheath. The position of the cricothyroid branch should be remembered, as it may prove the source of troublesome hæmorrhage during the operation of laryngotomy.

2. The **ascending pharyngeal artery** (fig. 711), the smallest branch of the external carotid artery, is a long, slender vessel, deeply seated in the neck. It arises close to the origin of the external carotid artery, and ascends vertically between the internal carotid artery and the side of the pharynx to the under surface of the base of the skull, being crossed by the Styloglossus and the Stylopharyngeus and lying on the Longus capitis; it anastomoses freely with the ascending palatine branch of the facial (external maxillary) artery.

Its branches are:

Pharyngeal.	Inferior tympanic.	Meningeal.

The **pharyngeal branches** are three or four in number. Two of these descend to supply the Inferior and Middle constrictor muscles and the Stylopharyngeus, ramifying in their substance and in the underlying mucous membrane. A branch of variable size is distributed to the palate, and may take the place of the ascending palatine branch of the facial (external maxillary) artery; it runs downwards and forwards between the superior border of the Superior constrictor and the Levator palati, and accompanies the latter muscle to the soft palate; it gives branches to the tonsil, and supplies a twig to the pharyngotympanic (auditory) tube.

The **inferior tympanic artery** is a small branch which passes through the temporal bone, in the canaliculus for the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity and anastomose with the other tympanic arteries.

The **meningeal branches** are several small vessels which supply the dura mater. One enters the cranium through the foramen lacerum; a second passes through the jugular foramen; and occasionally a third through the anterior condylar canal.

Numerous small vessels supply the Longi capitis et cervicis, the sympathetic trunk, the hypoglossal and vagus nerves, and the lymph glands; they anastomose with branches of the ascending cervical and vertebral arteries.

3. The **lingual artery** (fig. 711) arises from the anteromedial surface of the external carotid artery opposite to the tip of the greater cornu of the hyoid bone, and between the superior thyroid and facial arteries; it ends in the tongue. Running obliquely upwards and medially at first, it then curves downwards and forwards to the greater cornu of the hyoid bone, forming a loop which is characteristic of the vessel; it passes deep to the posterior border of the Hyoglossus, runs horizontally forwards under cover of that muscle, and finally, ascending almost perpendicularly, courses forwards on the under surface of the tongue as far as the tip.

Course and relations.—The *first part* of the lingual artery lies in the carotid triangle ; superficial to it are the skin, fascia and Platysma ; deep to it, the Middle constrictor muscle. It runs upwards and medially for a short distance, and then descends to the level of the hyoid bone, forming a loop, which is crossed by the hypoglossal nerve. The *second part* of the artery courses along the upper border of the hyoid bone, deep to the Hyoglossus, the tendon of the Digastric or its fascial retinaculum, the Stylohyoid, the lower part of the submandibular (submaxillary) gland and the posterior part of the Mylohyoid ; the Hyoglossus separates the artery from the hypoglossal nerve and its vena comitans ; in this part of its course it lies on the Middle constrictor muscle and crosses the stylohyoid ligament. The *third part* of the artery is named the *arteria profunda linguae.* It bends sharply upwards near the anterior border of the Hyoglossus, and then runs forwards on the inferior surface of the tongue near the frenulum, accompanied by the lingual nerve. Medially, it is related to the Genioglossus ; laterally, to the Longitudinalis linguæ inferior ; below, to the mucous membrane of the tongue. At the tip of the tongue it anastomoses with the lingual artery of the opposite side.

The branches of the lingual artery are :

Suprahyoid.	Sublingual.
Rami dorsales linguæ.	Arteria profunda linguæ.

The **suprahyoid artery** is very small ; it runs along the upper border of the hyoid bone, and anastomoses with its fellow of the opposite side.

The **rami dorsales linguæ** consist usually of two or three small branches ; they arise under cover of the Hyoglossus, ascend to the posterior part of the dorsum of the tongue, and supply the mucous membrane of the tongue, the palatoglossal arch, the tonsil, soft palate and epiglottis ; they anastomose with the vessels of the opposite side.

The **sublingual branch** arises at the anterior margin of the Hyoglossus, and runs forward between the Genioglossus and Mylohyoid to the sublingual gland. It supplies the gland and gives branches to the Mylohyoid and neighbouring muscles, and to the mucous membrane of the mouth and gums. One branch runs behind the alveolar part of the mandible in the substance of the gum to anastomose with a similar artery from the other side ; another pierces the Mylohyoid and anastomoses with the submental branch of the facial (external maxillary) artery.

The **arteria profunda linguæ**—the terminal portion of the lingual artery—is described above.

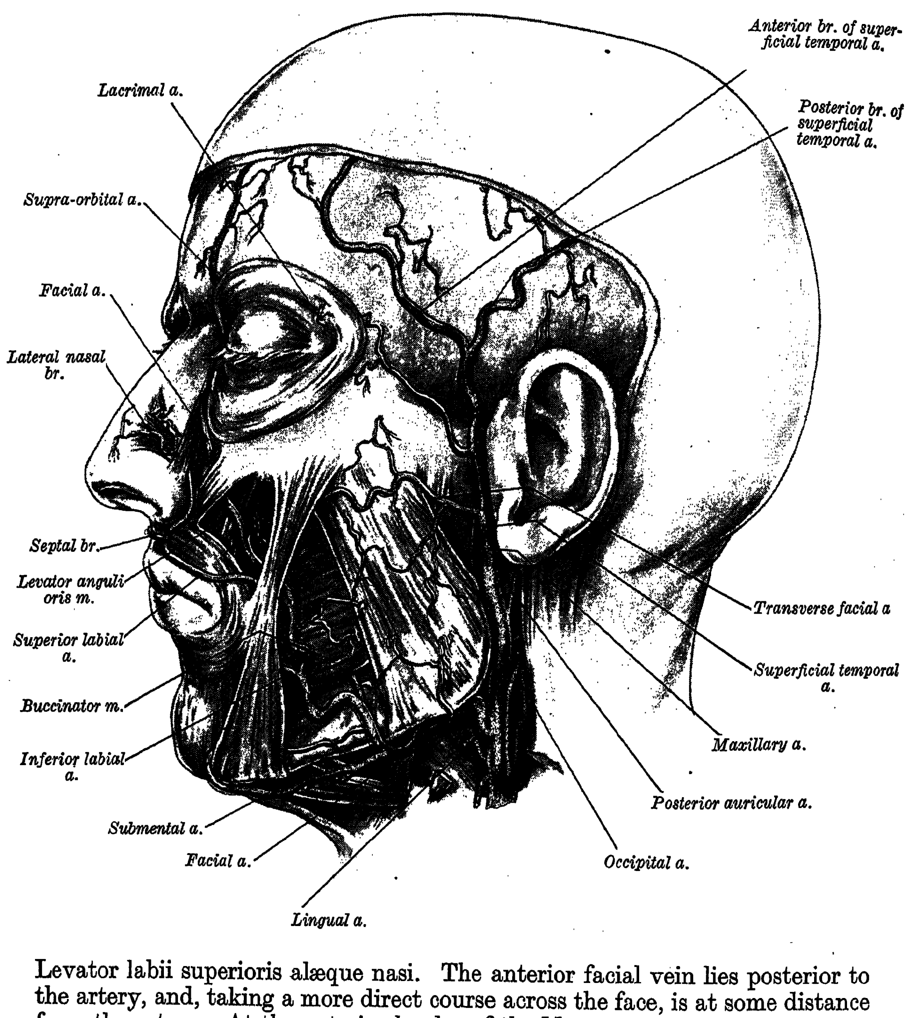
Applied Anatomy.—The lingual artery is not infrequently divided near its origin in cases of cut throat ; while severe hæmorrhage, which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case, the primary wound may be enlarged if necessary, and the bleeding vessel secured ; in the latter, it has been suggested that the lingual artery should be tied near its origin.

4. The **facial artery** (external maxillary artery) (fig. 706) arises from the front of the external carotid artery in the carotid triangle a little higher than the lingual artery, and immediately above the greater cornu of the hyoid bone. Sheltered by the ramus of the mandible, it arches upwards and enters a groove in the posterior border of the submandibular (submaxillary) gland. It next turns downwards and forwards between the gland and the Medial pterygoid muscle, and, reaching the lower border of the mandible, ascends over it at the anterior edge of the Masseter, and enters the face. On the face it passes forwards and upwards across the cheek to the angle of the mouth, then ascends along the side of the nose, and ends at the medial palpebral commissure, where it supplies branches to the lacrimal sac, and anastomoses with the dorsal nasal branch of the ophthalmic artery. The facial artery is remarkably tortuous : in the neck to accommodate itself to the movements of the pharynx during deglutition, and on the face to accommodate itself to the movements of the mandible, lips and cheeks.

Relations.—*In the neck,* at its origin, the artery is superficial, being placed under cover of the skin, Platysma, and fasciæ, and is frequently crossed by the hypoglossal nerve. It runs upwards and forwards, deep to the Digastric and Stylohyoid and to the posterior part of the submandibular (submaxillary) gland. At first on the surface of the Middle constrictor of the pharynx, it may reach as high as the lateral surface of the Styloglossus, and it is then separated from the tonsil only by that muscle and the lingual fibres of origin of the Superior

constrictor. Next, it descends to the lower border of the mandible, lying in a groove on the lateral aspect of the submandibular (submaxillary) gland. *In the face*, where it passes over the body of the mandible, it is comparatively superficial, lying immediately beneath the Platysma. In its course over the face, it is under cover of the skin, the fat of the cheek, and, near the angle of the mouth, the Platysma, Risorius and Zygomaticus major. It rests on the Buccinator and Levator anguli oris (Caninus), and passes either over or through the Levator labii superioris. Its terminal part is embedded in the fibres of the

FIG. 706.—The arteries of the left side of the face.



Levator labii superioris alæque nasi. The anterior facial vein lies posterior to the artery, and, taking a more direct course across the face, is at some distance from the artery. At the anterior border of the Masseter the two vessels are in contact; in the neck the vein is superficial to the artery. The branches of the facial nerve cross the artery from behind forwards.

The branches of the facial artery may be divided into two sets: those given off in the neck (cervical) and those on the face (facial).

Cervical branches.	*Facial branches.*
Ascending palatine.	Inferior labial.
Tonsillar.	Superior labial.
Glandular.	Lateral nasal.
Submental.	

The **ascending palatine artery** (fig. 711) arises close to the origin of the facial artery and passes up between the Styloglossus and Stylopharyngeus to the side of the pharynx,

along which it is continued between the Superior constrictor and the Medial pterygoid muscles towards the base of the skull. Near the Levator palati it divides into two branches: one follows the course of this muscle, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the greater (descending) palatine branch of the maxillary (internal maxillary) artery; the other pierces the Superior constrictor and supplies the tonsil and the pharyngotympanic (auditory tube), anastomosing with the tonsillar and ascending pharyngeal arteries.

The **tonsillar artery** (fig. 711) is the principal artery to the tonsil. Sometimes derived from the ascending palatine artery, it ascends between the Medial pterygoid and Styloglossus, and, at the upper border of the latter muscle, it perforates the Superior constrictor and ramifies in the tonsil and the root of the tongue.

The **glandular branches**, three or four large vessels, supply the submandibular (submaxillary) salivary gland and lymph glands, the neighbouring muscles and the skin.

The **submental artery**, the largest cervical branch of the facial artery, springs from that artery just as it quits the submandibular gland: it runs forwards upon the Mylohyoid (fig. 706), below the body of the mandible, and deep to the anterior belly of the Digastric. It supplies the surrounding muscles, and anastomoses with the sublingual branch of the lingual artery and with the mylohyoid branch of the inferior dental artery; at the chin it turns upwards over the inferior border of the mandible and divides into a superficial and a deep branch. The superficial branch passes between the skin and the Depressor labii inferioris, and anastomoses with the inferior labial artery; the deep branch runs between the muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **inferior labial artery** (fig. 706) arises near the angle of the mouth; it passes upwards and forwards under cover of the Depressor anguli oris (Triangularis), and, penetrating the Orbicularis oris, runs in a tortuous course near the edge of the lower lip between this muscle and the mucous membrane. It supplies the glands, mucous membrane and muscles of the lower lip; and anastomoses with the artery of the opposite side, and with the mental branch of the inferior dental artery.

The **superior labial artery** (fig. 706) is larger and more tortuous than the inferior. It follows a similar course near the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the upper lip, and gives off a *septal branch*, which ramifies on the lower and front part of the nasal septum, and an *alar branch*, which supplies the ala of the nose.

The **lateral nasal branch** (fig. 706) is derived from the facial artery as that vessel ascends along the side of the nose. It supplies the ala and dorsum of the nose, anastomosing with its fellow, with the septal and alar branches of the superior labial artery, with the dorsal nasal branch of the ophthalmic artery, and with the infra-orbital branch of the maxillary (internal maxillary) artery.

The anastomoses of the facial artery are very numerous, not only with the branches of the vessel of the opposite side, but, *in the neck*, with the sublingual branch of the lingual, with the ascending pharyngeal and with the palatine branch of the maxillary; *on the face*, with the mental branch of the inferior dental, the transverse facial branch of the superficial temporal, the infra-orbital branch of the maxillary and the dorsal nasal branch of the ophthalmic.

Peculiarities.—The facial artery not infrequently arises in common with the lingual artery. It varies in size, and in the extent to which it supplies the face; it occasionally ends at the submental, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by enlargement of one of the neighbouring arteries.

Applied Anatomy.—The passage of the facial artery over the body of the mandible would appear to afford a favourable position for the application of pressure in cases of hæmorrhage from the lips; but such application is useless, except for a very short time, on account of the free communication of the artery with its fellow, and with numerous branches from different sources. In a wound involving the lip, it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. The student should observe that the terminal part of the facial artery ascends on the nasal side of the lacrimal sac; in operating for fistula lacrimalis, the sac should always be opened on its lateral side, in order to avoid this vessel.

The facial artery is separated from the lower and hinder part of the tonsil by the Superior constrictor and Styloglossus muscles, and may be wounded in operations in that region.

The free anastomosis of the branches of the facial artery contributes to the success of plastic operations on the face.

5. The **occipital artery** (fig. 707) arises from the posterior part of the external carotid artery, opposite to the facial artery; and running at first on the deep

surface of the posterior belly of the Digastric, ends in the posterior part of the scalp.

Relations.—At its origin, it lies in the carotid triangle, and is crossed by the hypoglossal nerve, which winds round it from behind forwards. The artery passes backwards and upwards deep to the lower border of the posterior belly of the Digastric, crossing in its course the internal carotid artery, the internal jugular vein, and the hypoglossal, vagus and accessory nerves. Reaching the interval between the transverse process of the atlas and the mastoid process of the temporal bone, it comes into contact with the lateral border of the Rectus capitis lateralis. It then runs in the occipital groove on the temporal bone, and here is covered by the Sternomastoid, Splenius capitis, Longissimus capitis and Digastric, and lies successively on the Rectus capitis lateralis, Obliquus superior and Semispinalis capitis. Finally, it turns upwards and pierces the fascia connecting the cranial attachment of the Trapezius with the Sternomastoid, and ascends in a tortuous course in the superficial fascia of the scalp, where it divides into numerous branches. The terminal portion of the occipital artery is accompanied by the greater occipital nerve.

The branches of the occipital artery are:

Sternomastoid.	Auricular.	Meningeal.
Mastoid.	Muscular.	Occipital.
	Descending.	

The **sternomastoid branches** are usually two in number. The *lower branch* generally arises from the beginning of the occipital artery, but sometimes springs directly from the external carotid artery. It passes downwards and backwards over the hypoglossal nerve and the internal jugular vein, and enters the substance of the Sternomastoid; it anastomoses with the sternomastoid branch of the superior thyroid artery. The *upper branch* arises from the occipital artery as it crosses the accessory nerve, and runs downwards and backwards superficial to the internal jugular vein. It enters the deep surface of the Sternomastoid in company with the accessory nerve.

The **mastoid branch**, small in size and sometimes absent, enters the cranial cavity through the mastoid foramen; it gives branches to the mastoid air-cells and the dura mater, and anastomoses with the middle meningeal artery.

The **auricular branch** supplies the back of the concha and anastomoses with the posterior auricular artery.

Muscular branches are supplied to the Digastric, Stylohyoid, Splenius and Longissimus capitis.

The **descending branch** (fig. 707) arises from the occipital artery as the latter lies on the Obliquus superior, and divides into a superficial and a deep branch. The superficial branch passes deep to the Splenius, and anastomoses with the superficial branch of the transverse cervical artery; the deep branch descends between the Semispinales capitis et cervicis, and anastomoses with the vertebral artery, and with the deep cervical artery, a branch of the costocervical trunk (fig. 711). The anastomosis between these vessels assists in establishing the collateral circulation after ligature of the common carotid or subclavian artery.

The **meningeal branches** enter the skull through the jugular foramen and posterior condylar canal, to supply the dura mater in the posterior fossa.

The **occipital branches**, which are the terminal branches, are distributed to the scalp, and reach as high as the vertex of the skull; they are very tortuous, and lie between the skin and the occipital belly of Occipitofrontalis, anastomosing with the artery of the opposite side and with the posterior auricular and temporal arteries, and supplying the occipital belly of Occipitofrontalis, the skin and the pericranium. One of the terminal branches may give off a meningeal twig, which passes through the parietal foramen.

6. The **posterior auricular artery** (fig. 706) is small and arises from the posterior surface of the external carotid artery immediately above the Digastric and Stylohyoid. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the auricle and the mastoid process, where it divides into auricular and occipital branches.

In addition to supplying small branches to the Digastric, Stylohyoid, Sternomastoid, and parotid gland, this vessel gives off the three following branches:

Stylomastoid.	Auricular.	Occipital.

The **stylomastoid artery** enters the stylomastoid foramen, and supplies the tympanic cavity, the tympanic antrum, the mastoid air-cells and the semicircular canals. In the

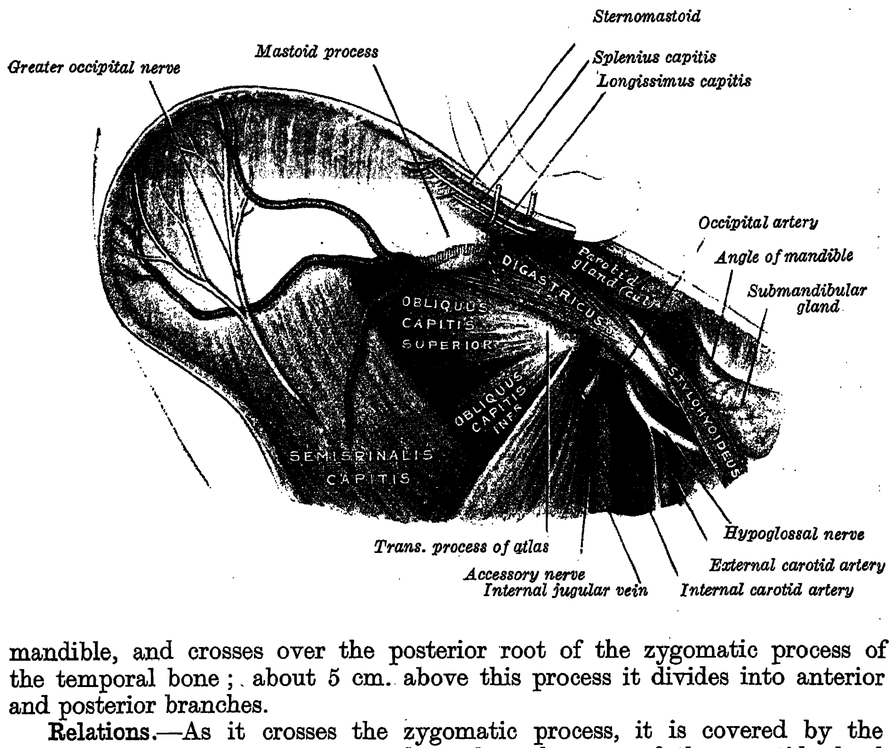
young subject a branch from this vessel (termed the *posterior tympanic artery*) forms, with the anterior tympanic artery from the maxillary (internal maxillary), a vascular circle which surrounds, and supplies small vessels to, the deep surface of the tympanic membrane. It anastomoses with the superficial petrosal branch of the middle meningeal artery.

The **auricular branch** ascends under cover of the Auricularis posterior, and ramifies on the cranial surface of the auricle; some of its branches pierce the auricle, and others curve round its margin to supply its lateral surface. It anastomoses with the posterior and auricular branches of the superficial temporal artery.

The **occipital branch** passes laterally across the front of the mastoid process and then backwards over the Sternomastoid to the occipital belly of the Occipitofrontalis muscle and to the scalp above and behind the ear; it anastomoses with the occipital artery.

7. The **superficial temporal artery** (fig. 702), the smaller terminal branch of the external carotid artery, begins in the parotid gland, behind the neck of the

FIG. 707.—A drawing of a dissection to show the course of the occipital artery.



mandible, and crosses over the posterior root of the zygomatic process of the temporal bone; about 5 cm. above this process it divides into anterior and posterior branches.

Relations.—As it crosses the zygomatic process, it is covered by the Auricularis anterior; it is crossed in the substance of the parotid gland by the temporal and zygomatic branches of the facial nerve, and is accompanied in the scalp by the auriculotemporal nerve, which lies immediately behind it.

It supplies some twigs to the parotid gland, the mandibular joint and the Masseter, and gives off the following branches:

Transverse facial.	Zygomatic.	Anterior.
Auricular.	Middle temporal.	Posterior.

The **transverse facial artery** (fig. 706) arises from the superficial temporal artery before that vessel quits the parotid gland; it runs forwards through the substance of the gland, passes across the Masseter between the parotid duct and the zygomatic arch, accompanied by one or two branches of the facial nerve. It divides into numerous branches, which supply the parotid gland and duct, the Masseter, and the skin, and anastomose with the facial (external maxillary), masseteric, buccal, and infra-orbital arteries.

The **auricular branches** are distributed to the lobule and anterior portion of the auricle, and to the external auditory meatus; they anastomose with the posterior auricular artery.

The **zygomatic artery**, sometimes a branch of the middle temporal artery, runs along the upper border of the zygomatic arch between the two layers of the temporal fascia to the lateral angle of the orbit. It supplies branches to the Orbicularis oculi, and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The **middle temporal artery** arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporalis; it anastomoses with the deep temporal branches of the maxillary artery.

The **anterior (frontal) branch** runs tortuously upwards and forwards towards the frontal eminence; it supplies the muscles, skin and pericranium in this region, and anastomoses with its fellow of the opposite side, and with the supra-orbital and supratrochlear (frontal) arteries.

The **posterior (parietal) branch**, larger than the anterior, curves upwards and backwards on the side of the head, lying superficial to the temporal fascia, and anastomosing with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

Applied Anatomy.—As the superficial temporal artery crosses the zygomatic process, it lies beneath the skin and fascia, and its pulsations may be readily felt during the administration of an anæsthetic, or in circumstances where the radial pulse is not available; it may be compressed easily against the bone in order to check bleeding from the temporal region of the scalp. When a flap is raised from this part of the head, for trephining, the incision should be shaped like a horseshoe, with its convexity upwards, so that the flap shall contain the superficial temporal artery, which ensures a sufficient supply of blood.

8. The **maxillary artery** (internal maxillary artery) (fig. 708), the larger terminal branch of the external carotid artery, arises behind the neck of the mandible and is at first imbedded in the parotid gland; it passes forwards between the neck of the mandible and the sphenomandibular ligament, and then running either superficial or deep to the lower head of the Lateral pterygoid, enters the pterygopalatine fossa between the two heads of that muscle. It may be divided into mandibular, pterygoid and pterygopalatine portions.

The *first* or *mandibular portion* passes horizontally forwards, between the neck of the mandible and the sphenomandibular ligament, where it lies parallel with and a little below the auriculotemporal nerve; it crosses the inferior dental nerve, and runs along the lower border of the Lateral pterygoid.

The *second* or *pterygoid portion* runs obliquely forwards and upwards under cover of the Temporal muscle, and superficial to the lower head of the Lateral pterygoid muscle; very frequently it lies deep to the latter, between it and the branches of the mandibular nerve, and in this case, before entering on the third part of its course, it often forms a wide loop which projects laterally between the two heads of the Lateral pterygoid muscle.

The *third* or *pterygopalatine portion* passes between the upper and lower heads of the Lateral pterygoid muscle, and through the pterygomaxillary fissure into the pterygopalatine fossa, where it lies in front of the sphenopalatine ganglion.

The branches of the vessel may be divided into three groups, corresponding with its three portions.

The Branches of the First or Mandibular Portion of the Maxillary Artery (fig. 708)

Deep auricular.	Middle meningeal.
Anterior tympanic.	Accessory meningeal.

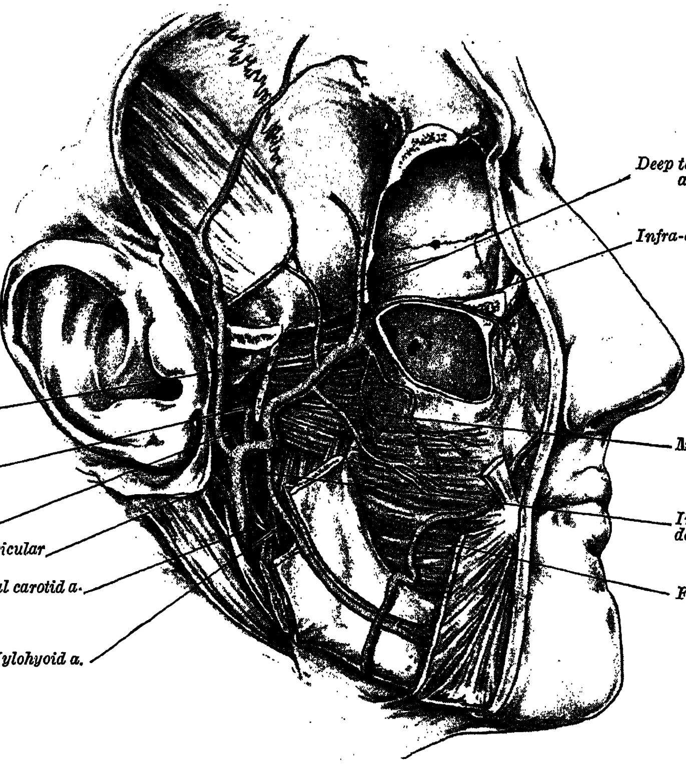
Inferior dental.

The **deep auricular artery**, a small branch, often arises in common with the anterior tympanic. It ascends in the substance of the parotid gland, behind the mandibular joint, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the tympanic membrane; it gives a branch to the mandibular joint.

The **anterior tympanic artery**, a small branch, ascends behind the mandibular joint, and enters the tympanic cavity through the squamotympanic fissure; it ramifies upon the tympanic membrane, and forms a vascular circle around it with the posterior tympanic branch of the stylomastoid artery; it anastomoses with the artery of the pterygoid canal and with the caroticotympanic branch from the internal carotid artery.

The **middle meningeal artery** is the largest of the meningeal arteries. It ascends between the sphenomandibular ligament and the Lateral pterygoid muscle, and between the two roots of the auriculotemporal nerve, and may lie on the lateral surface of the Tensor palati just before it enters the cranial cavity through the foramen spinosum of the sphenoid bone; it then runs forwards and laterally for a variable distance in a groove on the anterior part of the squamous part of the temporal bone, and divides into an anterior and a posterior branch. The *anterior branch*, the larger, crosses the greater wing of the sphenoid bone, reaches the groove, or canal, in the anterior inferior angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upwards as far as the vertex, and others backwards to the occipital region. One branch

FIG. 708 —The right maxillary (internal maxillary) artery.



An extensive dissection has been carried out, involving the removal of the parotid gland, the zygomatic arch, part of the ramus of the mandible, the lateral walls of the orbit and maxillary sinus and the orbital contents.

runs upwards, grooving the parietal bone about 1·5 cm. behind the coronal suture. It corresponds, in a general way, to the line of the precentral sulcus of the brain. The *posterior branch* curves backwards on the squamous part of the temporal bone, and, reaching the lower border of the parietal bone some distance in front of its posterior inferior angle, divides into branches which supply the posterior part of the dura mater and cranium. The branches of the middle meningeal artery anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal arteries.

The middle meningeal artery gives off the following branches within the cranial cavity: 1. Numerous small *ganglionic branches* supply the ganglion and the roots of the trigeminal nerve. 2. A *superficial petrosal branch* enters the hiatus for the greater superficial petrosal nerve, gives twigs to the facial nerve and the tympanic cavity, and anastomoses with the stylomastoid branch of the posterior auricular artery. 3. *A superior tympanic artery* runs in the canal for the Tensor tympani, and supplies this muscle and the lining membrane of

the canal. 4. *Temporal branches* pass through minute foramina in the greater wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries. 5. An *orbital branch* (p. 148) runs forwards and enters the orbit through the lateral part of the superior orbital fissure. It anastomoses with a recurrent meningeal branch of the lacrimal artery, and an enlargement of this anastomosis explains the occasional origin of the lacrimal from the middle meningeal artery.

Applied Anatomy.—The middle meningeal artery is of considerable surgical importance, as it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone without fracture. The injury may be followed by considerable hæmorrhage between the bone and dura mater, which produces symptoms of compression of the brain, and requires trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent symptom of the lesion. The anterior branch of this artery lies in a groove or a bony canal on the anterior inferior angle of the parietal bone at a point 4 cm. behind the zygomatic process of the frontal bone, and 4·5 cm. above the zygomatic arch. From this point it passes upwards and slightly backwards to the sagittal suture, lying about 1·25 to 2 cm. behind the coronal suture.

The **accessory meningeal branch** may arise from the maxillary artery or from the middle meningeal artery. It enters the cranial cavity through the foramen ovale, and supplies branches to the trigeminal ganglion and the dura mater.

The **inferior dental artery** descends posterior to the inferior dental nerve to the mandibular foramen on the medial surface of the ramus of the mandible. In this part of its course the artery lies between the bone on the lateral side, and the sphenomandibular ligament on the medial side. Before it enters the mandibular foramen, it gives off a *mylohyoid* branch, which pierces the sphenomandibular ligament, and descends with the mylohyoid nerve in the mylohyoid groove on the ramus of the mandible; it ramifies on the superficial surface of the Mylohyoid muscle and anastomoses with the submental branch of the facial (external maxillary) artery. The inferior dental artery then runs in the mandibular canal, accompanied by the inferior dental nerve, and, opposite the first premolar tooth, divides into two branches, incisor and mental. The *incisor* branch is continued forwards below the incisor teeth as far as the median plane, where it anastomoses with the artery of the opposite side. Within the canal the inferior dental artery and its incisor branch give off a few twigs to the mandible, and a series of branches which correspond in number to the roots of the teeth; these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth. The *mental* branch escapes at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior dental artery gives off a *lingual* branch, which descends with the lingual nerve and supplies the mucous membrane of the mouth.

The Branches of the Second or Pterygoid Portion of the Maxillary Artery (fig. 708)

Deep temporal. Pterygoid. Masseteric. Buccal.

The **deep temporal branches**, an anterior and a posterior, ascend between the Temporalis and the pericranium; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and greater wing of the sphenoid bone.

The **pterygoid branches**, irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric artery** is small and passes with the corresponding nerve behind the tendon of the Temporalis, and through the mandibular notch to the deep surface of the Masseter. In the substance of that muscle it anastomoses with the masseteric branches of the facial (external maxillary) and with branches of the transverse facial artery.

The **buccal artery** is small and runs obliquely forwards with the buccal nerve, between the Medial pterygoid and the insertion of the Temporal muscle, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial and infra-orbital arteries.

The Branches of the Third or Pterygopalatine Portion of the Maxillary Artery.

Posterior superior dental.	Pharyngeal.
Infra-orbital.	Artery of the pterygoid canal.
Greater palatine.	Sphenopalatine.

The **posterior superior dental artery** (posterior superior alveolar artery) is given off from the maxillary artery as that vessel enters the pterygopalatine fossa. Descending upon the posterior surface of the maxilla, it divides into branches, some of which enter the dental canals, and supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forwards on the alveolar process to supply the gums.

The **infra-orbital artery** often arises in conjunction with the posterior superior dental artery. It enters the orbital cavity through the posterior part of the inferior orbital fissure, runs along the infra-orbital groove and canal with the infra-orbital nerve, and emerges with the nerve on the face through the infra-orbital foramen, deep to the Levator labii superioris. Whilst in the canal, it gives off (*a*) *orbital* branches, which assist in supplying the Rectus inferior, the Obliquus inferior and the lacrimal sac, and (*b*) *anterior superior dental* branches, which descend through the anterior dental canals to supply the upper incisor and canine teeth, and the mucous membrane of the maxillary sinus. On the face, some branches ascend to the medial angle of the eye and the lacrimal sac, anastomosing with the terminal branches of the facial (external maxillary) artery; others run towards the nose, anastomosing with the dorsal nasal branch of the ophthalmic artery; and others descend between the Levator labii superioris and the Levator anguli oris (Caninus), and anastomose with the facial, transverse facial and buccal arteries.

The remaining branches of the maxillary artery arise from that portion of the artery which is contained in the pterygopalatine fossa.

The **greater palatine artery** (descending palatine artery) descends through the greater palatine (pterygopalatine) canal with the greater palatine nerve from the sphenopalatine ganglion, and gives off two or three *lesser palatine arteries*, which are transmitted through the lesser palatine canals to supply the soft palate and tonsil, and to anastomose with the ascending palatine artery. The greater palatine artery emerges on the oral surface of the palate through the greater palatine foramen, runs forwards, in a groove near the alveolar border of the hard palate, to the incisive canal; its terminal part passes upwards through this canal, and anastomoses with a branch of the sphenopalatine artery. Branches are distributed to the gums, the palatine glands and the mucous membrane of the roof of the mouth.

The **pharyngeal branch** is very small; it runs backwards through the pharyngeal canal with the pharyngeal branch of the sphenopalatine ganglion, and is distributed to the roof of the nose and pharynx, to the sphenoidal air-sinus and the pharyngotympanic tube.

The **artery of the pterygoid canal,** frequently a branch of the greater (descending) palatine artery, passes backwards along the pterygoid canal with the corresponding nerve. It is distributed to the upper part of the pharynx and to the pharyngotympanic tube, and sends into the tympanic cavity a small branch which anastomoses with the other tympanic arteries.

The pharyngeal branch is medial, and the artery of the pterygoid canal lateral, to the sphenopalatine ganglion, while the trunk of the maxillary artery is in front of it.

The **sphenopalatine artery** is really the terminal part of the maxillary artery; it passes through the sphenopalatine foramen into the cavity of the nose at the posterior part of the superior meatus. Here it gives off its *posterior lateral nasal* branches, which ramify over the conchæ and meatuses, anastomose with the ethmoidal arteries and the nasal branches of the greater palatine artery, and assist in supplying the frontal, maxillary, ethmoidal and sphenoidal sinuses. Crossing the anterior part of the under surface of the sphenoid bone, the sphenopalatine artery ends on the nasal septum as the *posterior septal* branches, which anastomose with the ethmoidal arteries; one branch descends in a groove on the vomer to the incisive canal and anastomoses with the terminal ascending branch of the greater palatine artery, and with the septal branch of the superior labial artery.

The Triangles of the Neck (fig. 709)

The side of the neck presents a somewhat quadrilateral outline, limited above by the base of the mandible, and a line drawn from the angle of the mandible to the mastoid process ; below, by the upper border of the clavicle ; in front, by the anterior median line of the neck ; behind, by the anterior margin of the Trapezius. This space is subdivided by the Sternomastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The area in front of this muscle is called the *anterior triangle* of the neck ; that behind it, the *posterior triangle.*

The Anterior Triangle of the Neck (figs. 709, 710)

The **anterior triangle** of the neck is bounded anteriorly by the anterior median line of the neck, posteriorly, by the anterior margin of the Sternomastoid; its base, directed upwards, is formed by the base of the mandible, and a line from the angle of the mandible to the mastoid process : its apex is below, at the sternum. This triangle may be subdivided into muscular, carotid, digastric and submental triangles.

The **muscular triangle** is bounded, in front, by the median line of the neck from the hyoid bone to the sternum ; behind and below, by the anterior margin of the Sternomastoid ; behind and above, by the superior belly of the Omohyoid. It is covered by the skin, superficial fascia, Platysma and deep fascia, ramifying in which are some of the branches of the anterior cutaneous cervical nerve (nervus cutaneus colli). The floor of the triangle is formed by the Sternohyoid, the Sternothyroid and the superior belly of the Omohyoid.

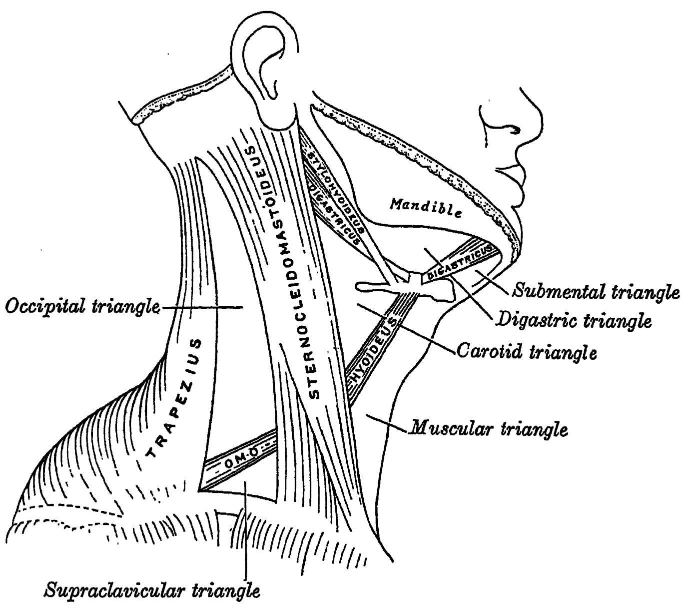
The **carotid triangle** is limited, behind, by the Sternomastoid ; in front and below, by the superior belly of the Omohyoid ; and above, by the Stylohyoid and the posterior belly of the Digastric. It is covered by the skin, superficial fascia, Platysma and deep fascia, ramifying in which are branches of the facial and the cutaneous cervical nerves. Its floor is formed by parts of the Thyrohyoid, Hyoglossus, and the Inferior and Middle constrictor muscles of the pharynx. When this space is dissected it is seen to contain the upper part of the common carotid artery, which divides opposite the superior border of the thyroid cartilage into the external and internal carotid arteries. These vessels are overlapped by the anterior margin of the Sternomastoid. The external and internal carotid arteries lie side by side, the external being the more anterior. The following branches of the external carotid artery are also encountered : the superior thyroid, running forwards and downwards ; the lingual, forwards with an upward loop ; the facial (external maxillary), forwards and upwards ; the occipital, upwards and backwards ; and the ascending pharyngeal, directly upwards on the medial side of the internal carotid. The veins encountered are : the internal jugular, which lies on the lateral side of the common and internal carotid arteries ; and veins corresponding to the above-mentioned branches of the external carotid artery—viz. the superior thyroid, the lingual, common facial, ascending pharyngeal, and sometimes the occipital—all of which end in the internal jugular vein. The hypoglossal nerve crosses both the internal and external carotid arteries, curving round the origin of the lower Sternomastoid branch of the occipital artery ; in this position it gives off its descending ramus, which runs down in the anterior wall of the carotid sheath. The vagus nerve lies within the sheath, between the common carotid artery and the internal jugular vein, and behind both ; behind the sheath is the sympathetic trunk. The accessory nerve appears at the lower border of the posterior belly of the Digastric, and descends for a short distance on the lateral side of the vessels before it pierces the deep surface of the Sternomastoid. On the medial side of the external carotid artery, below the hyoid bone, is the internal laryngeal nerve ; and, still more inferiorly, the external

laryngeal nerve. The upper portion of the larynx and lower portion of the pharynx are also found in the anterior part of this triangle.

It should be noted that many of the structures which have been included in the above description of the contents of the carotid triangle actually lie under cover of the Sternomastoid and can be seen only when the anterior border of the muscle is retracted.

The **digastric triangle** is bounded, above, by the base of the mandible and a line drawn from its angle to the mastoid process ; below, by the posterior belly of the Digastric and the Stylohyoid ; in front, by the anterior belly of the Digastric. It is covered by the skin, superficial fascia, Platysma and deep fascia, ramifying in which are branches of the facial and anterior cutaneous cervical nerves. Its floor is formed by the Mylohyoid and Hyoglossus muscles. It is divided into an anterior and a posterior part by the stylomandibular ligament. The anterior part contains the submandibular (submaxillary) gland, superficial

FIG. 709.—The triangles of the neck.



to which is the anterior facial vein, while deep to it is the facial artery, which crosses the lower border of the mandible at the anterior edge of the Masseter ; on the surface of the Mylohyoid are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle contains the lower part of the parotid gland ; the external carotid artery ascends between the gland and the Stylohyoid muscle and then in the substance of the gland ; in this triangle the external carotid artery lies superficial to the internal carotid and crosses lateral to it ; more deeply placed, and separated from the external carotid artery by the Styloglossus, the Stylopharnygeus and the glosso-pharnygeal nerve, are the internal carotid artery, the internal jugular vein and the vagus nerve.

The **submental triangle** is limited on each side by the anterior belly of the Digastric ; its apex is at the mandible ; its base is formed by the body of the hyoid bone, and its floor by the Mylohyoid muscles. It contains one or two lymph glands and some small veins ; the latter unite to form the anterior jugular vein.

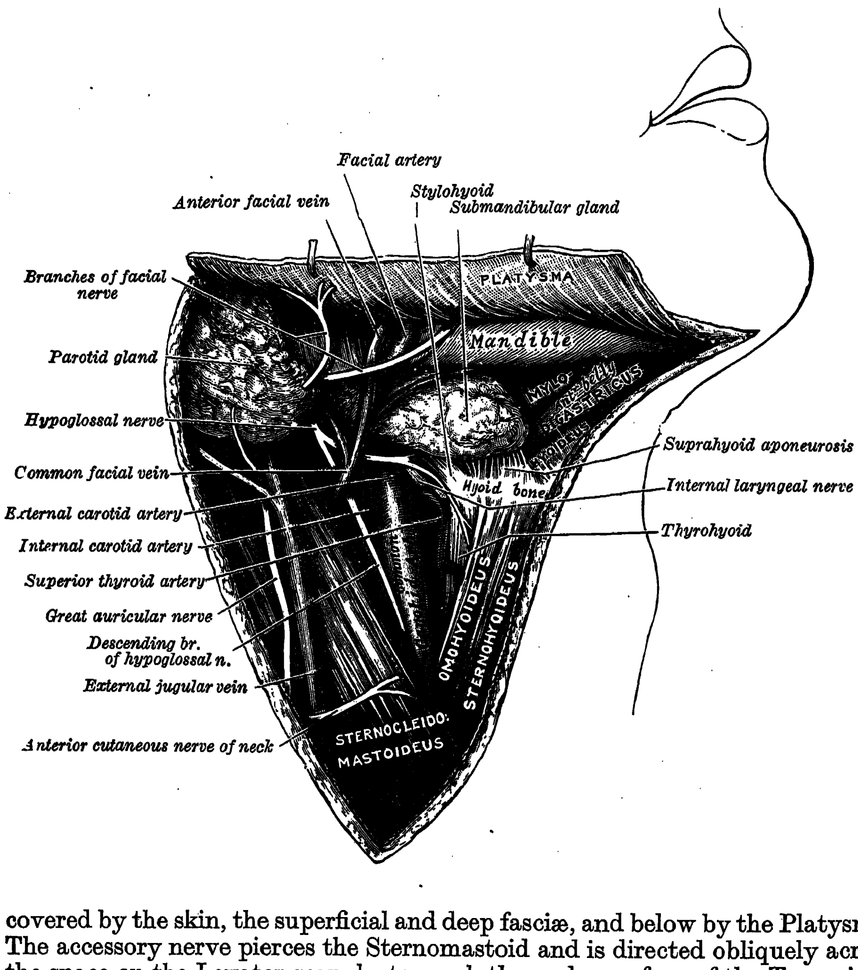
THE POSTERIOR TRIANGLE OF THE NECK (fig. 709)

The **posterior triangle** of the neck is bounded, in front, by the Sternomastoid ; behind, by the anterior margin of the Trapezius ; its base is formed by the

middle one-third of the clavicle; its apex is at the occipital bone between the attachments of the Sternomastoid and the Trapezius. The triangle is crossed, about 2·5 cm. above the clavicle, by the inferior belly of the Omohyoid, which divides the triangle into an occipital and a supraclavicular triangle.

The **occipital triangle**, the upper and larger division of the posterior triangle, is bounded in front by the Sternomastoid; behind, by the Trapezius; below, by the Omohyoid. Its floor is formed from above downwards by the Splenius capitis, Levator scapulæ, and the Scaleni medius et posterior; sometimes a small part of the Semispinalis capitis is seen at the apex of the triangle. It is

FIG. 710.—A drawing of a dissection of the carotid triangle of the neck.

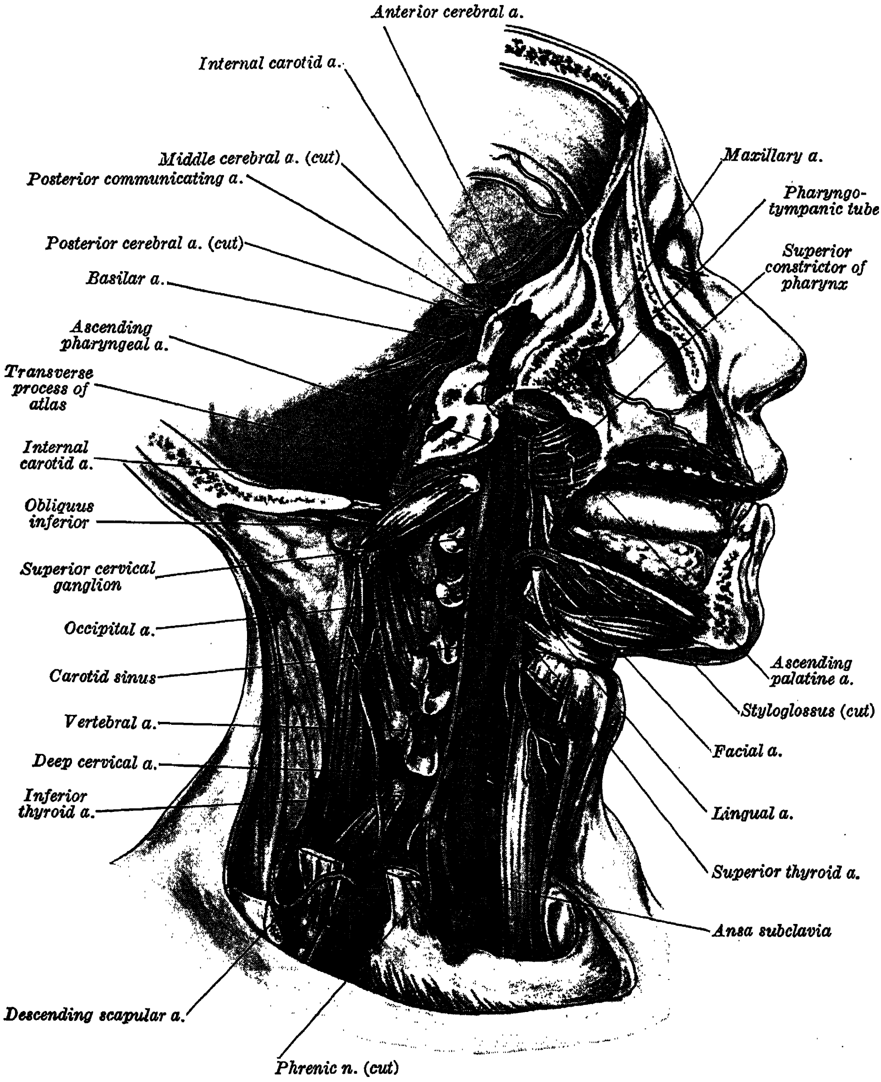


covered by the skin, the superficial and deep fasciæ, and below by the Platysma. The accessory nerve pierces the Sternomastoid and is directed obliquely across the space on the Levator scapulæ to reach the under surface of the Trapezius; the cutaneous and muscular branches of the cervical plexus appear at the posterior border of the Sternomastoid; below, the supraclavicular nerves and the transverse cervical vessels and the upper part of the brachial plexus cross the space. A chain of lymph glands is also found running along the posterior border of the Sternomastoid, from the mastoid process to the root of the neck.

The **supraclavicular triangle**, the lower and smaller division of the posterior triangle, is bounded, above, by the inferior belly of the Omohyoid; below, by the clavicle; its base is formed by the lower part of the posterior border of the Sternomastoid. Its floor consists of the first rib, the insertion of the Scalenus medius and the first digitation of the Serratus anterior. The size of this triangle varies with the extent of attachment of the clavicular portions of

the Sternomastoid and Trapezius, and also with the level at which the inferior belly of the Omohyoid crosses the neck; this level is lowered when the arm is raised, and raised when the arm is depressed. The triangle is covered by the skin, the superficial and deep fasciæ, and the Platysma, and crossed by the supraclavicular nerves. Just above the level of the clavicle, the third portion of the subclavian artery curves laterally and downwards from the lateral

FIG. 711.—A dissection to show the whole course of the right vertebral and internal carotid arteries.



margin of the Scalenus anterior, across the first rib, to the axilla. The subclavian vein lies behind the clavicle, and is not usually seen in this space; but in some cases it rises as high as the artery, and has even been seen to accompany that vessel behind the Scalenus anterior. The brachial plexus of nerves lies partly above and partly behind the artery, and in close contact with it. The suprascapular (transverse scapular) vessels pass transversely behind the clavicle; and running in the same direction, but at a slightly higher level, are the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of the Sternomastoid, to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which form a plexus in front of the third part of the subclavian artery, and occasionally it is joined

by a small vein which crosses the clavicle from the cephalic vein. The small nerve to the Subclavius also crosses this triangle about its middle, and some lymph glands are contained within the space.

The Internal Carotid Artery

The **internal carotid artery** (fig. 711) supplies the greater part of the cerebral hemisphere, the eye and its appendages, and sends branches to the forehead and nose. It begins at the bifurcation of the common carotid artery, where it usually presents a localised dilatation, termed the carotid sinus (p. 700). It ascends to the base of the skull, and enters the cranial cavity through the carotid canal of the temporal bone. It then runs forward through the cavernous sinus, lying in the carotid groove on the side of the body of the sphenoid bone, and ends below the anterior perforated substance of the brain by dividing into the anterior and the middle cerebral arteries.

The internal carotid artery may accordingly be divided into four portions : cervical, petrous, cavernous and cerebral.

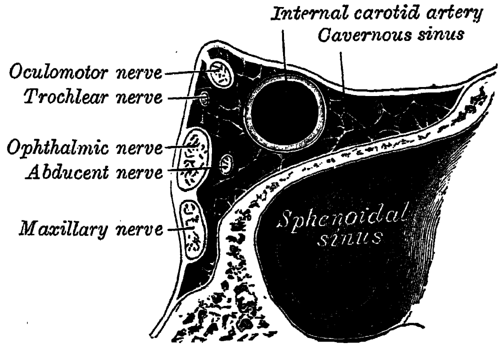
The cervical portion.—This portion of the internal carotid artery begins at the bifurcation of the common carotid artery, at the upper border of the thyroid cartilage, and ascends in front of the transverse processes of the upper three cervical vertebræ to the lower end of the carotid canal in the petrous portion of the temporal bone. It is comparatively superficial at its commencement, where it is contained in the carotid triangle, but after passing deep to the posterior belly of the Digastric muscle it lies on a much deeper plane. It presents important relations with the *internal jugular vein*, the *vagus nerve* and the *external carotid artery*. Except at the base of the skull, the internal jugular vein and the vagus nerve lie on its lateral side ; the external carotid artery is at first anterior and medial to the internal carotid but on leaving the carotid triangle it curves backwards so as to lie superficial to the vessel.

The cervical portion of the internal carotid artery has many additional relations. *Posteriorly*, it rests on the Longus capitis muscle, but the superior cervical sympathetic ganglion intervenes and the superior laryngeal nerve crosses obliquely behind the vessel. *Medially*, the artery is related to the wall of the pharynx (from which it is separated by an interval containing some fat, connective tissue and the pharyngeal veins), the ascending pharyngeal artery and the superior laryngeal nerve. *Anterolaterally*, the internal carotid artery is covered throughout by the Sternomastoid muscle. In addition, *below the Digastric*, the hypoglossal nerve and its descending branch, the lingual and common facial veins are superficial to the artery. *At the level of the Digastric* the vessel is crossed by the Stylohyoid muscle and by the occipital and posterior auricular arteries. *Above the Digastric*, it is separated from the external carotid artery by the styloid process, the Styloglossus and Stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus and the deeper part of the parotid gland. At the base of the skull the glossopharyngeal, vagus, accessory and hypoglossal nerves are between the internal carotid artery and the internal jugular vein, which here lies posterior to the artery.

The petrous portion.—When the internal carotid artery enters the carotid canal in the petrous portion of the temporal bone, it first ascends, and then curves forwards and medially. As it leaves the canal to enter the cranial cavity, it runs upwards and medially across the upper part of the foramen lacerum and above the fibrocartilage which it contains. Finally, it passes between the lingula and petrosal process of the sphenoid bone. The artery lies at first in front of the cochlea and tympanic cavity ; it is separated from the latter cavity and from the pharyngotympanic tube (auditory tube) by a thin, bony lamella, which is cribriform in the young subject, and often partly absorbed in old age. Farther forwards it is separated from the trigeminal ganglion by a thin plate of bone, which forms the floor of the trigeminal impression and the roof of the horizontal portion of the carotid canal ; frequently this bony plate is more or less deficient. The artery is surrounded by a number of small veins and by the carotid plexus of nerves, which is derived from the internal carotid branch of the superior cervical ganglion of the sympathetic trunk.

The **cavernous portion** of the internal carotid artery is situated in the cavernous sinus, but is covered by the lining endothelium of the sinus. It at first ascends towards the posterior clinoid process, then passes forwards on the side of the body of the sphenoid, and again curves upwards on the medial side of the anterior clinoid process, and perforates the dura mater forming the roof of the sinus; occasionally the anterior and middle clinoid processes form a bony ring round the artery. The cavernous portion of the artery is surrounded by a sympathetic plexus, and the oculomotor, trochlear, ophthalmic and abducent nerves (fig. 712) are on its lateral side.

Fig. 712.—An oblique section through the left cavernous sinus.



The **cerebral portion.**—After perforating the dura mater at the medial side of the anterior clinoid process, the internal carotid artery turns backwards below the optic nerves, and then passes between the optic and oculomotor nerves to the anterior perforated substance at the medial end of the lateral cerebral sulcus, where it divides into the anterior and middle cerebral arteries.

Peculiarities.—The length of the internal carotid artery varies with the length of the neck, and with the point of bifurcation of the common carotid. It arises occasionally from the arch of the aorta, and then has been found on the medial side of the external carotid, as far as the larynx, where it crossed behind the latter vessel to reach its usual position. The course of the cervical part of the artery, instead of being straight, may be very tortuous. When this occurs the vessel approaches nearer to the pharynx than usual, and may lie directly lateral to the tonsil.* A few instances are recorded in which it was absent; in one of these the common carotid artery passed up the neck, and gave off the branches normally arising from the external carotid; the cranial portion of the internal carotid artery was replaced by two branches of the maxillary artery, which entered the skull through the foramen rotundum and foramen ovale, and joined to form a single vessel.

Applied Anatomy.—Obstruction of the internal carotid by embolism or thrombosis may give rise to symptoms of cerebral anæmia and softening if the collateral circulation is ill-developed. The patient suffers from giddiness, with failure of the mental powers; and convulsions, coma, or hemiplegia on the opposite side of the body, may be observed.

Branches.—No branches arise from the cervical portion of the internal carotid artery. Those from the other portions are:

From the petrous portion	1. Caroticotympanic. 2. Pterygoid.
From the cavernous portion	3. Cavernous. 4. Hypophyseal. 5. Meningeal. 6. Ophthalmic.
From the cerebral portion	7. Anterior cerebral. 8. Middle cerebral. 9. Posterior communicating. 10. Anterior choroid.

1. The **caroticotympanic branch** is small; it enters the tympanic cavity through a foramen in the wall of the carotid canal, and anastomoses with the anterior tympanic branch of the maxillary artery, and with the stylomastoid artery.

2. A small, inconstant **pterygoid branch** passes into the pterygoid canal with the nerve of that canal, and anastomoses with a branch of the greater palatine artery.

* Consult an article by John Cairney, *Journal of Anatomy*, vol. lix. page 87.

3. The **cavernous branches** are numerous small vessels which supply the trigeminal ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of them anastomose with branches of the middle meningeal artery.

4. The **hypophyseal branches** are one or two minute vessels which supply the hypophysis cerebri.

5. The **meningeal branch** is a minute branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior cranial fossa ; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

6. The **ophthalmic artery** (fig. 713) arises from the internal carotid artery, as that vessel emerges from the cavernous sinus on the medial side of the anterior clinoid process ; it enters the orbital cavity through the optic foramen, below and lateral to the optic nerve. In the orbital cavity it runs for a short distance lateral to the optic nerve and medial to the oculomotor and abducent nerves, the ciliary ganglion and the Rectus lateralis. It next crosses obliquely above the optic nerve and below the Rectus superior to reach the medial wall of the orbit. It then runs forwards between the Obliquus superior and the Rectus medialis, and, at the medial end of the upper eyelid, divides into two branches, named *supratrochlear* (frontal) and *dorsal nasal*. As the artery crosses the optic nerve it is accompanied by the nasociliary nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris ; the terminal part of the artery is accompanied by the infratrochlear nerve. In about 15 per cent. of subjects the ophthalmic artery crosses below the optic nerve.

The branches of the ophthalmic artery are :

Central artery of the retina.	Long posterior ciliary.	Meningeal.
Lacrimal.	Anterior ciliary.	Medial palpebral.
Muscular.	Supra-orbital.	Supratrochlear.
Short posterior ciliary.	Posterior ethmoidal.	Dorsal nasal.
	Anterior ethmoidal.	

The **central artery of the retina**, the first and one of the smallest branches of the ophthalmic artery, arises from that vessel whilst it lies below the optic nerve. It runs for a short distance within the dural sheath of the optic nerve, and about 1·25 cm. behind the eyeball it pierces the inferomedial surface of the nerve, and runs forward in the centre of the nerve to the retina. Its mode of distribution is described with the anatomy of the eye (p. 1176).

The **lacrimal artery** arises from the ophthalmic artery close to the optic foramen, and is one of its largest branches ; sometimes it is given off before the ophthalmic artery enters the orbit ; occasionally its place is taken by a branch of the middle meningeal artery (p. 713). It accompanies the lacrimal nerve along the upper border of the Rectus lateralis, and supplies the lacrimal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva : of those supplying the eyelids, two are of considerable size and are named the **lateral palpebral arteries** ; they run medially in the upper and lower lids respectively and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two **zygomatic branches**, one of which passes through the zygomaticotemporal foramen to the temporal fossa, and anastomoses with the deep temporal arteries ; another appears on the cheek through the zygomaticofacial foramen and anastomoses with the transverse facial artery. A **recurrent meningeal branch** passes backwards through the lateral part of the superior orbital fissure and anastomoses with a branch of the middle meningeal artery.

The **muscular branches** frequently spring from a common trunk. They consist of a superior and an inferior group, and most of them accompany the branches of the oculomotor nerve. The superior group supplies the Levator palpebræ superioris, Recti superior et lateralis, and Obliquus superior. The inferior group, more constantly present, is distributed to the Recti medialis et inferior, and the Obliquus inferior. This group gives off most of the anterior ciliary arteries. Additional muscular branches are derived from the lacrimal and supra-orbital arteries, or from the trunk of the ophthalmic artery.

The **ciliary arteries** are divisible into three groups, long and short posterior, and anterior.

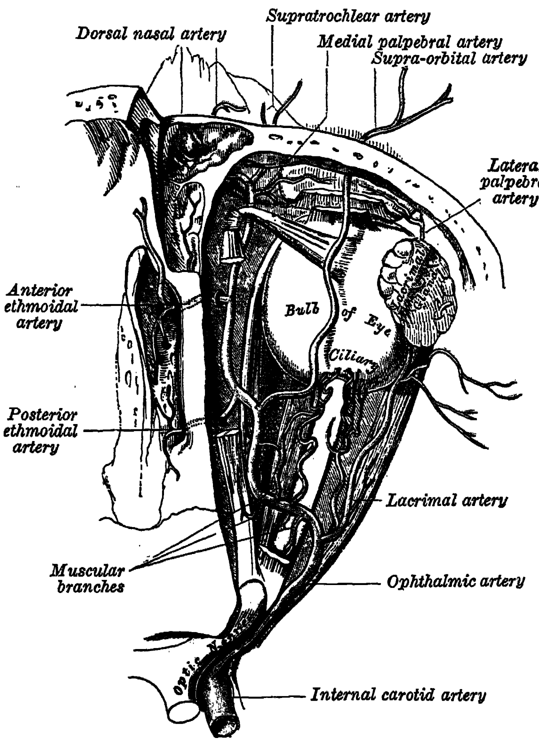
The **long posterior ciliary arteries**, two in number, pierce the posterior part of the sclera a short distance from the entrance of the optic nerve, and run forwards, one on each side of the eyeball, between the sclera and choroid, to the ciliary muscle, where each divides into a superior and an inferior branch ; these form, together with the anterior ciliary arteries,

a *greater arterial circle*, around the circumference of the iris, from which numerous converging branches run in the substance of the iris to its pupillary margin, where they form a *lesser arterial circle*.

The **short posterior ciliary arteries**, about seven in number, pass forwards around the optic nerve to the posterior part of the eyeball, and, after dividing into from fifteen to twenty branches, pierce the sclera around the entrance of the nerve, and supply the choroid coat and the ciliary processes. At the entrance of the optic nerve they anastomose with twigs of the central artery of the retina, and at the ora serrata with branches of the long posterior and anterior ciliary arteries.

The **anterior ciliary arteries** are derived from the muscular branches of the ophthalmic artery; they run to the front of the eyeball in company with the tendons of the Recti, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the sclerocorneal junction and end in the greater arterial circle.

FIG. 713.—The ophthalmic artery and its branches.



The **supra-orbital artery** leaves the ophthalmic artery as that vessel crosses the optic nerve. It ascends on the medial borders of the Rectus superior and Levator palpebræ superioris, and meeting the supra-orbital nerve accompanies it between the periosteum and Levator palpebræ superioris to the supra-orbital foramen; passing through this foramen it divides into a superficial and a deep branch, which supply the skin, muscles and pericranium of the forehead, anastomosing with the supratrochlear (frontal) artery, the anterior branch of the superficial temporal artery, and the artery of the opposite side. In the orbit it supplies twigs to the Rectus superior and the Levator palpebræ, and sends a branch across the pulley of the Obliquus superior, to the parts at the medial angle of the eye. At the supra-orbital foramen it frequently sends a branch to the diploë of the frontal bone.

The **posterior ethmoidal artery** runs through the posterior ethmoidal canal, supplies the posterior ethmoidal sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches which descend into the nasal cavity through the cribriform plate of the ethmoid bone, to anastomose with branches of the sphenopalatine artery.

The **anterior ethmoidal artery** accompanies the anterior ethmoidal nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal and frontal sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches; the latter descend into the nasal cavity with the anterior ethmoidal nerve and, running along the groove on the inner surface of the nasal bone, supply twigs to the lateral wall and septum of the nose, and a terminal branch which appears on the dorsum of the nose between the nasal bone and the upper nasal cartilage.

The **meningeal branch** is a small branch which passes backwards through the superior orbital fissure to the middle cranial fossa, and anastomoses with the middle and accessory meningeal arteries.

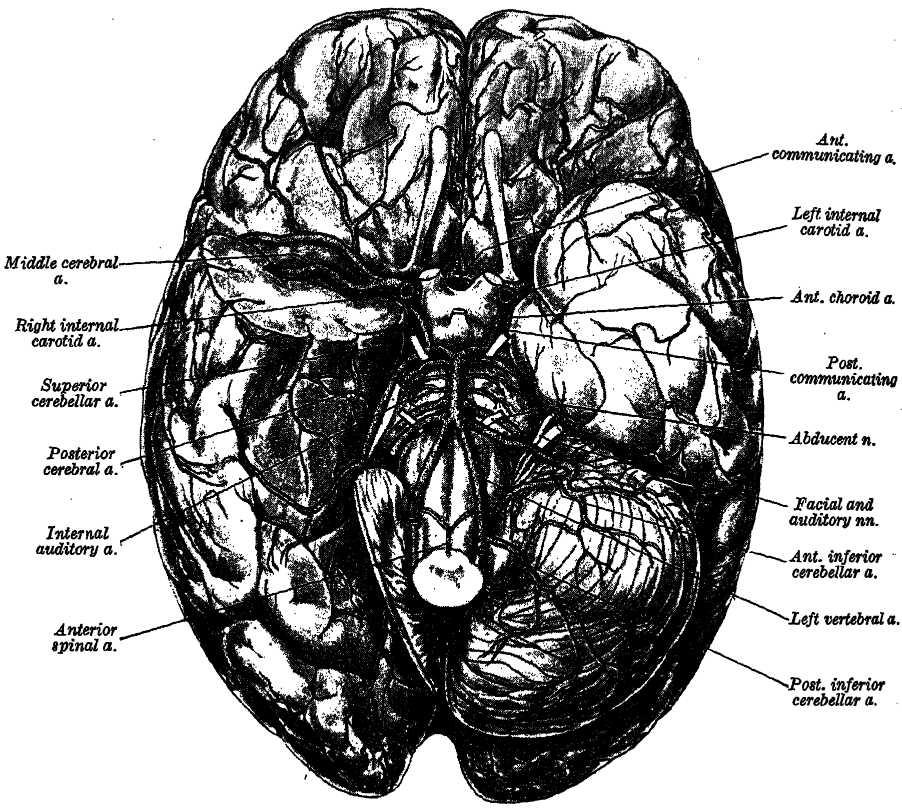
The **medial palpebral arteries**, two in number, superior and inferior, arise from the ophthalmic artery below the pulley of the Obliquus superior. They descend behind the lacrimal sac, and enter the eyelids, where each divides into two branches which course laterally along the edges of the tarsi, thus forming two arches (a superior and an inferior) in each eyelid. The superior palpebral artery anastomoses with the supra-orbital artery, and, at the lateral part of the eyelid, with the zygomatic branch of the superficial temporal artery, and with the upper of the two lateral palpebral branches of the lacrimal artery. The inferior palpebral artery anastomoses at the lateral part of the eyelid with the lower

of the two lateral palpebral branches of the lacrimal artery and with the transverse facial artery, and at the medial part of the eyelid with a twig from the facial (external maxillary) artery; from this last anastomosis a branch passes to the nasolacrimal duct, ramifying in its mucous membrane, as far as the inferior meatus of the nasal cavity.

The **supratrochlear artery** (frontal artery), one of the terminal branches of the ophthalmic artery, leaves the orbital opening at its upper medial angle, with the supratrochlear nerve, and, ascending on the forehead, supplies the skin, muscles and pericranium, anastomosing with the supraorbital artery and with the artery of the opposite side.

The **dorsal nasal artery**, the other terminal branch of the ophthalmic artery, emerges from the orbit between the trochlea of the Obliquus superior and the medial palpebral

FIG. 714.—The arteries at the base of the brain.



The right temporal pole and most of the right hemisphere of the cerebellum have been removed.

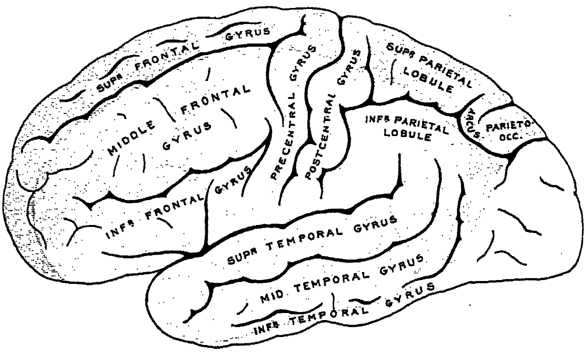
ligament, and, after giving a twig to the upper part of the lacrimal sac, divides into two branches, one of which crosses the root of the nose, and anastomoses with the terminal part of the facial artery; the other runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the facial artery.

7. The **anterior cerebral artery** (figs. 714, 715, 716) arises from the internal carotid artery, at the medial end of the lateral cerebral sulcus. It passes forwards and medially above the optic nerve, to the commencement of the longitudinal fissure. Here it comes into close relationship with the opposite artery and is joined to it by a short transverse trunk (sometimes duplicated) named the anterior communicating artery. From this point, the two anterior cerebral arteries run side by side in the longitudinal cerebral fissure, curving round the genu of the corpus callosum, and running backwards along the upper

surface of this structure to its posterior extremity, where they end by anastomosing with the posterior cerebral arteries.

The *anterior communicating artery* has an average length of about 4 mm. and connects the two anterior cerebral arteries across the commencement of the

FIG. 715.—The lateral surface of the cerebral hemisphere, showing the areas supplied by the cerebral arteries. In this and the next figure the areas supplied by the anterior cerebral artery are coloured *blue*; those by the middle cerebral artery, *pink*; and those by the posterior cerebral artery, *yellow*.



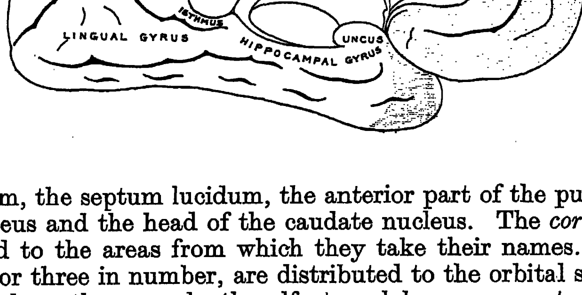
longitudinal fissure; in about 7 per cent. of subjects it is double. It gives off a few anteromedial central branches.

In its course the anterior cerebral artery gives off the following branches:

Central.	Cortical { Orbital. Frontal. Parietal.

The *central branches* are a group of small arteries which arise from the commencement of the anterior cerebral artery; they pierce the anterior perforated substance and lamina terminalis, and supply the rostrum of the

FIG. 716.—The medial surface of the cerebral hemisphere, showing the areas supplied by the cerebral arteries (see description of fig. 715).



corpus callosum, the septum lucidum, the anterior part of the putamen of the lentiform nucleus and the head of the caudate nucleus. The *cortical branches* are distributed to the areas from which they take their names. The *orbital branches*, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus and medial orbital gyrus. The *frontal branches* supply the corpus callosum, the cingulate gyrus, the medial frontal gyrus and the paracentral lobule, and send twigs over the superomedial border of the cerebral hemisphere to the superior and middle frontal gyri and the upper part of the precentral gyrus. The *parietal branches* supply the precuneus and adjacent lateral surface of the hemisphere.

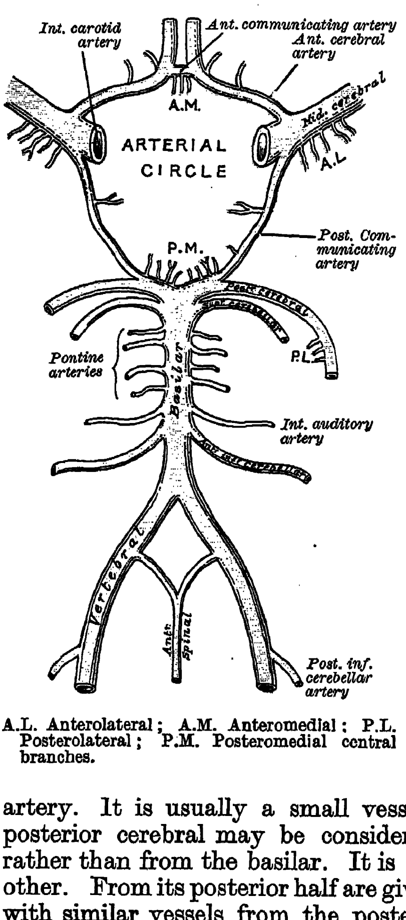
8. The **middle cerebral artery** (figs. 714, 715), the largest branch of the internal carotid artery, runs at first laterally in the lateral cerebral sulcus and then backwards and upwards on the surface of the insula, where it divides into branches which are distributed to the insula and to the lateral surface of the cerebral hemisphere.

The branches of the middle cerebral artery are the

Central.	Cortical { Orbital. Frontal. Parietal. Temporal.

The *central branches* comprise a group of small arteries which arise from the commencement of the middle cerebral artery and enter the substance of the brain through the anterior perforated substance.* They are arranged in two sets: one, termed the *medial striate*, ascends through the lentiform nucleus, and supplies it, the caudate nucleus, and the internal capsule; the other, termed the *lateral striate*, ascends over the lower part of the lateral aspect of the lentiform nucleus and then, bending medially, traverses the nucleus and the internal capsule to reach and supply the caudate nucleus. One artery of this group is larger than the rest, and of special importance as being the artery in the brain most frequently ruptured; it has been termed by Charcot the '*artery of cerebral hæmorrhage*.' Of the *cortical branches*, the *orbital branches* supply the inferior frontal gyrus and the lateral part of the orbital surface of the frontal lobe. The *frontal* supplies the precentral and the middle frontal gyrus. The *parietal branches*, two in number, are distributed to the postcentral gyrus, the lower part of the superior parietal lobule, and the whole of the inferior parietal lobule. The *temporal branches*, two or three in number, are distributed to the lateral surface of the temporal lobe.

FIG. 717.—A diagram of the arteries at the base of the brain.



A.L. Anterolateral; A.M. Anteromedial; P.L. Posterolateral; P.M. Posteromedial central branches.

9. The **posterior communicating artery** (figs. 714, 717) runs backwards from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral, a branch of the basilar artery. It is usually a small vessel, but is occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From its posterior half are given off several small *central branches*, which, with similar vessels from the posterior cerebral artery, pierce the posterior perforated substance and supply the medial surface of the thalamus and the walls of the third ventricle.

10. The **anterior choroid artery**,† a small but constant branch, arises from the internal carotid, near the posterior communicating artery. Passing backwards above the medial part of the uncus, it crosses the optic tract and comes into

* Consult an article on "The Basal Arteries of the Forebrain," by Joseph L. Shellshear, *Journal of Anatomy*, vol. lv. 1920.

† Consult articles by A. A. Abbie on "The Blood-Supply of the Lateral Geniculate Body, with a Note on the Morphology of the Choroidal Arteries," *Journal of Anatomy*, vol. lxvii. 1933, and "The Morphology of the Forebrain Arteries," *Journal of Anatomy*, vol. lxviii. 1934.

relation with the basis pedunculi, to which it gives several minute branches. It then turns laterally, again crossing the optic tract, and comes into relation with the lateral aspect of the lateral geniculate body, to which it supplies a number of branches. Finally it enters the inferior horn of the lateral ventricle through the choroidal fissure and terminates in the choroid plexus. In addition, it supplies branches to the globus pallidus, the posterior limb of the internal capsule, the optic radiation, the optic tract, the hippocampus and the fimbria.

The circulus arteriosus.—A considerable part of the brain is supplied by the two vertebral arteries (p. 732), and a remarkable anastomosis, named the *circulus arteriosus*, exists between these vessels and the two internal carotid arteries. This circle is situated in the cisterna interpeduncularis at the base of the brain, and encloses the optic chiasma and the structures in the interpeduncular fossa (p. 971). It is formed as follows : in front, the two anterior cerebral arteries are joined to each other by the anterior communicating artery ; behind, the basilar artery (formed by the union of the vertebral arteries) divides into the two posterior cerebral arteries, each of which is joined to the internal carotid artery of the same side by the posterior communicating artery (fig. 717).

THE ARTERIES OF THE BRAIN

The mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the pathological lesions which may occur in this part of the nervous system.

The arteries which supply the brain give origin to two systems of vessels. One of these is named the **central system**, and its vessels supply the thalami and corpora striata ; the other is the **cortical system**, and its vessels ramify in the pia mater and supply the cortex and subjacent brain-substance. These two systems are independent of each other and do not communicate at any point of their peripheral distribution, and there is between the parts supplied by them a borderland of diminished nutritive activity where, it is said, softening of the brain is especially liable to occur.

The central system.—All the vessels of this system are given off from the circulus arteriosus, or from the vessels close to it. They form six principal groups: (I) an **anteromedial group**, derived from the anterior cerebral and anterior communicating arteries ; (II) a **posteromedial group**, from the posterior cerebral and posterior communicating arteries ; (III and IV) right and left **anterolateral groups**, from the middle cerebral arteries ; and (V and VI) right and left **posterolateral groups**, from the posterior cerebral arteries after they have wound round the cerebral peduncles. The vessels of the central system are larger than those of the cortical system, and are known as end arteries or terminal arteries—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that, through any one vessel only a limited area of the thalamus or corpus striatum can be injected.

The cortical system.—The vessels of this system are the terminal branches of the anterior, middle and posterior cerebral arteries. They divide in the substance of the pia mater, give off branches which penetrate the brain-cortex prependicularly, and are divisible into two classes, long and short. The **long** or **medullary arteries** pass through the grey matter and penetrate the subjacent white matter to the depth of 3 or 4 cm., without intercommunicating, and thus constitute so many independent small systems. The **short vessels** are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the grey matter, the outer and inner zones being sparingly supplied with blood. The vessels of the cortical system are not so strictly ' terminal ' as those of the central system, but they approach this type very closely, for, although neighbouring vessels anastomose with one another very freely on the surface of the brain, they become end arteries as soon as they pierce its substance.

THE ARTERIES OF THE UPPER LIMB

The artery which supplies the upper limb runs as a single trunk as far as the elbow ; but it is differently named, according to the regions it traverses. From its origin to the outer border of the first rib it is termed *subclavian* ; from the outer border of the first rib to the lower border of the tendon of the Teres major it is named *axillary* ; and from the lower border of the Teres major to a point opposite the neck of the radius it is called *brachial*.

The Subclavian Arteries

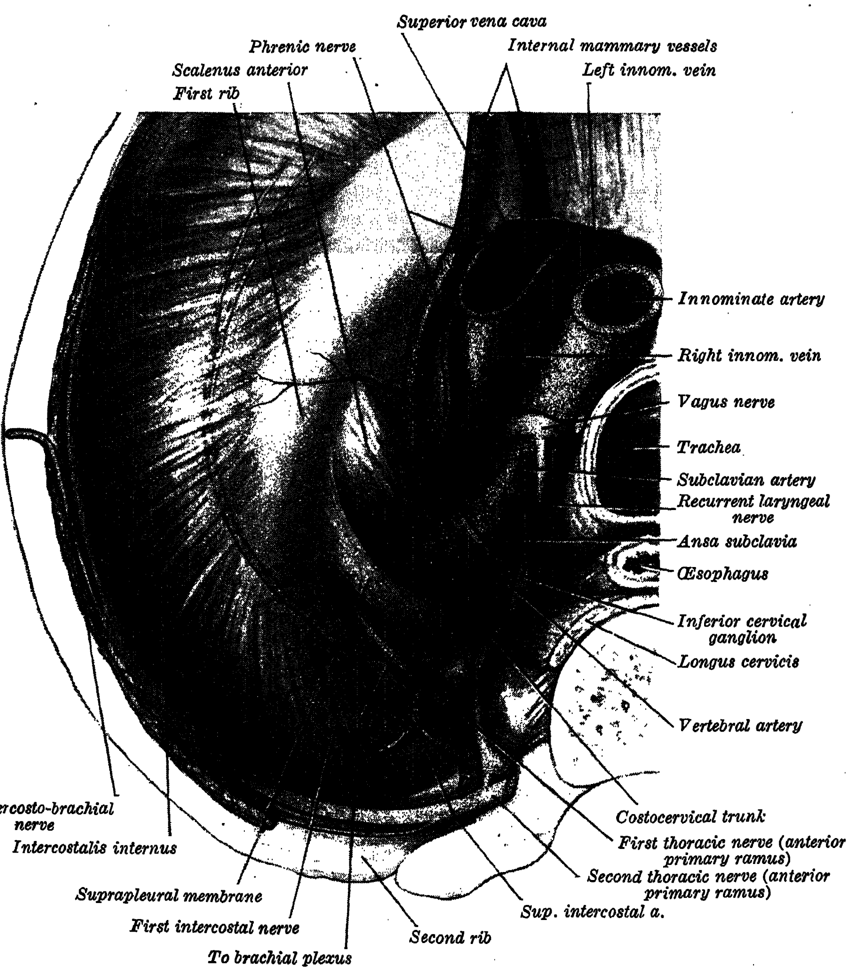
The right subclavian artery arises from the innominate artery; the left, from the arch of the aorta. The vessels, therefore, in the first parts of their courses, differ in their length, direction and relations.

To facilitate description, each subclavian artery is divided into three parts; the first extends from the origin of the vessel to the medial border of the Scalenus anterior, the second lies behind this muscle, and the third runs from the lateral margin of the muscle across the first rib to its outer border, where it becomes the axillary artery; each artery arches over the cervical portion of the pleura. The first portions of the two vessels differ from one another in their origin, course and relations, and therefore require separate descriptions. The relations of the second and third parts are almost alike on the two sides of the neck.

The First Part of the Right Subclavian Artery (figs. 718, 719)

The **first part** of the **right subclavian artery** arises from the innominate artery, behind the upper part of the right sternoclavicular joint, and passes

Fig. 718.—Structures in relation with the cervical pleura of the right side. Seen from below.



upwards and laterally to the medial margin of the Scalenus anterior. It ascends, on an average, about 2 cm. above the clavicle, but the height it reaches varies considerably in different cases.

Relations.—*In front*, the artery is covered by the skin, superficial fascia, Platysma, medial supraclavicular nerves, deep fascia, the clavicular origin of the Sternomastoid, the Sternohyoid and Sternothyroid. At its origin it is placed behind the origin of the right common carotid artery ; more laterally it is crossed by the vagus nerve and the cardiac branches of the vagus and sympathetic, by the internal jugular and vertebral veins ; the subclavian loop of the sympathetic trunk encircles the vessel. The anterior jugular vein is directed laterally in front of the artery, but is separated from it by the Sternohyoid and Sternothyroid. *Below and behind*, the artery is related to the pleura and the apex of the lung, but it is separated from them by the suprapleural membrane (p. 1247), the ansa subclavia, a small accessory vertebral vein (p. 812), and the right recurrent laryngeal nerve, which winds round the lower and posterior part of the vessel ; *behind*, the artery is related to the sympathetic trunk, the Longus cervicis (Longus colli), the right recurrent laryngeal nerve and the first thoracic vertebra.

THE FIRST PART OF THE LEFT SUBCLAVIAN ARTERY (figs. 697, 700, 703)

The **first part** of the **left subclavian artery** arises from the arch of the aorta, behind the left common carotid, usually at the level of the disc between the third and fourth thoracic vertebræ ; it ascends to the root of the neck and then arches laterally to the medial border of the Scalenus anterior.

Relations. (1) **Within the thorax.**—It is related, *in front*, to the left common carotid artery and the commencement of the left innominate vein, from which it is separated by the left vagus, cardiac and phrenic nerves. Superficial to these structures, the anterior margin of the left lung and pleura and the Sternothyroid and Sternohyoid muscles intervene between the vessel and the upper, left portion of the manubrium sterni. *Behind*, it lies, successively, on the left edge of the œsophagus, the thoracic duct and the Longus cervicis (Longus colli), and it is in contact posteriorly, on its lateral aspect, with the left lung and pleura. *Medially* it is related, successively, to the trachea, the left recurrent laryngeal nerve, the œsophagus and the thoracic duct. *Laterally* the artery grooves the mediastinal surface of the left lung and pleura, and these structures, as already indicated, tend to encroach on its anterior and posterior aspects.

(2) **Within the neck.**—Near the medial border of the Scalenus anterior the artery is crossed *anteriorly* by the left phrenic nerve and the terminal part of the thoracic duct. Otherwise the relations are the same as those previously described for the first part of the right subclavian artery. *Posteriorly* and *inferiorly*, the relations of the two vessels are identical, but the left recurrent laryngeal nerve, which was related to the left subclavian artery in the thorax, is not related to its cervical portion.

THE SECOND AND THIRD PARTS OF THE SUBCLAVIAN ARTERY (figs. 719, 720)

The **second portion** of the subclavian artery lies behind the Scalenus anterior ; it is very short, and forms the highest part of the arch described by the vessel.

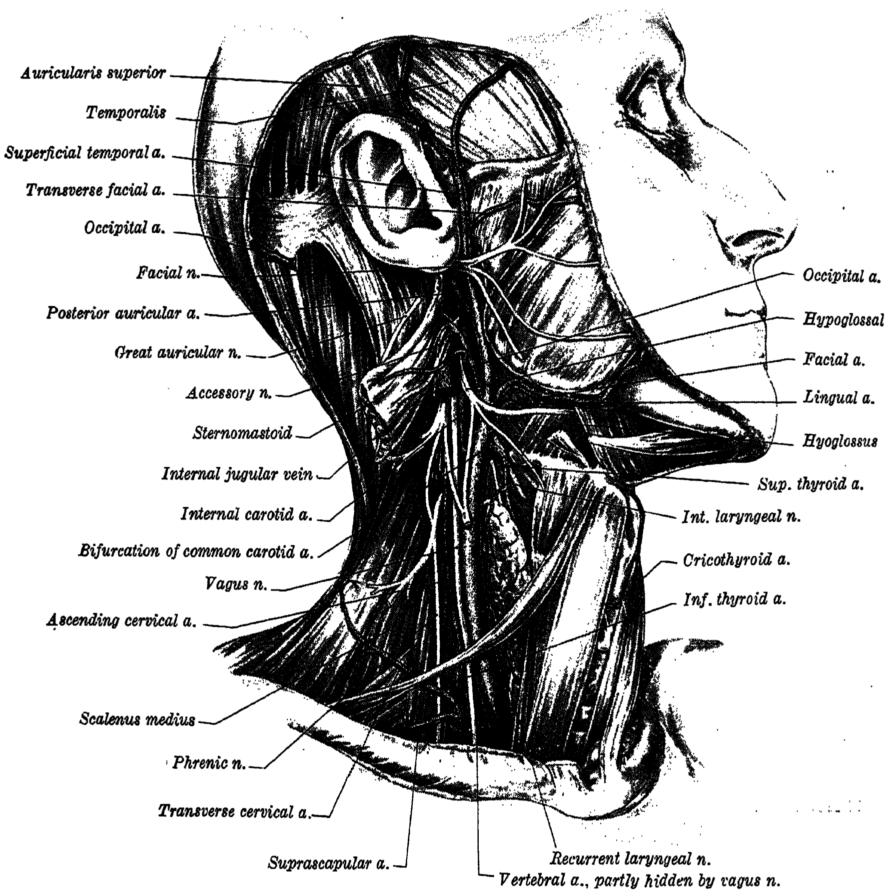
Relations.—*In front* of it are the skin, superficial fascia, Platysma, deep cervical fascia, Sternomastoid and Scalenus anterior. On the right side of the neck the phrenic nerve is separated from the second part of the artery by the Scalenus anterior, while on the left side it crosses the first part of the artery close to the medial edge of the muscle. *Behind* and *below* the vessel are the pleura and lung ; *above*, the upper and middle trunks of the brachial plexus of nerves. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anterior (fig. 720).

The **third portion** of the subclavian artery runs downwards and laterally from the lateral margin of the Scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. This is the most superficial portion of the vessel, and is contained in the supraclavicular triangle (p. 718).

Relations.—*In front* of it are the skin, the superficial fascia, the Platysma, the supraclavicular nerves and the deep cervical fascia. The external jugular vein crosses its medial part and receives the suprascapular (transverse scapular), transverse cervical and anterior jugular veins, which frequently form a plexus

in front of the artery. The nerve to the Subclavius descends behind the veins and in front of the artery. The terminal part of the artery lies behind the clavicle and the Subclavius, and is crossed by the suprascapular vessels. The subclavian vein is in front of, and at a slightly lower level than, the artery. The lower trunk of the brachial plexus lies *behind* the artery and intervenes between it and the Scalenus medius. *Above*, and to its *lateral side*, are the upper and middle trunks of the brachial plexus, and the inferior belly of the Omohyoid. *Below*, it rests on the upper surface of the first rib.

FIG. 719.—A dissection of the right side of the neck showing the carotid and subclavian arteries and their branches.



The parotid and submandibular glands and the posterior belly of the digastric have been removed together with the lower part of the internal jugular vein, the upper part of the stylohyoid and the lower part of the sternomastoid muscle. The upper part of the sternomastoid muscle has been retracted to expose the structures under cover of it.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The right subclavian may arise from the innominate above or below the level of the sternoclavicular joint. It may arise as a separate trunk from the arch of the aorta, and may then be either its first or last branch. When it is the first branch, it occupies the ordinary position of the innominate artery; and when the last it arises from the left extremity of the arch, and ascends obliquely towards the right side, behind the trachea, œsophagus, and right carotid to the upper border of the first rib, whence it follows its ordinary course. In these cases, the proximal part of the artery represents a persistent part of the right dorsal aorta, and the right fourth aortic arch takes no part in its formation (p. 148). Sometimes, when it arises as the last branch of the arch of the aorta, the right subclavian artery passes between the trachea and the œsophagus.

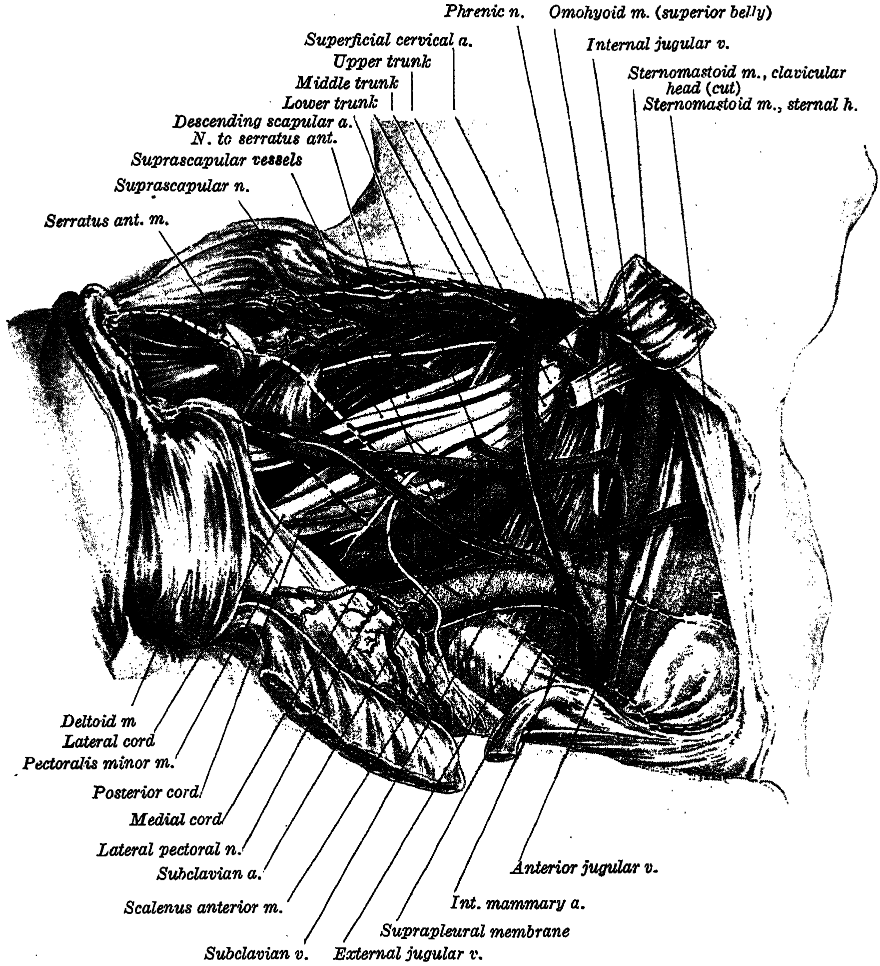
Occasionally the subclavian artery perforates the Scalenus anterior; very rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery

behind the Scalenus anterior. The artery may ascend as high as 4 cm. above the clavicle or may only reach the level of the upper border of the bone.

The left subclavian is occasionally joined at its origin with the left carotid. It is more deeply placed than the right subclavian in the first part of its course, and, as a rule, does not reach quite as high a level in the neck.

The posterior border of the Sternomastoid corresponds closely to the lateral border of the Scalenus anterior, so that the third portion of the artery, the part most accessible for operation, lies immediately lateral to the posterior border of the Sternomastoid.

FIG. 720.—The relations of the third part of the right subclavian artery.



N.B.—The clavicle has been removed but is shown as a dotted outline.

Applied Anatomy.—An aneurysm may form on any part of the subclavian artery, except the intrathoracic portion of the left vessel, which is said never to be the seat of aneurysm. The most common site is the third portion (especially on the right side). In this situation it may cause pressure on the brachial plexus, producing pain and numbness in the arm and fingers, with loss of power or paralysis of the muscles of these parts. Œdema of the arm may result from pressure on the subclavian vein. The external jugular vein may become distended and varicose. The collateral circulation is so good that blocking of the subclavian artery by embolism or thrombosis often fails to give rise to any striking signs or symptoms, beyond occasional pains in the neck and shoulder and some degree of weakness and wasting in the muscles of the arm.

Compression of the subclavian artery may be required to control hæmorrhage, and can be applied effectually in one situation only, viz. where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed and pressure exercised downwards, backwards, and medially in the angle formed by the posterior border of the Sternomastoid with the upper border of the clavicle.

Ligature of the subclavian artery may be required in cases of wounds, or of aneurysm in the axilla, or in cases of aneurysm on the cardiac side of the point of ligature.

The third part of the artery is that which is most favourable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurysmal tumour in the axilla, the artery lies at a great depth from the surface, and this materially increases the difficulty.

The second part of the subclavian artery, the portion which rises highest in the neck, has been considered favourable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anterior; the phrenic nerve lies on the anterior surface of the muscle, and the internal jugular vein is situated in front of its medial edge; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact below with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising medial to this point is a further objection to the operation.

In those cases of aneurysm of the axillary or subclavian artery which encroach upon the lateral portion of the Scalenus anterior to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side, this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome. On the right side, the operation is practicable, the main difficulty being the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The exact position of the vagus, recurrent laryngeal and phrenic nerves and the sympathetic trunk should be borne in mind, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the collateral circulation is established mainly by three sets of vessels: *

1. A posterior set, consisting of the suprascapular (transverse scapular) artery and the deep branch of the transverse cervical artery, both derived from the subclavian, anastomosing with the subscapular from the axillary.
2. A medial set, produced by the connexion of the internal mammary on the one hand, with the superior intercostal, the lateral thoracic and subscapular arteries on the other.
3. A middle or axillary set, consisting of a number of small vessels derived from branches of the subclavian and, passing through the axilla, terminating either in the axillary artery, or some of its branches. In the case quoted, this last set presented most conspicuously the peculiar character of newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

The chief agent in the restoration of the axillary artery below the aneurysm was the subscapular artery, which communicated freely with the internal mammary, suprascapular, and deep branch of the transverse cervical arteries of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by the following anastomoses: 1, between the superior and inferior thyroids; 2, the two vertebrals; 3, the internal mammary with the inferior epigastric and the posterior (aortic) intercostals; 4, the costocervical with the posterior intercostals; 5, the deep cervical with the descending branch of the occipital; 6, the scapular branches of the thyrocervical trunk with the branches of the axillary; and 7, the thoracic branches of the axillary with the posterior intercostals.

Branches.—The branches of the subclavian artery are:

Vertebral.	Thyrocervical trunk.
Internal mammary.	Costocervical trunk.

On the left side of the neck all four branches generally rise from the first portion of the artery; on the right side the costocervical trunk usually springs from the second portion. On both sides, the first three branches originate close together at the medial border of the Scalenus anterior.

1. The **vertebral artery** (figs. 703, 711) arises from the upper and posterior part of the first portion of the subclavian artery. It ascends through the fora-

* *Guy's Hospital Reports*, vol. i. 1836. Case of axillary aneurysm, in which Aston Key had tied the subclavian artery at the lateral edge of the Scalenus anterior, twelve years previously.

mina in the transverse processes of the upper six cervical vertebræ,* winds behind the lateral mass of the atlas, enters the skull through the foramen magnum, and, at the lower border of the pons, unites with the vessel of the opposite side to form the basilar artery.

Relations.—The vertebral artery may be divided into four parts. The *first part* runs upwards and backwards between the Longus cervicis (Longus colli) and the Scalenus anterior and behind the common carotid artery. In front it is related to the common carotid artery and the vertebral vein, and is crossed by the inferior thyroid artery; on the left side it is crossed also by the thoracic duct. Behind, it is related to the transverse process of the seventh cervical vertebra, the inferior cervical ganglion (fig. 997) and the anterior primary rami of the seventh and eighth cervical nerves. The *second part* ascends through the foramina transversaria of the upper six cervical vertebræ, and is accompanied by a large branch derived from the inferior cervical sympathetic ganglion, and by a plexus of veins which unite to form the vertebral vein at the lower part of the neck. It lies in front of the anterior primary rami of the cervical nerves (C. 2-C. 6) (fig. 703), and pursues an almost vertical course as far as the transverse process of the axis, through which it runs upwards and laterally to the foramen transversarium of the atlas. The *third part* issues from the latter foramen on the medial side of the Rectus capitis lateralis, and curves backwards behind the lateral mass of the atlas, the anterior primary ramus of the first cervical nerve being on its medial side; it then lies in the groove on the upper surface of the posterior arch of the atlas, and enters the vertebral canal by passing below the lower, arched border of the posterior atlanto-occipital membrane. This part of the artery is covered by the Semispinalis capitis and is contained in the *suboccipital triangle*, which is bounded by the Rectus capitis posterior major, the Obliquus superior and the Obliquus inferior. The posterior primary ramus of the first cervical nerve lies between the artery and the posterior arch of the atlas (fig. 591). The *fourth part* pierces the dura and the arachnoid mater, ascends in front of the roots of the hypoglossal nerve (fig. 839), and inclines medially to the front of the medulla oblongata, where, at the lower border of the pons, it unites with the vessel of the opposite side to form the basilar artery (fig. 714).

The branches of the vertebral artery may be divided into two sets—those given off in the neck, and those within the cranium.

Cervical branches.	*Cranial branches.*
Spinal.	Meningeal.
Muscular.	Posterior spinal.
	Anterior spinal.
	Posterior inferior cerebellar.
	Medullary.

Spinal branches enter the vertebral canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebræ, and others communicate with similar branches from the opposite side; from these communications small twigs arise which join similar branches above and below, to form a central anastomotic chain on the posterior surfaces of the bodies of the vertebræ.

Muscular branches arise from the vertebral artery as it curves round the lateral mass of the atlas. They supply the deep muscles of this region and anastomose with the occipital artery, and with the ascending and deep cervical arteries.

One or two **meningeal branches** spring from the vertebral artery opposite the foramen magnum; they ramify between the bone and dura mater in the cerebellar fossa, and supply the falx cerebelli.

The **posterior spinal artery** may arise from the vertebral artery at the side of the medulla oblongata, but is most frequently derived from the posterior inferior cerebellar artery. It

* The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra.

passes backwards, and then descends as two branches, one in front of and the other behind the posterior roots of the spinal nerves; these are reinforced by a succession of spinal twigs which arise from the vertebral, ascending cervical, posterior intercostal and lumbar arteries, and enter the vertebral canal through the intervertebral foramina; by means of these branches the posterior spinal arteries are continued to the lower part of the spinal cord, and to the cauda equina. Branches from the posterior spinal arteries form a free anastomosis with those of the opposite side. Near its origin each posterior spinal artery gives off an ascending branch, which ends at the side of the fourth ventricle.

The **anterior spinal artery** is a small branch, which arises near the termination of the vertebral artery; it descends in front of the medulla oblongata and unites with its fellow of the opposite side near the level of the lower end of the olive of the medulla oblongata. The single trunk, thus formed, descends on the front of the spinal cord, and is reinforced by a succession of small spinal branches which enter the vertebral canal through the intervertebral foramina; these branches are derived from the vertebral, the ascending cervical, posterior intercostal, and lumbar arteries. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord, and is continued as a slender twig on the filum terminale. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the spinal cord, and sends off branches at its lower part to be distributed to the cauda equina. Branches pass from the anterior spinal arteries, and from the beginning of the trunk formed by their union, to the medulla oblongata, where they are distributed to its central portion, being sharply limited dorsally to the region of the trigonum hypoglossi.*

The **posterior inferior cerebellar artery** (fig. 714) is the largest branch of the vertebral artery, but is not infrequently absent. It arises near, and winds backwards round, the lower end of the olive of the medulla oblongata; it then ascends behind the roots of the glossopharyngeal and vagus nerves to the lower border of the pons, where it turns downwards along the inferolateral border of the fourth ventricle. Finally, it runs laterally into the vallecula of the cerebellum, where it divides into a medial and a lateral branch. The medial branch runs backwards between the cerebellar hemisphere and the inferior vermis, supplying branches to both; the lateral branch supplies the under surface of the hemisphere, as far as its lateral border, and anastomoses with the anterior inferior cerebellar and superior cerebellar branches of the basilar artery. The trunk of the artery supplies branches to the medulla oblongata and to the choroid plexus of the fourth ventricle, and sends a branch upwards lateral to the tonsil of the cerebellum to supply the dentate nucleus of the cerebellum (Shellshear †). The area supplied in the medulla oblongata lies dorsal to the olivary nucleus (inferior olivary nucleus) and lateral to the hypoglossal nucleus and its emerging fila, and usually includes the nucleus of the spinal tract of the trigeminal nerve and the spino-thalamic tracts.

The **medullary arteries** are several minute vessels which spring from the vertebral and its branches, and are distributed to the medulla oblongata.

The **basilar artery** (figs. 714, 717), so named from its position at the base of the skull, is formed by the junction of the two vertebral arteries; it extends from the lower to the upper border of the pons, and is contained within the cisterna pontis. It lies in a shallow, median groove on the ventral surface of the pons. It is placed between the two abducent nerves at the lower border, and between the two oculomotor nerves at the upper border, of the pons, where it divides into the two posterior cerebral arteries.

Its branches, on each side, are the following:

Pontine.	Anterior inferior cerebellar.
Internal auditory.	Superior cerebellar.
Posterior cerebral.	

The **pontine branches** are a number of small vessels which come off from the front and sides of the basilar artery, and supply the pons and adjacent parts of the brain.‡

The **internal auditory artery**, a long slender branch, may arise from the lower part of the basilar artery but is more often derived from the anterior inferior cerebellar artery ; it accompanies the facial and auditory nerves into the internal auditory meatus, and is distributed to the internal ear.

The **anterior inferior cerebellar artery** (fig. 714) arises from the lower part of the basilar artery. It runs backwards and laterally, usually ventral to the abducent nerve, the facial and auditory nerves, and curves round the margin of the flocculus to be distributed to the anterior and lateral parts of the under surface of the cerebellum, where it anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches are supplied by the anterior inferior cerebellar artery to the lower and lateral parts of the pons, and sometimes to the upper part of the medulla oblongata.

The **superior cerebellar artery** (fig. 714) arises near the termination of the basilar. It passes laterally immediately below the oculomotor nerve, which separates it from the posterior cerebral artery, winds round the cerebral peduncle close to and below the trochlear nerve, and, arriving at the superior surface of the cerebellum, divides into branches which ramify in the pia mater, supplying this aspect of the cerebellum and anastomosing with branches of the inferior cerebellar arteries. In addition, branches are given to the pons, the pineal body, the superior medullary velum and the tela chorioidea of the third ventricle.

The **posterior cerebral artery** (figs. 714, 715, 716), frequently double, is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve, and on the side of the mesencephalon by the trochlear nerve. Passing laterally, parallel with the superior cerebellar artery, and receiving the posterior communicating branch from the internal carotid artery, it winds round the cerebral peduncle, and reaches the tentorial surface of the cerebrum, where it breaks up into branches for the supply of the temporal and occipital lobes.

The branches of the posterior cerebral artery are divided into two sets, central and cortical :

Central	Posteromedial. Posterior choroid. Posterolateral.	*Cortical*	Temporal. Occipital. Parieto-occipital.

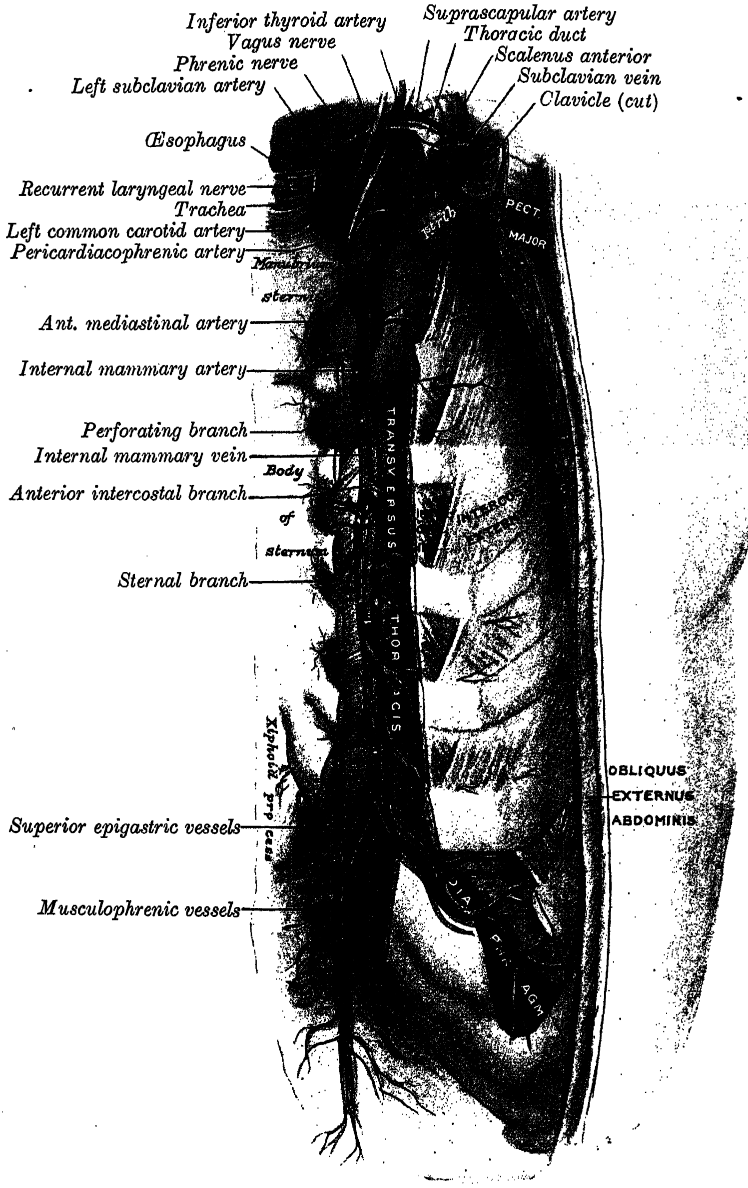
Central branches.—The *posteromedial central branches* (fig. 717) are several small arteries which arise at the commencement of the posterior cerebral artery ; these, with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the anterior part of the thalamus, the lateral wall of the third ventricle and the globus pallidus of the lentiform nucleus. The *posterior choroid branches* are usually three or four in number. One, or more, courses over the lateral geniculate body and helps to supply it, before entering the posterior part of the inferior horn through the lower part of the choroidal fissure. The others curl round the posterior end of the thalamus and pass through the transverse fissure, to enter the tela chorioidea of the third ventricle, and through the upper part of the choroidal fissure ; they supply the choroid plexuses of the third and lateral ventricles, and give some twigs to the fornix. The *posterolateral central branches* are small arteries which arise from the posterior cerebral artery after it has turned round the cerebral peduncle ; they supply the cerebral peduncle, the posterior part of the thalamus, and the pineal, quadrigeminal and medial geniculate bodies.

Cortical branches.—The *temporal branches*, usually two in number, are distributed to the uncus, the hippocampal, the medial and lateral occipito-temporal gyri ; the *occipital branches* supply the cuneus, gyrus lingualis and the posterior part of the lateral surface of the occipital lobe ; and the *parieto-occipital* supply the cuneus and the precuneus.

2. The **internal mammary artery** (fig. 721) arises from the under surface of the first portion of the subclavian artery, opposite the thyrocervical trunk. It descends behind the cartilages of the upper six ribs at a distance of 1·25 cm. from the lateral border of the sternum, and at the level of the sixth intercostal space divides into the *musculophrenic* and *superior epigastric* arteries.

Relations.—It runs at first downwards, forwards, and medially behind the sternal end of the clavicle, the internal jugular and innominate veins, and the first costal cartilage. As the artery enters the thorax, the phrenic nerve crosses it obliquely from the lateral to the medial side, the nerve usually passing in front of the artery. Below the first costal cartilage it descends almost vertically

Fig. 721.—The left internal mammary artery.



to its point of bifurcation. It is covered in front by the Pectoralis major, the cartilages of the upper six ribs and the intervening anterior intercostal membranes and Internal intercostals, and is crossed by the terminal portions of the upper six intercostal nerves. It is separated from the pleura, as far as the second or third costal cartilage, by a strong layer of fascia ; below this level, by the Sternocostalis (Transversus thoracis). It is accompanied by a chain of lymph glands and a pair of veins : about the level of the third costal cartilage

the veins unite to form a single vessel, which runs medial to the artery and ends in the innominate vein.

The branches of the internal mammary artery are:

Pericardiacophrenic.	Sternal.	Musculophrenic.
Mediastinal.	Anterior intercostal.	Superior epigastric.
Pericardial.	Perforating.	

The **pericardiacophrenic artery** is a long, slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm; it gives branches to the pleura, pericardium, and Diaphragm, and anastomoses with the musculophrenic and phrenic (inferior phrenic) arteries.

The **mediastinal arteries** are small vessels, distributed to the areolar tissue and lymph glands in the anterior mediastinum, and to the remains of the thymus.

The **pericardial branches** supply the upper part of the anterior surface of the pericardium.

The **sternal branches** are distributed to the Sternocostalis (Transversus thoracis) and to the posterior surface of the sternum.

The anterior mediastinal, pericardial and sternal branches, together with some twigs from the pericardiacophrenic, anastomose with branches from the posterior intercostal and bronchial arteries, and form a **subpleural mediastinal plexus.**

The **anterior intercostal branches** are distributed to the upper six intercostal spaces. Two in each space, they pass laterally, one lying near the lower margin of the upper rib, and the other near the upper margin of the lower rib, and anastomose with the posterior intercostal arteries. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Intercostales intimi and the Internal intercostals. They supply the Intercostal muscles and send branches through them to the Pectoral muscles and the mamma.

The **perforating branches** emerge through the upper five or six intercostal spaces, with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce the Pectoralis major, and curving laterally, supply that muscle and the skin. Those of the second, third and fourth spaces give branches to the mamma, and during lactation are of large size.

The **musculophrenic artery** is directed obliquely downwards and laterally, behind the cartilages of the seventh, eighth and ninth ribs; it perforates the Diaphragm near the ninth costal cartilage, and ends opposite the last intercostal space. It anastomoses with the phrenic artery, the lower two posterior intercostal arteries and the ascending branch of the deep circumflex iliac artery. It gives off two anterior intercostal branches to each of the seventh, eighth and ninth intercostal spaces; these are distributed in a manner similar to the anterior intercostals from the internal mammary. The musculophrenic also gives branches to the lower part of the pericardium and to the abdominal muscles.

The **superior epigastric artery** descends through the interval between the costal and xiphoid origins of the Diaphragm, lying on the lower fibres of the Sternocostalis (Transversus thoracis) and the upper fibres of the Transversus abdominis. It enters the sheath of the Rectus abdominis, at first lying behind the muscle, and then perforating and supplying it, and anastomosing with the inferior epigastric artery from the external iliac. Branches perforate the sheath of the Rectus, and supply the skin of the abdomen, and a small branch passes in front of the xiphoid process and anastomoses with the artery of the opposite side. The superior epigastric artery also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

3. The **thyrocervical trunk** (figs. 703, 719), a short, wide trunk, arises from the front of the first portion of the subclavian artery, close to the medial border of the Scalenus anterior, and divides almost immediately into three branches, the *inferior thyroid, suprascapular* and *transverse cervical.*

The **inferior thyroid artery** runs upwards in front of the medial border of the Scalenus anterior; it then turns medially in front of the vertebral vessels and behind the carotid sheath and its contents, and usually behind the sympathetic trunk, the middle cervical ganglion of which rests upon the vessel; it finally descends on the Longus cervicis (Longus colli) to the lower border of the lobe of the thyroid gland. At a little distance from the gland the inferior thyroid artery usually passes behind the recurrent laryngeal nerve, but when

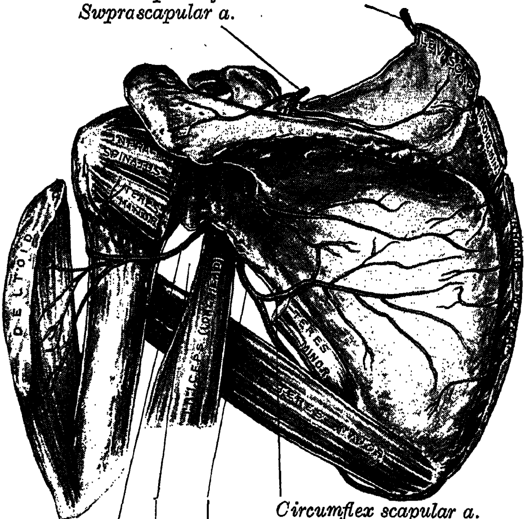
the gland is reached the nerve is often behind the branches of the artery or it may pass between them.*

The branches of the inferior thyroid are :

Muscular.	Inferior laryngeal.	Œsophageal.
Ascending cervical.	Tracheal.	Glandular.

The **muscular branches** supply the depressor muscles of the hyoid bone, the Longus cervicis, Scalenus anterior and Inferior constrictor of the pharynx.

FIG. 722.—The scapular anastomosis of the left side; dorsal aspect.



The **ascending cervical artery** is a small branch which arises from the inferior thyroid artery as that vessel turns medially behind the carotid sheath; it ascends on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anterior and Longus capitis and medial to the phrenic nerve. It gives twigs to the muscles of the neck, and sends one or two spinal branches into the vertebral canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ, in the same manner as the spinal branches of the vertebral artery. It anastomoses with branches of the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

The **inferior laryngeal artery** ascends upon the trachea in company with the recurrent laryngeal nerve; it enters the larynx deep to the lower border of the Inferior constrictor muscle, and supplies its muscles and mucous membrane, anastomosing with the artery from the opposite side, and with the superior laryngeal branch of the superior thyroid artery.

The **tracheal branches** are distributed to the trachea and anastomose below with the bronchial arteries.

The **œsophageal branches** supply the œsophagus and anastomose with the œsophageal branches of the descending thoracic aorta.

The **glandular branches** comprise an inferior and an ascending branch; they are distributed to the posterior and inferior parts of the thyroid gland, and anastomose with the superior thyroid artery and with the opposite inferior thyroid artery; the ascending branch supplies the superior parathyroid gland.

The **suprascapular artery** (transverse scapular artery) (fig. 720) passes at first downwards and laterally across the Scalenus anterior and the phrenic nerve, under cover of the internal jugular vein and the Sternomastoid; it then crosses the subclavian artery and the brachial plexus, and runs behind and parallel with the clavicle and Subclavius, and deep to the inferior belly of the Omohyoid, to the superior border of the scapula; here it passes above (occasionally below) the suprascapular ligament, which separates it from the suprascapular nerve, and enters the supraspinous fossa (fig. 722). In this situation it lies on the bone, and supplies branches to the Supraspinatus. It then descends behind the neck of the scapula, through the great scapular notch and deep to the spinoglenoid ligament, to reach the deep surface of the Infraspinatus, where it anastomoses with the circumflex scapular artery, and the deep branch of the transverse cervical artery. Besides distributing branches to the Sternomastoid, Subclavius, and neighbouring muscles, it gives off a *suprasternal branch*, which crosses over the sternal end of the clavicle

* F. G. Parsons, *Journal of Anatomy*, vol. liv. p. 172.

to the skin of the upper part of the chest; and an *acromial branch*, which pierces the Trapezius and supplies the skin over the acromion, anastomosing with the acromiothoracic artery. As the suprascapular artery passes above the suprascapular ligament, it sends a branch into the subscapular fossa, where it ramifies beneath the Subscapularis, and anastomoses with the subscapular artery and with the deep branch of the transverse cervical artery.. The suprascapular artery also sends articular branches to the acromioclavicular and shoulder-joints, and nutrient arteries to the clavicle and scapula. Not infrequently the suprascapular artery arises from the third part of the subclavian artery.

The **transverse cervical artery** (fig. 720) lies at a higher level than the suprascapular artery; it crosses in front of the phrenic nerve and the Scalenus anterior, and in front of the brachial plexus, and is covered by the internal jugular vein, Sternomastoid and Platysma. It crosses the floor of the posterior triangle of the neck, to reach the anterior margin of the Levator scapulæ, where it divides into a superficial and a deep branch.

The *superficial branch* ascends deep to the anterior part of the Trapezius, distributing branches to it and the neighbouring muscles, and to the lymph glands in the neck; it anastomoses with the superficial branch of the ramus descendens of the occipital artery.

The *deep branch* (fig. 722) passes under cover of the Levator scapulæ to the superior angle of the scapula, and then descends under cover of the Rhomboids along the medial border of the scapula as far as the inferior angle of the bone. It supplies branches to the Rhomboids, Latissimus dorsi and Trapezius, and anastomoses with the suprascapular and subscapular arteries, and with the posterior branches of some of the posterior intercostal arteries.

Peculiarities.—Frequently the superficial branch [superficial cervical artery] arises directly from the thyrocervical trunk, and the deep branch [descending scapular artery] from the third, more rarely from the second, part of the subclavian (fig. 726). When the deep branch arises in this way it usually passes between the upper and middle trunks of the brachial plexus.

4. The **costocervical trunk** (figs. 711, 718) arises from the back of the second part of the subclavian artery on the right side, but from the first part of the artery on the left side. It arches backwards above the cervical pleura to the neck of the first rib, and divides into the superior intercostal and deep cervical arteries.

The **superior intercostal artery** descends behind the pleura in front of the necks of the first and second ribs, and anastomoses with the third posterior (first aortic) intercostal artery. As it crosses the neck of the first rib it is medial to the anterior primary ramus of the first thoracic nerve, which it crosses at a lower level (fig. 718), and lateral to the first thoracic ganglion of the sympathetic trunk. In the first intercostal space, it gives off the first posterior intercostal artery, which is distributed in a manner similar to the distribution of the lower posterior intercostals. The second posterior intercostal artery usually joins with a branch from the third posterior (first aortic) intercostal artery; the second posterior intercostal artery is not constant, but is more commonly found on the right side; when absent, its place is supplied by a branch from the aorta.

The **deep cervical artery** (fig. 711) arises, in most cases, from the costocervical trunk, and is analogous to the posterior branch of a posterior intercostal artery: occasionally it is a separate branch from the subclavian artery. Passing backwards above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib (sometimes between the transverse processes of the sixth and seventh cervical vertebræ, it ascends on the back of the neck, between the Semispinales capitis et cervicis, as high as the second cervical vertebra, supplying the adjacent muscles, and anastomosing with the deep division of the descending branch of the occipital artery (p. 709) and with branches of the vertebral artery. It gives off a spinal twig which enters the vertebral canal through the foramen between the seventh cervical and first thoracic vertebræ.

The Axilla

The axilla is a pyramidal space, situated between the upper part of the chest wall and the upper part of the medial side of the upper arm.

The *apex* of the axilla is directed upwards towards the root of the neck, and corresponds to the interval between the outer border of the first rib, the superior border of the scapula and the posterior surface of the clavicle; through it the axillary vessels and nerves enter the space from the neck. The *base*, directed downwards, is broad at the chest but narrow and pointed at the arm; it is formed by the skin and a thick layer of fascia, termed the *axillary fascia*, extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind. The *anterior wall* is formed by the Pectorales major et minor, the former covering the whole of this wall, the latter only its central part. The space between the upper border of the Pectoralis minor and the clavicle is occupied by the clavipectoral fascia (costo-coracoid membrane). The *posterior wall* is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *medial side* are the first four ribs with their corresponding Intercostal muscles, and the upper part of the Serratus anterior. On the *lateral side*, where the anterior and posterior walls converge, the space is narrow, and is bounded by the humerus, the Coraco-brachialis and the Biceps.

The axilla contains the axillary vessels, the infraclavicular part of the brachial plexus of nerves, with its branches, the lateral branches of some of the intercostal nerves, and a large number of lymph glands, together with a quantity of fat and loose areolar tissue. The axillary vessels and the brachial plexus of nerves run from the apex to the base along the lateral wall of the axilla; they are placed nearer to the anterior than to the posterior wall, the axillary vein lying to the thoracic side of the axillary artery and partially concealing it. The thoracic branches of the axillary artery are in contact with the Pectoral muscles, and along the lower margin of the Pectoralis minor the lateral thoracic artery passes to the side of the thorax. The subscapular vessels descend on the posterior wall in contact with the lower margin of the Subscapularis, and the subscapular nerves and the nerve to Latissimus dorsi cross the anterior surface of the muscle with different degrees of obliquity; the circumflex scapular vessels wind round the lateral (axillary) border of the scapula, and the posterior circumflex humeral vessels and the circumflex (axillary) nerve curve backwards close to the surgical neck of the humerus. No vessel of any importance lies on the medial or thoracic side, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. The nerve to Serratus anterior (long thoracic nerve) descends on the surface of the muscle which it supplies; and the intercostobrachial nerve perforates the upper and anterior part of this wall, and passes across the axilla to the medial side of the upper arm.

The position and arrangement of the lymph glands are described on pp. 858 and 859.

Applied Anatomy.—Penetrating wounds in the axilla are sometimes accompanied by extensive hæmorrhage, either from wound of the main vessels, or of one of the large branches of the axillary artery, e.g. the lateral thoracic or the subscapular. Where the blood cannot find an easy exit it collects in the space and forms a large swelling which projects in the floor of the axilla and also bulges forwards the Pectoralis major. The treatment consists in freely opening up the cavity, searching for and securing the bleeding vessel.

When suppuration occurs in the axilla, the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on p. 588, the clavipectoral fascia, after covering the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and at its lower border is incorporated with the axillary fascia at the anterior fold of the axilla. Suppuration may take place either superficial or deep to this layer of fascia; that is, either between the Pectoral muscles or behind the Pectoralis minor; in the former case, the abscess would point either at the border of the anterior axillary fold, or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Its progress towards the surface is prevented by the axillary fascia; its progress backwards,

by the insertion of the Serratus anterior; forwards, by the clavipectoral fascia; medially, by the wall of the thorax; and laterally by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum. Instances have been recorded where the pus found its way along the vessels into the upper arm.

When an axillary abscess is opened, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space so as to avoid the lateral thoracic, subscapular, and axillary vessels which are in contact respectively with the anterior, posterior and lateral walls of the axilla.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is the universal procedure to remove the lymph glands from the axilla in operating for cancer of the breast. When such an operation is performed, it is necessary to proceed with much caution in the direction of the lateral wall and apex of the space, as here the axillary vessels are in danger of being wounded.

The Axillary Artery (fig. 723)

The **axillary artery**, the continuation of the subclavian artery, begins at the outer border of the first rib, and ends at the lower border of the Teres major, beyond which the artery takes the name of brachial. Its direction varies with the position of the limb: thus the vessel is nearly straight when the arm is directed at right angles with the trunk, concave upwards when the arm is elevated above the shoulder, and convex upwards and laterally when the arm lies by the side of the trunk. The first part of the artery is deeply situated, but its terminal part is superficial and is covered only by the skin and fasciæ. The Pectoralis minor crosses the vessel and divides it into three portions; the first part is proximal, the second posterior, and the third distal, to the muscle.

Relations of the first part.—*In front* the first part of the axillary artery is covered by the skin, superficial fascia, Platysma, supraclavicular nerves from the cervical plexus, deep fascia, clavicular fibres of the Pectoralis major and the clavipectoral fascia. This part of the artery is crossed by the lateral pectoral (lateral anterior thoracic) nerve, the loop of communication between it and the medial pectoral nerve, and by the acromiothoracic and cephalic veins. *Behind*, the artery is related to the first intercostal space and External intercostal muscle, the first and second digitations of the Serratus anterior, the nerve to Serratus anterior and medial pectoral nerve, and the medial cord of the brachial plexus. On the *lateral side* it is related to the lateral and posterior cords of the brachial plexus; on the *medial side*, to the axillary vein, by which it is overlapped. The first part of the artery is enclosed, together with the axillary vein and the brachial plexus, in a fibrous sheath, termed the *axillary sheath*, continuous above with the prevertebral layer of the deep cervical fascia.

Relations of the second part.—*In front*, the second part of the axillary artery is related to the skin, superficial and deep fascia, and the Pectoralis major and minor; *behind*, to the posterior cord of the brachial plexus and some areolar tissue, which intervene between it and the Subscapularis; on the *medial side*, to the axillary vein, separated from it by the medial cord of the brachial plexus and the medial pectoral nerve; on the *lateral side*, to the lateral cord of the brachial plexus, which separates it from the Coracobrachialis muscle. The cords of the brachial plexus thus surround the second part of the artery on three sides, and separate it from direct contact with the vein and adjacent muscles.

Relations of the third part.—The third part of the axillary artery extends from the lower border of the Pectoralis minor to the lower border of the Teres major. Its upper part is covered *in front* by the lower part of the Pectoralis major; its lower part by the skin and fasciæ only. *Behind*, it is related to the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major. On its *lateral side* is the Coracobrachialis, and on its *medial side*, the axillary vein. The nerves of the brachial plexus bear the following relations to this part of the artery; on the *lateral side* are the lateral root and the trunk of the median, and, for a short distance, the musculocutaneous; on the *medial side*, the medial cutaneous nerve of the forearm lies between the axillary artery and vein anteriorly, and the ulnar nerve between the artery and vein posteriorly;

the medial cutaneous nerve of the upper arm is on the medial side of the vein; *in front* is the medial root of the median nerve, and *behind*, the radial and circumflex nerves, the latter only as far as the lower border of the Subscapularis.

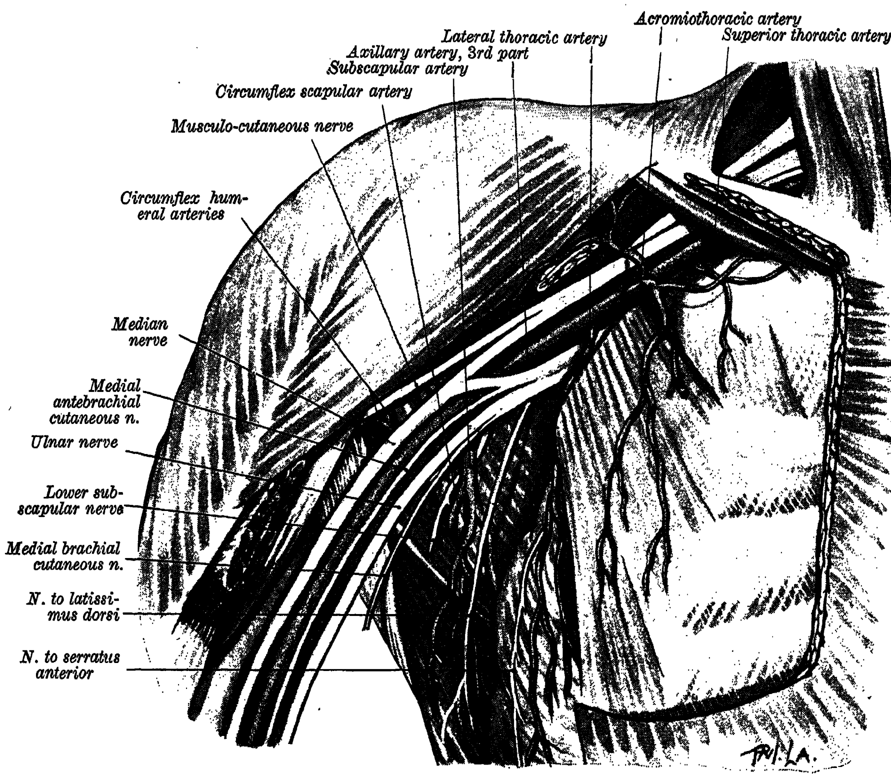
The branches of the axillary artery are :

From first part. 1. Superior thoracic. *From second part* { 2. Acromiothoracic. 3. Lateral thoracic.

From third part { 4. Subscapular. 5. Anterior circumflex humeral. 6. Posterior circumflex humeral.

1. The **superior thoracic artery** (fig. 723) is a small vessel which arises from the axillary artery near the lower border of the Subclavius muscle, but it may

Fig. 723.—The right axillary artery and its branches. The Pectoralis major has been removed and a portion of the Pectoralis minor has been excised.



take origin from the acromiothoracic artery. Running forwards and medially along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies branches to these muscles, and to the thoracic wall, and anastomoses with the internal mammary and intercostal arteries.

2. The **acromiothoracic artery** (fig. 723) is a short trunk which arises from the front of the axillary artery, its origin being overlapped by the upper edge of the Pectoralis minor. Passing forwards round the upper border of this muscle, it pierces the clavipectoral fascia and divides into four branches—pectoral, acromial, clavicular and deltoid. The *pectoral branch* descends between the two Pectoral muscles, and is distributed to them and to the breast, anastomosing with the intercostal branches of the internal mammary artery and with the lateral thoracic artery. The *acromial branch* runs laterally over the coracoid process and under the Deltoid, to which it gives branches; it then pierces that muscle and ends on the acromion, where it anastomoses with the branches of the suprascapular (transverse scapular), acromiothoracic and

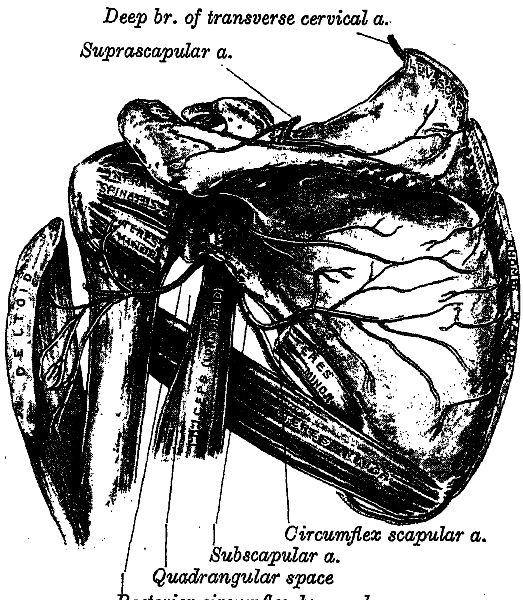
posterior circumflex humeral arteries. The *clavicular branch* runs upwards and medially between the clavicular part of the Pectoralis major and the clavipectoral fascia; it gives branches to the sternoclavicular joint, and to the Subclavius. The *deltoid*, or *humeral*, *branch* often arises with the acromial branch; it crosses over the Pectoralis minor and runs with the cephalic vein in the interval between the Pectoralis major and Deltoid, giving branches to both muscles.

3. The **lateral thoracic artery** (fig. 723) follows the lower border of the Pectoralis minor to the side of the chest, supplies the Serratus anterior and the Pectoral muscles, and sends branches to the axillary lymph glands, and to the Subscapularis; it anastomoses with the internal mammary, subscapular, and intercostal arteries, and with the pectoral branch of the acromiothoracic artery. In the female, the lateral thoracic artery is large, and gives off an *external mammary branch*, which turns round the lower border of the Pectoralis major and supplies the mamma.

4. The **subscapular artery** (fig. 723) is the largest branch of the axillary artery; usually it arises at the lower border of the Subscapularis, which it follows to the inferior angle of the scapula, where it anastomoses with the lateral thoracic and intercostal arteries and with the deep branch of the transverse cervical artery; finally it ends in the neighbouring muscles and adjacent part of the chest-wall. In the lower part of its course it is accompanied by the nerve to the Latissimus dorsi; about 4 cm. from its origin it gives off the *circumflex scapular artery*.

The **circumflex scapular artery** is generally larger than the continuation of the subscapular. It curves round the lateral border of the scapula, traversing the triangular space between the Subscapularis above, the Teres major below, and the long head of the Triceps laterally (fig. 724); it enters the infraspinous fossa under cover of the Teres minor, and anastomoses with the suprascapular artery and the deep branch of the transverse cervical artery. It gives off two branches: one (*infrascapular*) enters the subscapular fossa deep to the Subscapularis, which it supplies, and anastomoses with the suprascapular artery and the deep branch of the transverse cervical artery; the other is continued along the lateral border of the scapula, between the Teres major and the Teres minor, and at the dorsal surface of the inferior angle anastomoses with the deep branch of the transverse cervical artery. In addition, small branches are distributed to the posterior part of the Deltoid and the long head of the Triceps, and anastomose with an ascending branch of the arteria profunda brachii.

FIG. 724.—The scapular anastomosis of the left side; dorsal aspect.



5. The **anterior circumflex humeral artery** (fig. 724) is a small artery which arises from the lateral side of the axillary artery at the lower border of the Subscapularis. It runs horizontally, behind the Coracobrachialis and short head of the Biceps, in front of the surgical neck of the humerus. On reaching the bicipital groove (intertubercular sulcus), it gives off a branch which ascends in it to supply the head of the humerus and the shoulder-joint. The artery is then continued laterally under cover of the long head of the

Biceps and the Deltoid, and anastomoses with the posterior circumflex humeral artery.

6. **The posterior circumflex humeral artery** (fig. 724) is considerably larger than the anterior. It arises from the axillary artery at the lower border of the Subscapularis, and runs backwards with the circumflex (axillary) nerve through the quadrangular space, which is bounded by the Subscapularis, the capsule of the shoulder-joint and the Teres minor above, the Teres major below, the long head of the Triceps medially, and the surgical neck of the humerus laterally. It winds round the neck of the humerus and distributes branches to the shoulder-joint, the Deltoid, the Teres major and minor, and the long and lateral heads of the Triceps, and gives off a descending branch which anastomoses with the arteria profunda brachii. It also anastomoses with the anterior circumflex humeral, suprascapular and acromiothoracic arteries.

Peculiarities.—The branches of the axillary artery vary considerably in different subjects. One, named *alar thoracic*, and frequently derived from the second part of the artery, is distributed to the fat and the lymph glands in the axilla. Occasionally the subscapular, circumflex humeral and profunda arteries arise from a common trunk, and when this occurs the branches of the brachial plexus surround this trunk instead of the main vessel. The posterior circumflex humeral artery may arise from the arteria profunda brachii; it then passes backwards below the Teres major, instead of accompanying the circumflex nerve through the quadrangular space. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally it gives origin to the anterior interosseous artery of the forearm.

Applied Anatomy.—Compression of the axillary artery may be required in the removal of tumours, or in amputation of the upper part of the arm. The only situation in which compression can be effectually made is in the lower part of its course; by pressing the artery against the humerus in this situation the circulation may be effectually arrested.

With the exception of the popliteal, the axillary artery is perhaps more frequently lacerated than any other artery in the body by violent movements, particularly in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint, especially where the artery has become fixed to the capsule of the joint.

Collateral Circulation.—If the axillary artery be tied above the origin of the acromiothoracic artery, the collateral circulation will be carried on by the same branches as after the ligature of the third part of the subclavian (p. 733); if at a lower point, between the acromiothoracic and the subscapular arteries, the latter vessel, by its free anastomoses with the suprascapular and transverse cervical arteries, will become the chief agent in carrying on the circulation; the lateral thoracic artery, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the ligature be applied below the origin of the subscapular artery, it will most probably also be below the origins of the two circumflex humeral arteries; the chief agents in restoring the circulation will then be the subscapular and the two circumflex humeral arteries through anastomoses with the arteria profunda brachii.

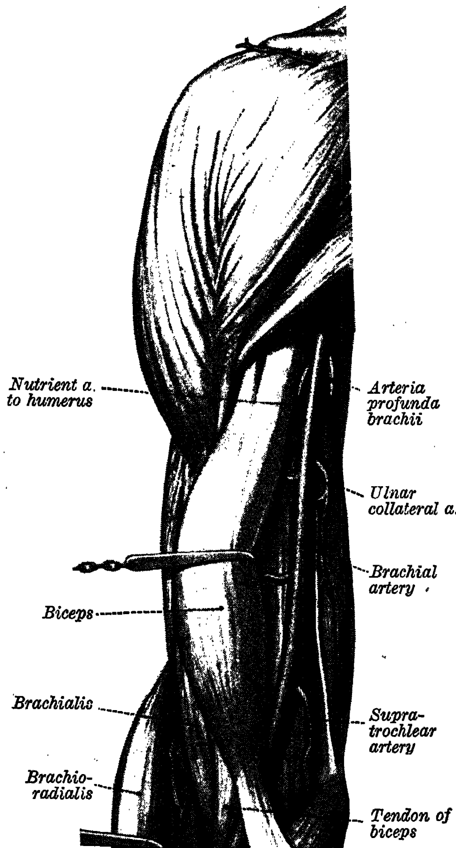
The Brachial Artery (figs. 725, 726, 727)

The **brachial artery** is a continuation of the axillary artery. It begins at the lower border of the tendon of the Teres major, runs down the arm, and ends about 1 cm. below the elbow-joint by dividing into radial and ulnar arteries. At first it lies on the medial side of the humerus, but, largely owing to the inclination of the humerus, it gradually passes to the front of the upper arm and is placed midway between the humeral epicondyles at the elbow.

Relations.—The artery is superficial throughout its entire extent, being covered with the skin and the superficial and deep fasciæ; the bicipital aponeurosis (lacertus fibrosus) lies in front of it opposite the elbow and separates it from the median cubital vein; the median nerve crosses the artery from the lateral to the medial side opposite the insertion of the Coracobrachialis. *Posteriorly* it lies at first on the long head of the Triceps separated by the radial nerve and the profunda brachii artery. It then lies successively on the medial head of the Triceps, the insertion of the Coracobrachialis, and the Brachialis. *Laterally*, it is in relation above with the median nerve and the Coracobrachialis,

below with the Biceps, the two muscles overlapping the artery to some extent. *Medially*, its upper half is in relation with the medial antebrachial cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on its medial side, but is separated from it in the lower part of the upper arm by the deep fascia. The artery is closely accompanied by two venæ comitantes, which are connected at intervals by short transverse branches.

FIG. 725.—The right brachial artery.



THE CUBITAL FOSSA

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, which is named the *cubital fossa*. The base of the triangle is represented by a line connecting the two humeral epicondyles; the sides are formed by the medial edge of the Brachioradialis and the lateral margin of the Pronator teres; the floor consists of the Brachialis and Supinator. This fossa contains the tendon of the Biceps, the terminal part of the brachial artery, and its accompanying veins, the origins of the radial and ulnar arteries, and parts of the median and radial nerves. The brachial artery occupies the middle of the fossa, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the skin, the superficial fascia, and the median cubital vein, the last being separated from the artery by the bicipital aponeurosis (lacertus fibrosus). *Behind*, the Brachialis separates it from the elbow-joint. The median nerve lies close to the medial side of the artery above, but is separated from its ulnar branch below by the ulnar head of the Pronator teres. The tendon of the Biceps is lateral to the artery; the radial nerve rests upon the Supinator, and is concealed by the Brachioradialis.

Peculiarities.—The brachial artery, accompanied by the median nerve, may leave the medial border of the Biceps, and descend towards the medial epicondyle of the humerus; in such cases it usually passes behind the *supracondylar process* of the humerus, from which a fibrous arch is in most cases thrown over the artery; it then runs behind or through the substance of the Pronator teres, to the bend of the elbow. This variation bears considerable analogy with the normal condition of the artery in some of the carnivora, and has been referred to in the description of the humerus (p. 346). Occasionally, the upper part of the artery splits into two trunks which reunite. Frequently it divides at a higher level than usual, and the vessels concerned in this high division are three: viz. radial, ulnar and interosseous arteries. Most frequently the radial is given off high up, the other limb of the division consisting of the ulnar and interosseous; in some instances the ulnar originates above the ordinary level, and the radial and interosseous form the other limb of the division; occasionally the interosseous arises high up.

Sometimes long, slender vessels, termed *vasa aberrantia,* connect the brachial or the axillary artery with one or other of the arteries of the forearm. These vessels usually join the radial.

FIG. 726.—A transverse section through the arm at the junction of the proximal with the intermediate one-third of the humerus.

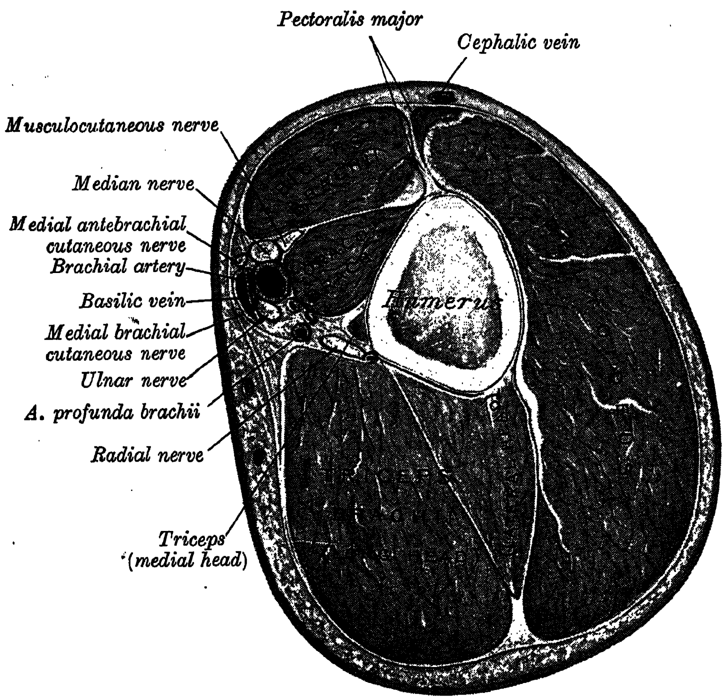


FIG. 727.—A transverse section through the arm, a little below the middle of the body of the humerus.

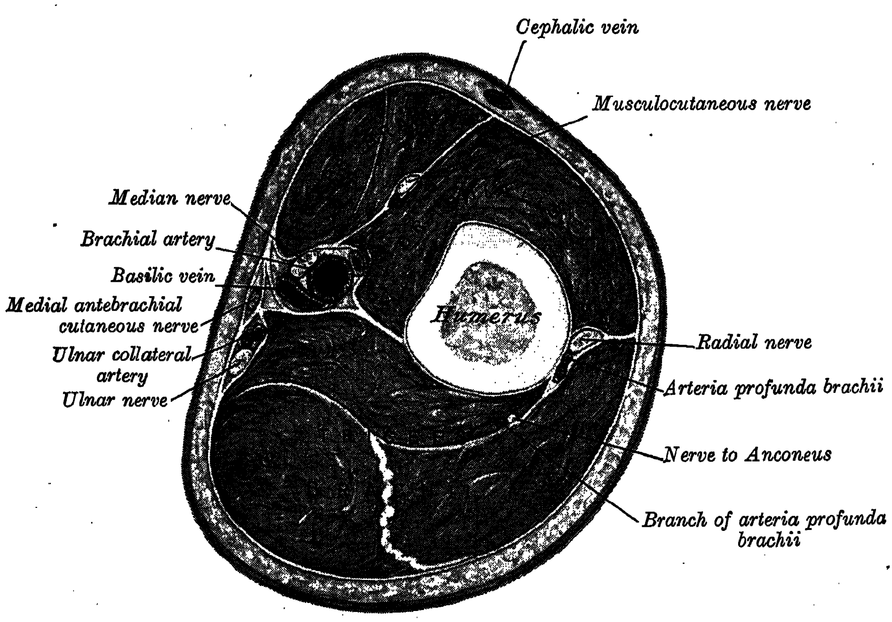


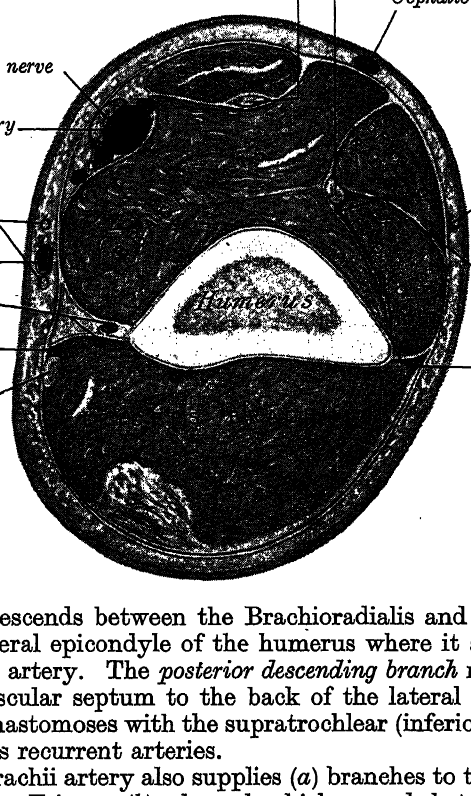
The brachial artery is occasionally concealed in some part of its course, by muscular or tendinous slips derived from the Coracobrachialis, Biceps, Brachialis or Pronator teres.

The branches of the brachial artery are:

1. Profunda brachii.
2. Nutrient.
3. Ulnar collateral.
4. Supratrochlear.
5. Muscular.

1. The **profunda brachii artery** (figs. 725, 726) is a large vessel which arises from the medial and posterior part of the brachial artery, just below the lower border of the Teres major. It follows the radial nerve closely, running at first backwards between the long and medial heads of the Triceps, then along the spiral groove (sulcus for the radial nerve), where it is covered by the lateral head of the Triceps. Reaching the lateral side of the arm, it divides into anterior and posterior descending branches. The *anterior descending branch*, which is usually the smaller, pierces the lateral intermuscular septum with the

FIG. 728.—A transverse section through the arm, 2 cm. above the medial epicondyle of the humerus.



radial nerve, and descends between the Brachioradialis and the Brachialis to the front of the lateral epicondyle of the humerus where it anastomoses with the radial recurrent artery. The *posterior descending branch* runs down behind the lateral intermuscular septum to the back of the lateral epicondyle of the humerus where it anastomoses with the supratrochlear (inferior ulnar collateral) and the interosseous recurrent arteries.

The profunda brachii artery also supplies (*a*) branehes to the Deltoid and to the three heads of the Triceps, (*b*) a branch which ascends between the long and lateral heads of the Triceps and anastomoses with the posterior circumflex humeral artery, and (*c*) a collateral twig which descends in the medial head of the Triceps with the nerve to the Anconeus, and takes part in the anastomosis above the olecranon. Sometimes the profunda brachii artery supplies a *nutrient artery* to the humerus, which enters the bone behind the deltoid tuberosity.

2. The **nutrient artery** of the humerus arises usually about the middle of the upper arm; it enters the nutrient canal near the insertion of the Coracobrachialis, and is directed downwards.

3. The **ulnar collateral artery** (superior ulnar collateral artery) (figs. 725, 727) is a small vessel which arises from the brachial a little below the middle of the upper arm; it frequently springs from the upper part of the arteria

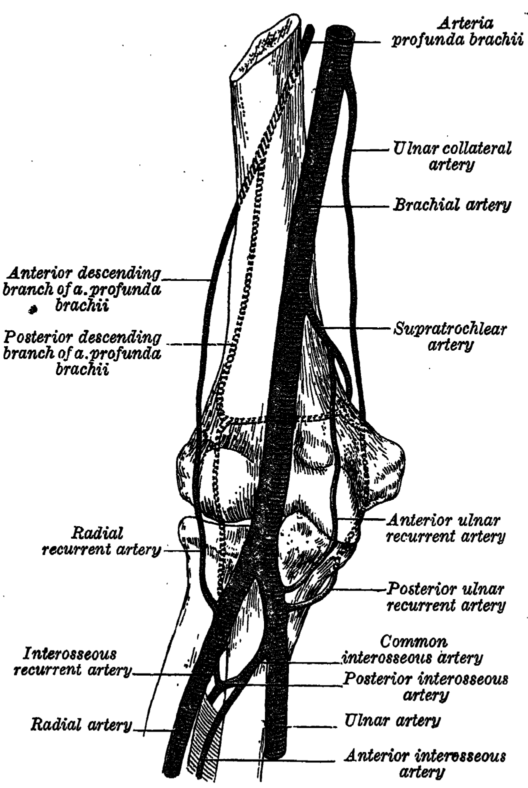
profunda brachii. It accompanies the ulnar nerve, pierces the medial intermuscular septum, descends between the medial epicondyle and the olecranon, and ends under cover of the Flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and supratrochlear arteries. It sometimes sends a branch in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery.

4. The **supratrochlear artery** (inferior ulnar collateral artery) (figs. 725, 728) arises about 5 cm. above the elbow. It passes medially behind the median nerve and upon the Brachialis and, piercing the medial intermuscular septum, winds round the back of the humerus between the Triceps and the bone, forming, by its junction with the posterior descending branch of the arteria profunda brachii, an arch above the olecranon fossa. As the vessel lies on the Brachialis, it gives off branches which ascend to join the ulnar collateral artery; others descend in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery. Behind the medial epicondyle a branch anastomoses with the ulnar collateral and posterior ulnar recurrent arteries.

5. The **muscular branches**, three or four in number, are distributed to the Coracobrachialis, Biceps and Brachialis.

The anastomosis around the elbow-joint (fig. 729).—The vessels engaged in this anastomosis may be conveniently divided into those *in front* of the medial and lateral epicondyles of the humerus and those *behind*. The branches anastomosing *in front* of the medial epicondyle are: the anterior branches of the ulnar collateral, and supratrochlear and the anterior ulnar recurrent artery. Those anastomosing *behind* the medial epicondyle are: the ulnar collateral, the supratrochlear and the posterior ulnar recurrent artery. The branches anastomosing *in front* of the lateral epicondyle are: the anterior descending branch of the profunda brachii artery, and the radial recurrent artery. Those anastomosing *behind* the lateral epicondyle are: the posterior descending branch of the profunda brachii artery and the interosseous recurrent artery. There is also an arch of anastomosis above the olecranon fossa formed by the supratrochlear artery joining with the posterior descending branch of the arteria profunda brachii, and with the interosseous recurrent and the posterior ulnar recurrent arteries (fig. 729).

FIG. 729.—A diagram of the arterial anastomosis around the elbow-joint.



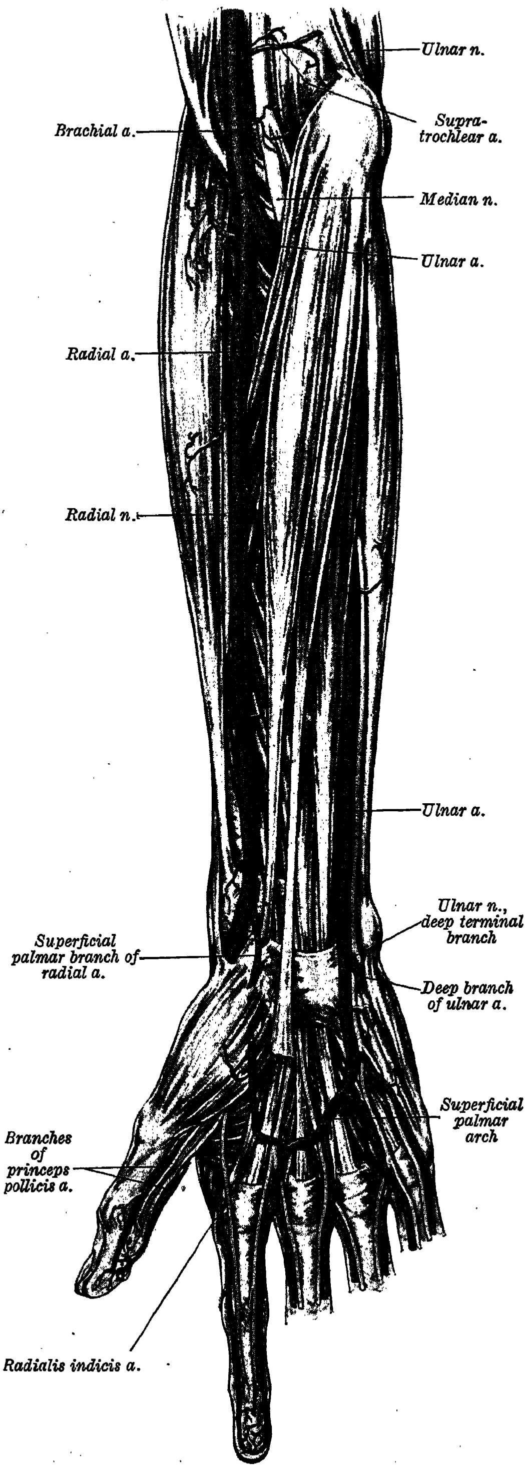
Applied Anatomy.—In spite of the fact that the brachial artery is very superficial and but little protected by surrounding parts, it is seldom wounded. This, no doubt, is due to its situation on the medial side of the upper arm, which is little exposed to injury.

Compression of the brachial artery is required in case of amputation and some other operations in the upper arm and forearm, and may be effected in almost any part of the course of the artery. If pressure be made in the upper part of the upper arm, it should be directed laterally; if in the lower part, backwards, as the artery lies on the medial side of the humerus above, and in front of it below. The most favourable situation is about the middle of the arm, where the artery lies on the tendon of the Coracobrachialis on the medial surface of the humerus.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the upper arm, the circulation is carried on by branches from the circumflex

humeral and subscapular arteries anastomosing with ascending branches from the arteria profunda brachii. If the artery be tied below the origins of the arteria profunda brachii and ulnar collateral artery, the circulation is maintained through the anastomoses around the elbow-joint (p. 748).

Fig. 730.—The right radial and ulnar arteries. Superficial dissection.



The Radial Artery (figs. 730, 731, 733)

The **radial artery**, though smaller than the ulnar artery, appears, from its course, to be the more direct continuation of the brachial trunk. It begins at the division of the brachial, about 1 cm. below the bend of the elbow, and passes along the radial side of the forearm to the wrist. It then winds backwards, round the lateral side of the carpus, under cover of the tendons of the Abductor pollicis longus and Extensores pollicis brevis et longus to the proximal end of the space between the first and second metacarpal bones where it passes forwards between the two heads of the first Dorsal interosseous muscle, into the palm of the hand; it crosses towards the ulnar side of the palm, and forms the deep palmar arch by uniting with the deep branch of the ulnar artery. The radial artery is therefore divisible into three portions, one in the forearm, a second at the wrist, and a third in the hand.

Relations.—(*a*) *In the forearm* (figs. 730, 731, 732, 734), the radial artery extends from the neck of the radius to the front part of its styloid process, being placed to the medial side of the shaft of the bone above, and in front of it below. Its upper part is overlapped by the fleshy belly of the Brachioradialis; the rest of the artery is covered only with the skin, and the superficial and deep fasciæ. It lies successively upon the tendon of the Biceps, the Supinator, the insertion of the Pronator teres, the radial origin of the Flexor digitorum sublimis, the Flexor pollicis longus, the Pronator quadratus and the lower end of the radius. The Pronator teres is medial, and the Brachioradialis lateral, to the upper one-third of the artery; the tendon of the Flexor carpi radialis is medial, and the tendon of the Brachioradialis lateral to its

lower two-thirds. The radial nerve (superficial branch) is close to the lateral side of the middle one-third of the vessels; and some filaments of the lateral cutaneous nerve of the forearm run along the lower part of the artery as it winds round the wrist. Throughout its course the vessel is accompanied by a pair of venæ comitantes. The portion of the radial artery which lies in front of the lower end of the radius and on the lateral side of the tendon of the Flexor carpi radialis is used clinically for observations on the pulse.

(*b*) *At the wrist* (figs. 734, 736), the radial artery reaches the back of the carpus by passing between the lateral ligaments of the wrist and the tendons of the Abductor pollicis longus and Extensor pollicis brevis. It then descends on the scaphoid bone and the trapezium (os multangulum majus), and before disappearing between the heads of the first Dorsal interosseous muscle is crossed by the tendon of the Extensor pollicis longus. In the interval between the two Extensores pollicis it is crossed by the origin of the cephalic vein, and by the digital branches of the radial nerve which go to the thumb and index finger.

(*c*) *In the hand* (fig. 732), the radial artery passes from the proximal end of the first interosseous space, between the heads of the first Dorsal interosseous muscle, transversely across the palm; it lies at first deep to the oblique head of the Adductor pollicis, then runs between the oblique and transverse heads, or through the transverse head, of that muscle. At the base of the fifth metacarpal bone it anastomoses with the deep branch from the ulnar artery, and so completes the *deep palmar arch* (fig. 732).

Peculiarities.—In about 12 per cent. of subjects the origin of the radial artery is higher than usual; it then arises more often from the axillary or upper part of the brachial artery than from the lower part of the latter vessel. In the forearm it sometimes lies on the deep fascia instead of beneath it, and on the surface of the Brachioradialis instead of under cover of its medial border; in turning round the wrist, it occasionally lies on, instead of deep to, the extensor tendons of the thumb.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the forearm.	*At the wrist.*	*In the hand.*
Radial recurrent.	Posterior carpal.	Princeps pollicis.
Muscular.	First dorsal metacarpal.	Radialis indicis.
Anterior carpal.		
Superficial palmar.		

The **radial recurrent artery** arises immediately below the elbow. It passes between the radial nerve and its posterior interosseous branch, and ascends under cover of the Brachioradialis, lying on the Supinator and Brachialis; it supplies these muscles and the elbow-joint, and anastomoses with the anterior descending branch of the arteria profunda brachii.

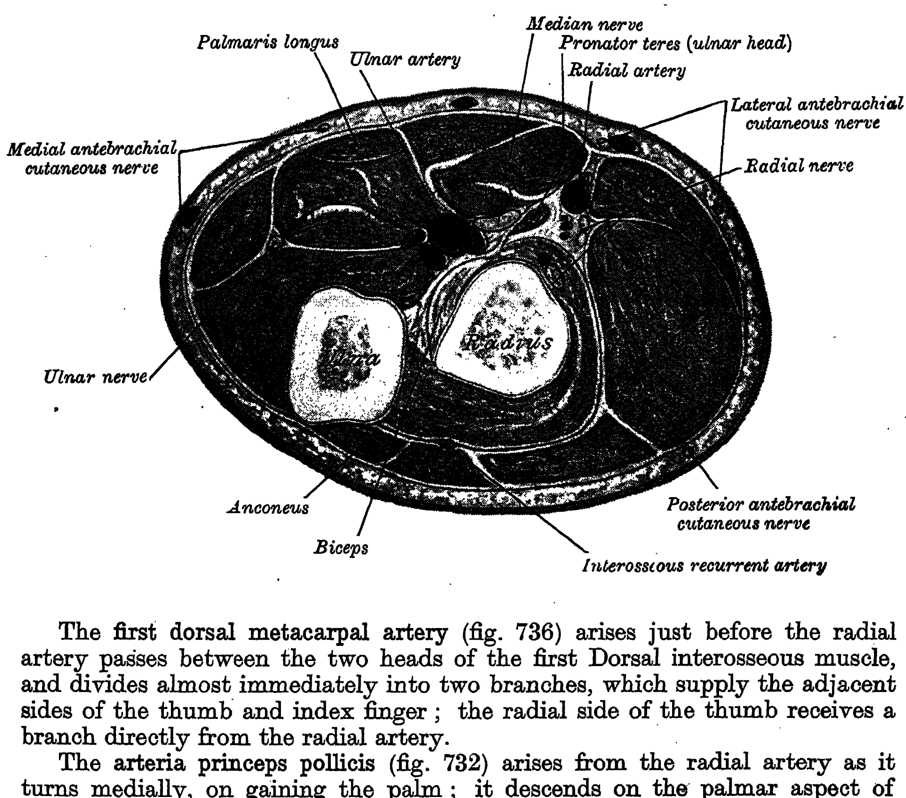
The **muscular branches** are distributed to the muscles on the radial side of the forearm.

The **anterior carpal branch** is a small vessel which arises near the lower border of the Pronator quadratus, and, running medially across the anterior surface of the carpus, anastomoses under cover of the flexor tendons with the anterior carpal branch of the ulnar artery. This anastomosis is joined by a branch from the anterior interosseous artery, and by recurrent branches from the deep palmar arch, thus forming an *anterior carpal arch*, which supplies the articulations of the wrist and carpus.

The **superficial palmar branch** (fig. 730) arises from the radial artery where this vessel is about to wind round the lateral side of the wrist. It passes through, occasionally over, the muscles of the ball of the thumb, which it supplies, and sometimes anastomoses with the terminal portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and ends in the muscles of the thumb; sometimes it is as large as the continuation of the radial artery.

The **posterior carpal branch** (fig. 736) is a small vessel which arises deep to the extensor tendons of the thumb, and, running medially across the posterior surface of the carpus under cover of the extensor tendons, anastomoses with the posterior carpal branch of the ulnar artery, and with the anterior and posterior interosseous arteries, to form a *posterior carpal arch*. Arising from this arch, three slender *dorsal metacarpal arteries* descend on the second, third and fourth Dorsal interosseous muscles and bifurcate into dorsal digital branches for the supply of the adjacent sides of the index, middle, ring and little fingers; they anastomose with the palmar digital branches of the superficial palmar arch; near their origins they anastomose with the deep palmar arch by the *superior perforating arteries*, and, near their points of bifurcation, with the palmar digital vessels of the superficial palmar arch by the *inferior perforating arteries*.

FIG. 731.—A transverse section through the forearm at the level of the radial tuberosity.



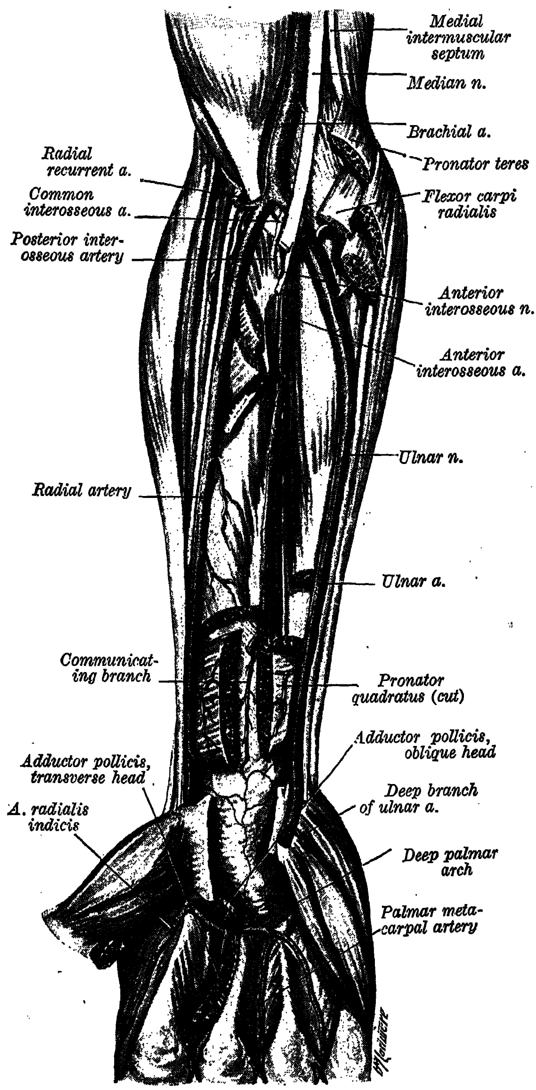
The **first dorsal metacarpal artery** (fig. 736) arises just before the radial artery passes between the two heads of the first Dorsal interosseous muscle, and divides almost immediately into two branches, which supply the adjacent sides of the thumb and index finger; the radial side of the thumb receives a branch directly from the radial artery.

The **arteria princeps pollicis** (fig. 732) arises from the radial artery as it turns medially, on gaining the palm; it descends on the palmar aspect of the first metacarpal bone under cover of the oblique head of the Adductor pollicis and lateral to the first palmar interosseous muscle (deep head of the Flexor pollicis brevis). At the base of the proximal phalanx, where it lies behind the tendon of the Flexor pollicis longus, it divides into two branches. These make their appearance between the medial and lateral insertions of the oblique head of the Adductor pollicis, and run along the sides of the thumb, forming on the palmar surface of the distal phalanx an arch, from which branches are distributed to the skin and subcutaneous tissue of the thumb.

The **arteria radialis indicis** (fig. 732), which frequently arises from the proximal part of the arteria princeps pollicis, descends between the first Dorsal interosseous and the transverse head of the Adductor pollicis, and runs along the lateral side of the index finger to its extremity: it anastomoses with the digital artery supplying the medial side of the finger. At the

lower border of the transverse head of the Adductor pollicis this vessel anastomoses with the arteria princeps pollicis, and gives a communicating branch to the superficial palmar arch.

Fig. 732.—The arteries of the forearm and hand. Deep dissection.



The arteria princeps pollicis and arteria radialis indicis may spring from a common trunk, which is named the *first palmar metacarpal artery*.

The **deep palmar arch** (fig. 732) is formed by the anastomosis of the terminal part of the radial artery with the deep branch of the ulnar artery. It lies upon the proximal ends of the metacarpal bones and on the Interossei, and is covered by the oblique head of the Adductor pollicis, the flexor tendons of the fingers and the Lumbrical muscles. In its concavity, but running towards the lateral side of the hand, is the deep branch of the ulnar nerve.

The branches of the deep palmar arch are: palmar metacarpal, perforating and recurrent.

The **palmar metacarpal arteries** (fig. 732), three in number, arise from the convexity of the deep palmar arch; they run distally upon the Interossei of the second, third and fourth spaces, and, at the clefts of the fingers, join the digital branches of the superficial palmar arch.

The **perforating branches**, three in number, pass backwards from the deep palmar arch, through the second, third and fourth interosseous spaces and between the heads of the corresponding Dorsal interosseous muscles, to anastomose with the dorsal metacarpal arteries.

The **recurrent branches** arise from the concavity of the deep palmar arch; they ascend in front of the wrist, supply the intercarpal articulations, and end in the anterior carpal arch.

The Ulnar Artery (figs. 730 to 735)

The **ulnar artery**, the larger of the two terminal branches of the brachial artery, begins opposite to the neck of the radius, about 1 cm. below the bend of the elbow, and, passing downwards and medially, reaches the medial side of the forearm at a point about midway between the elbow and the wrist. It then runs along the medial side of the forearm to the wrist, and crosses the flexor retinaculum (transverse carpal ligament) on the lateral side of the ulnar nerve and the pisiform bone. Immediately beyond this bone it gives off a deep branch, and is then continued across the palm under the name of the superficial palmar arch.

Relations.—(*a*) *In the forearm.*—The *upper half* of the vessel (figs. 730, 731, 732) is deeply seated, passing obliquely under cover of the Pronator teres, Flexor carpi radialis, Palmaris longus and Flexor digitorum sublimis to the medial side of the forearm, where it is overlapped by the Flexor carpi ulnaris; it lies upon the Brachialis and the Flexor digitorum profundus. Below the elbow the median nerve is on the medial side of the artery for about 2·5 cm. and then crosses the vessel, but is separated from it by the ulnar head of the Pronator teres. The *lower half* of the vessel (figs. 730, 735) lies upon the Flexor digitorum profundus; it is covered by the skin, superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor digitorum sublimis.

It is accompanied by two venæ comitantes, and is overlapped in its middle one-third by the Flexor carpi ulnaris; the ulnar nerve lies close to the medial side of the lower two-thirds of the artery, and the palmar cutaneous branch of this nerve descends on the lower part of the vessel to the palm of the hand.

(*b*) *At the wrist* (figs. 732, 733, 734) the ulnar artery is covered by the skin and fasciæ and the Palmaris brevis muscle, and lies between the superficial and the main part of the flexor retinaculum (p. 609). The ulnar nerve and the pisiform bone are on its medial side.

Peculiarities.—The ulnar artery varies in its origin in about 8 per cent. of cases; it frequently arises above the elbow, the brachial being more often the source of origin than the axillary. When its origin is normal, the course of the vessel is rarely changed. When the artery arises high up, it is usually superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and skin; the brachial artery then gives off the common interosseous artery, and the latter, the anterior and posterior ulnar recurrent arteries. Occasionally it is subcutaneous in the upper part of the forearm, and subfascial in the lower part.

When the ulnar artery is superficial there is some danger of its being wounded when the median cubital vein is opened for the purpose of transfusing blood or injecting saline solution.

The branches of the ulnar artery may be arranged in the following groups:

In the forearm	Anterior recurrent. Posterior recurrent. Common interosseous. Muscular.	*At the wrist* *In the hand*	Anterior carpal. Posterior carpal. Deep branch. Superficial palmar arch.

The **anterior ulnar recurrent artery** (figs. 729, 732), a small branch, arises immediately below the elbow-joint, runs upwards between the Brachialis and Pronator teres, supplies twigs to those muscles, and, in front of the medial epicondyle, anastomoses with the ulnar collateral and supratrochlear arteries.

The **posterior ulnar recurrent artery** (figs. 729, 732) is much larger, and arises somewhat lower than the anterior artery. It passes backwards and medially on the Flexor digitorum profundus, behind the Flexor digitorum sublimis, and ascends behind the medial epicondyle of the humerus. In the interval between this process and the olecranon, it lies deep to the Flexor carpi ulnaris, and ascends between the two heads of this muscle, in contact with the ulnar nerve; it supplies the neighbouring muscles and the elbow-joint, and anastomoses with the ulnar collateral, the supratrochlear and the interosseous recurrent arteries (fig. 736).

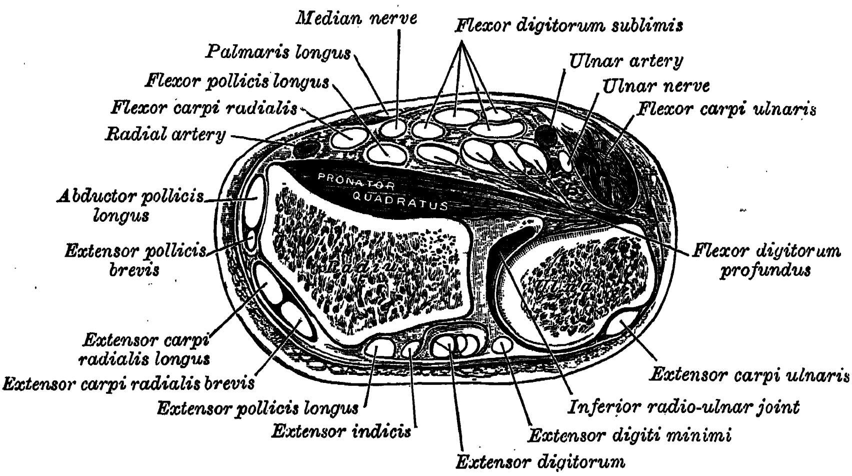
The **common interosseous artery** (fig. 732), about 1 cm. in length, arises immediately below the tuberosity of the radius, and, passing backwards to the upper border of the interosseous membrane of the forearm, divides into two branches, termed the *anterior* and *posterior interosseous arteries*.

The **anterior interosseous artery** (figs. 732, 735) descends on the anterior surface of the interosseous membrane of the forearm, accompanied by the anterior interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor digitorum profundus and Flexor pollicis longus; it gives off *muscular* branches, and the *nutrient* arteries of the radius and ulna. At the upper border of the Pronator quadratus it pierces the interosseous membrane and reaches the back of the forearm, where it anastomoses with the

posterior interosseous artery and descends on the back of the wrist in the compartment of the extensor retinaculum (dorsal carpal ligament) containing the tendons of the Extensor digitorum and Extensor indicis, and joins the posterior carpal arch. Before the artery pierces the interosseous membrane, it sends a branch downwards behind the Pronator quadratus to join the anterior carpal arch. The *arteria mediana*, a long, slender branch, arises from the beginning of the anterior interosseous artery, and accompanies the median nerve closely. Sometimes it is much enlarged and runs with the nerve into the palm of the hand (p. 152), where it may join the superficial palmar arch or end as one or two of the palmar digital arteries.

The **posterior interosseous artery** (figs. 735, 736), usually smaller than the anterior interosseous artery, passes backwards between the oblique cord and the upper border of the antebrachial interosseous membrane. It appears on

FIG. 733.—A transverse section through the lower ends of the left radius and ulna. Superior aspect.



the back of the forearm between the contiguous borders of the Supinator and the Abductor pollicis longus, and descends between the superficial and deep layers of muscles, to both of which it distributes branches. As it lies upon the Abductor pollicis longus, it is accompanied by the posterior interosseous nerve (deep branch of the radial nerve). At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery, and with the posterior carpal arch. It gives off, near its origin, the *interosseous recurrent artery*, which ascends to the interval between the lateral epicondyle and olecranon, on or through the fibres of the Supinator, but deep to the Anconeus, and anastomoses with the posterior descending branch of the arteria profunda brachii, and with the posterior ulnar recurrent, and supratrochlear (inferior ulnar collateral) arteries.

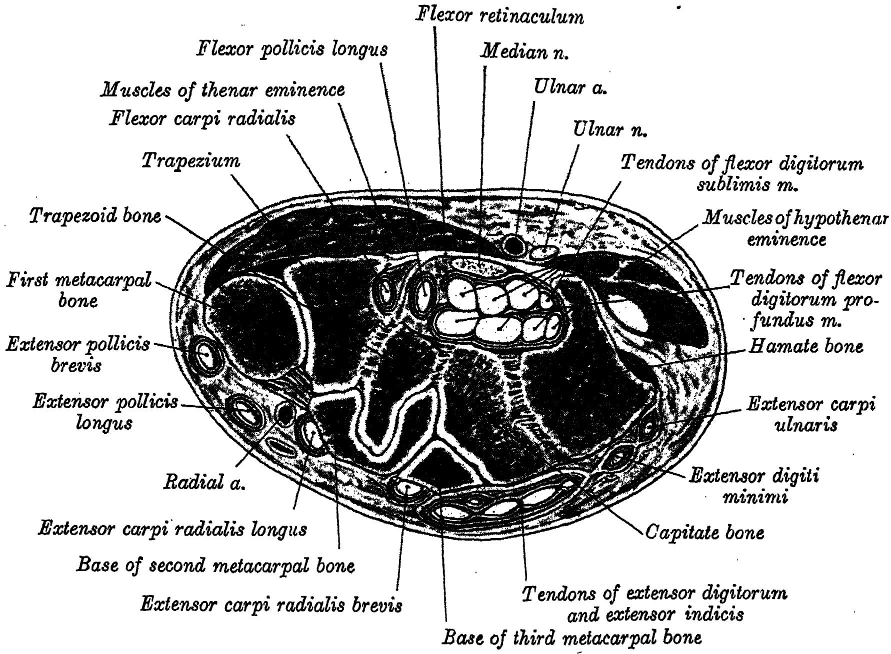
The **muscular branches** are distributed to the muscles along the ulnar side of the forearm.

The **anterior carpal branch** is a small vessel which crosses the front of the carpus behind the tendons of the Flexor digitorum profundus ; it anastomoses with the anterior carpal branch of the radial artery, and assists in forming the anterior carpal arch (p. 750).

The **posterior carpal branch** arises immediately above the pisiform bone, and winds backwards deep to the tendon of the Flexor carpi ulnaris ; it passes laterally across the posterior surface of the carpus under cover of the extensor tendons, anastomoses with the posterior carpal branch of the radial artery, and assists in forming the posterior carpal arch (p. 751). Near to its origin it gives off a small branch which runs along the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

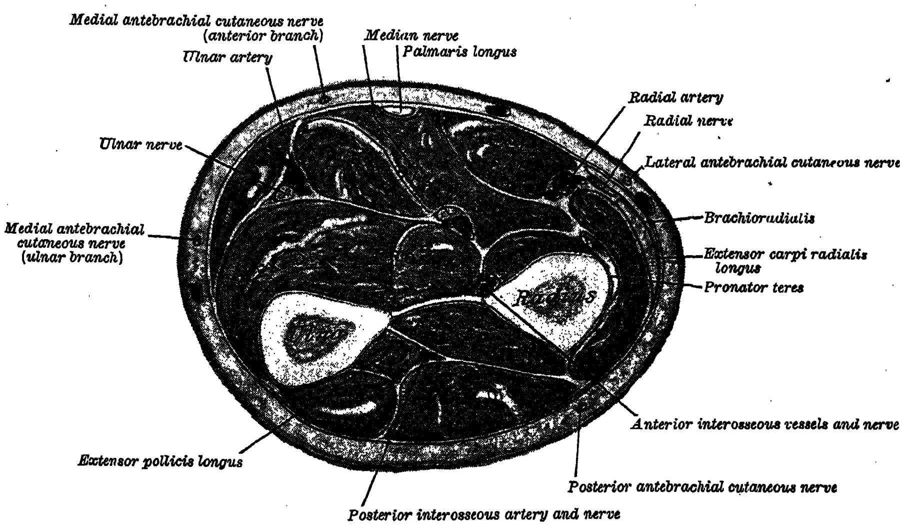
The **deep branch** (fig. 732) passes between the Abductor digiti minimi and Flexor digiti minimi, and through or deep to the origin of the Opponens digiti

FIG. 734.—A transverse section through the left wrist. Superior aspect.



The section is slightly oblique and divides the distal row of the carpus, and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure is not diagrammatic but represents the actual condition at this level. Observe that the carpometacarpal joint of the thumb is shut off from the joint between the trapezium and the base of the second metacarpal bone.

FIG. 735.—A transverse section through the middle of the forearm.

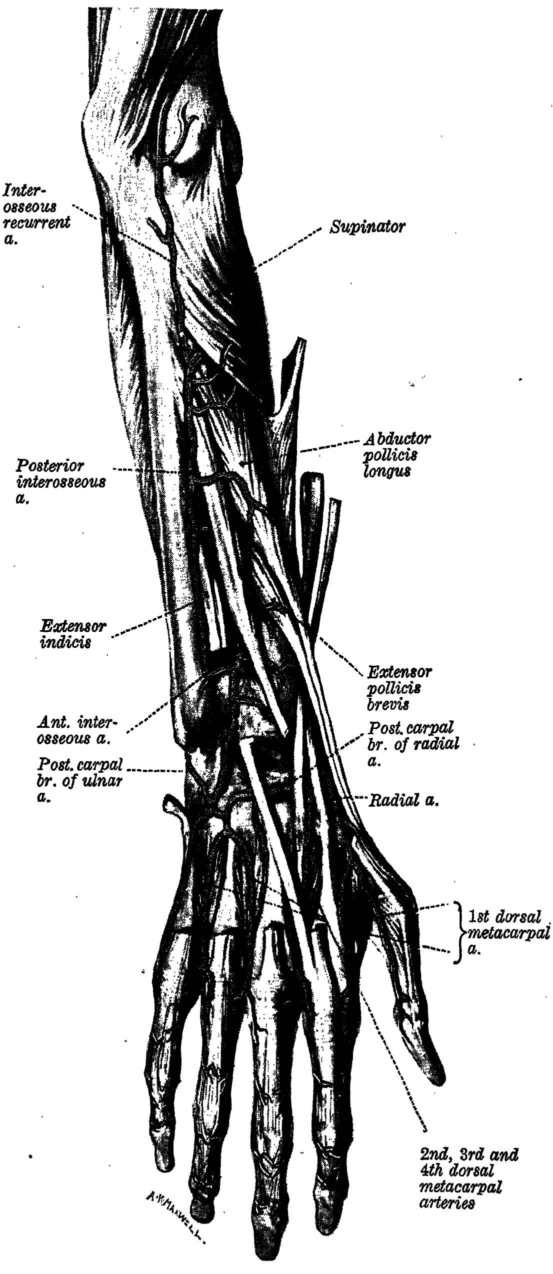


minimi; it anastomoses with the radial artery, and completes the deep palmar arch; it is accompanied by the deep branch of the ulnar nerve.

The **superficial palmar arch** (superficial volar arch) (fig. 730) is formed mainly by the ulnar artery, which enters the hand with the ulnar nerve in

front of the flexor retinaculum (transverse carpal ligament), and on the lateral side of the pisiform bone. It then passes across the palm, forming the superficial palmar arch, the convexity of which is directed towards the fingers, and is placed at the level of a line drawn across the hand from the distal border of the root of the extended thumb. The arch is usually completed by a branch of the arteria radialis indicis, but sometimes by the superficial palmar artery or a branch of the arteria princeps pollicis. The arch is covered by the palmaris brevis and the palmar aponeurosis, and lies on the Flexor digiti minimi, the branches of the median nerve, the flexor tendons and the Lumbricals.

FIG. 736.—The arteries of the posterior surface of the right forearm and hand.



Three **palmar digital arteries** (fig. 730) arise from the convexity of the superficial palmar arch and proceed downwards on the second, third and fourth Lumbricals. Each is joined by the corresponding palmar metacarpal artery from the deep palmar arch, and then divides into a pair of vessels, which run along the contiguous sides of the index, middle, ring and little fingers, behind the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger tips and by smaller branches near the interphalangeal joints. Each gives off two dorsal branches, which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the middle and distal phalanges, including the matrix of the finger-nail. The palmar digital artery for the medial side of the little finger springs from the arch under cover of the Palmaris brevis.

A free anastomosis takes place between the radial and ulnar arteries, (*a*) on the front and back of the wrist through the anterior and posterior carpal arches, and (*b*) in the hand through the superficial and deep palmar arches, and their digital and metacarpal branches.

Applied Anatomy.—Wounds of the palmar arches are always difficult to deal with. When the superficial arch is involved it is generally possible (enlarging the wound when necessary) to secure the vessel and tie it on both sides of the bleeding point; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of artery clips may be applied and left on for twenty-four or forty-eight hours. Failing this, the wound

may be plugged with gauze and an outside dressing carefully bandaged on. The plug should remain untouched for three or four days. It is useless in these cases to ligature one of the arteries of the forearm alone, and simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal networks. Therefore, upon the failure of pressure to arrest hæmorrhage, it is expedient to apply a ligature to the brachial artery.

When an incision for deep-seated suppuration in the synovial sheath of the flexor tendons is required, the situation of the superficial arch must always be borne in mind, and the incisions placed either above or below it. The position of the digital branches of the artery must also be remembered, and the incisions made in front of the heads of the metacarpal bones and not between them.

THE ARTERIES OF THE TRUNK

The Descending Aorta

The **descending aorta** is divided into two portions, *descending thoracic* and *abdominal*, in correspondence with the two great cavities in which it is situated.

The Descending Thoracic Aorta (fig. 737)

The **descending thoracic aorta** is contained in the posterior mediastinum. It begins at the lower border of the fourth thoracic vertebra, where it is continuous with the aortic arch (p. 694), and ends in front of the lower border of the twelfth thoracic vertebra at the aortic opening in the Diaphragm. At its origin it is situated on the left of the vertebral column; as it descends it approaches the median plane, and at its termination lies in front of the column.

Relations.—It is in relation, *anteriorly*, from above downwards, with the root of the left lung, the pericardium—which separates it from the left atrium—the œsophagus and the Diaphragm; *posteriorly*, with the vertebral column and the hemiazygos veins; on the *right side*, with the azygos vein and thoracic duct and, in the lower part of its course, with the right pleura and lung; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying plexus of nerves, lies on the right side of the aorta above; but at the lower part of the thorax it is placed in front of the vessel, and, close to the Diaphragm, is placed anteriorly and to its left side.

The Branches of the Descending Thoracic Aorta

Visceral	Pericardial.	*Parietal*	Mediastinal.
	Bronchial.		Phrenic.
	Œsophageal.		Posterior intercostal.
			Subcostal.

The **pericardial branches** consist of a few small vessels which are distributed to the posterior surface of the pericardium.

The **bronchial arteries** vary in number, size and origin. There is as a rule one **right bronchial artery**, which arises from the third posterior (first aortic) intercostal artery, or from the upper left bronchial artery. It runs on the posterior surface of the right bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lung and the bronchopulmonary lymph glands; it also sends branches to the pericardium and the œsophagus. The **left bronchial arteries**, usually two in number, arise from the descending thoracic aorta, the upper opposite the fifth thoracic vertebra, and the lower just below the left bronchus. They run on the posterior surface of the left bronchus and have a distribution similar to that of the right bronchial artery.

The **œsophageal arteries**, four or five in number, arise from the front of the aorta, and pass obliquely downwards to the œsophagus; on this they form a vascular chain, which anastomoses above with the œsophageal branches of the inferior thyroid arteries, and below with ascending branches from the left phrenic and left gastric arteries.

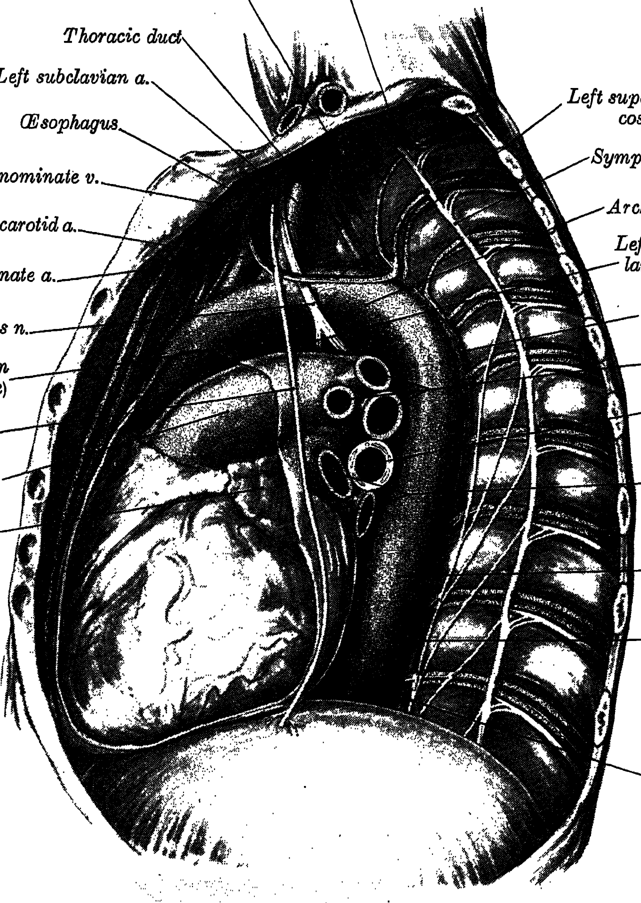
The **mediastinal branches** are numerous small vessels which supply the lymph glands and the areolar tissue in the posterior mediastinum.

The **phrenic branches** are small, and arise from the lower part of the descend-

ing thoracic aorta; they are distributed to the posterior part of the upper surface of the Diaphragm, and anastomose with the musculophrenic and pericardiacophrenic arteries.

The posterior intercostal arteries.—There are usually nine pairs of posterior intercostal arteries derived from the descending thoracic aorta. They arise from the back of the vessel, and are distributed to the lower nine intercostal

FIG. 737.—The heart and the thoracic aorta. Left lateral aspect.



spaces, the first and second spaces being supplied by the superior intercostal artery, a branch of the costocervical trunk of the subclavian artery (p. 739). The *right* posterior intercostal arteries are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they cross the bodies of the vertebræ behind the œsophagus, thoracic duct and vena azygos, and are covered with the right lung and pleura. The *left* posterior intercostal arteries run backwards on the sides of the vertebræ and are covered with the left lung and pleura; the upper two vessels are crossed by the left superior intercostal vein, the lower vessels by the hemiazygos veins. The further course of the posterior intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic trunk passes downwards in front of them, and the splanchnic nerves also descend in front of the lower arteries.

Each artery (fig. 737) crosses its intercostal space obliquely towards the

angle of the upper rib, and thence is continued forward in the costal groove. It is placed at first between the pleura and the posterior intercostal membrane, as far as the angle of the rib ; from this onward it runs between the Internal intercostal and the Intercostalis intimus muscle (p. 553), and anastomoses in front with the anterior intercostal branch of the internal mammary or musculophrenic artery. Each artery is accompanied by a vein and a nerve, the former being above and the latter below the artery, except in the upper spaces, where the nerve is at first above the artery. The third posterior (first aortic) intercostal artery anastomoses with the superior intercostal artery, and may form the chief supply of the second intercostal space. The lower two posterior intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall and anastomose with the subcostal, superior epigastric and lumbar arteries.

Each posterior intercostal artery gives off the following branches :

Posterior.	Muscular.
Collateral intercostal.	Lateral cutaneous.
Mammary.	

Each **posterior branch** runs backwards through a space which is bounded above and below by the necks of the ribs, medially by the body of a vertebra, and laterally by a superior costotransverse ligament (anterior costotransverse ligament). It gives off a *spinal branch*, which enters the vertebral canal through the intervertebral foramen, and is distributed to the vertebræ and to the spinal cord and its membranes, anastomosing with the spinal arteries above and below and with the artery of the opposite side. The posterior branch then courses over the transverse process with the posterior primary ramus of the thoracic nerve, supplies offshoots to the muscles of the back, and a cutaneous twig which accompanies the cutaneous branch of the posterior primary ramus of the nerve.

The **collateral intercostal branch** comes off the posterior intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with an intercostal branch of the internal mammary or musculophrenic artery. The collateral branches of the lower two vessels are sometimes absent ; if present, they are small and end in the abdominal muscles.

Muscular branches are given to the Intercostal and Pectoral muscles and to the Serratus anterior ; they anastomose with the superior and lateral thoracic branches of the axillary artery.

The **lateral cutaneous branches** accompany the lateral cutaneous branches of the thoracic nerves.

Mammary branches are given off by the vessels in the second, third and fourth spaces ; they increase considerably in size during the period of lactation.

The **right bronchial artery** may arise from the right third posterior (first aortic) intercostal artery (p. 757).

Applied Anatomy.—The position of the posterior intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the posterior median line than the angle of the rib, as the artery crosses the space medial to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The relation of the Diaphragm to the deep surface of the lower intercostal spaces must be remembered, otherwise the abdominal cavity may be opened inadvertently while making incisions in these spaces.

The **subcostal arteries**, the last pair of arteries arising from the descending thoracic aorta, are in series with the posterior intercostal arteries, but are named *subcostal* because they are situated below the twelfth rib. Each artery runs laterally over the body of the twelfth thoracic vertebra, and behind the splanchnic nerves, the gangliated trunk of the sympathetic, the pleura and the Diaphragm. The right artery also passes behind the thoracic duct and the vena azygos, and the left behind the inferior hemiazygos vein. Each artery then enters the abdomen under cover of the lateral arcuate ligament (lateral lumbocostal arch), and courses with the twelfth thoracic nerve along the lower

border of the twelfth rib, anterior to the Quadratus lumborum and posterior to the kidney. The right artery runs behind the ascending, and the left behind the descending, colon. Each artery then pierces the aponeurosis of origin of the Transversus abdominis, and, passing forward between this muscle and the Obliquus internus, anastomoses with the superior epigastric, lower posterior intercostal and lumbar arteries. Each subcostal artery gives off a posterior branch, which is distributed like the posterior branch of a posterior intercostal artery.

A small **aberrant artery** is sometimes found arising from the right side of the descending thoracic aorta near the origin of the right bronchial. It passes upwards and to the right behind the trachea and the œsophagus, and may anastomose with the right superior intercostal artery. It represents the remains of the right dorsal aorta (p. 149), and in a small proportion of cases is enlarged to form the first part of the right subclavian artery.

Peculiarities.—The lumen of the aorta is occasionally found to be partly or completely obliterated, either at the aortic isthmus, or close to the point where the ductus arteriosus opens into it. This condition is known as *coarctation of the aorta.* It may be either congenital or acquired. In the former case the infant usually dies at or soon after birth. When acquired, it is apparently due to an abnormal extension of the peculiar tissue of the ductus into the aortic wall, giving rise to a simultaneous stenosis of both vessels as it contracts after birth. This form of coarctation is compatible with many years of normal life, and leads to the establishment of an extensive collateral circulation to carry blood to the aorta immediately below the stenosis. In one case the following vessels were involved—Firstly, the internal mammary anastomosed with the posterior intercostal arteries and with the phrenic of the abdominal aorta by means of the musculophrenic and pericardiacophrenic, and its superior epigastric branch anastomosed freely with the inferior epigastric. Secondly, the costocervical trunk anastomosed anteriorly by means of a large branch with the third posterior (first aortic) intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the third posterior intercostal. Fourthly, the transverse cervical, by means of very large communications, anastomosed with the posterior branches of the posterior intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest anastomosed freely with the lateral branches of the intercostals. In a second case Wood described the anastomoses in a somewhat similar manner, adding the remark, that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis; while the supply to the lower extremities had passed through the internal mammary and epigastrics."

Applied Anatomy.—Aneurysm of the descending thoracic aorta most commonly extends backwards along the left side of the vertebral column and leads to absorption of the bodies of the vertebræ (but not of the intervertebral discs) and of the ribs; pressure on the intercostal nerves may give rise to radiating pains in the left upper intercostal spaces; after erosion of the vertebræ the aneurysm may compress the spinal nerve-roots or ultimately the spinal cord, producing pains in the chest, back or loins, or paralysis below the site of the lesion; at the same time the aneurysm may project backwards under the skin as a pulsating swelling. If the aneurysm extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; it may displace or compress the œsophagus, causing pain and difficulty of swallowing, and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the aneurysm extend to the right side, it may press upon the thoracic duct; it may burst into the pleural cavity, or into the lung; or it may open into the posterior mediastinum. Pressure on one of the bronchi, usually the left, will cause cough, and in time set up bronchiectasis. Of late years, the diagnosis of thoracic aneurysm has been much facilitated by the employment of the x-rays, by means of which the outline of the sac may be demonstrated.

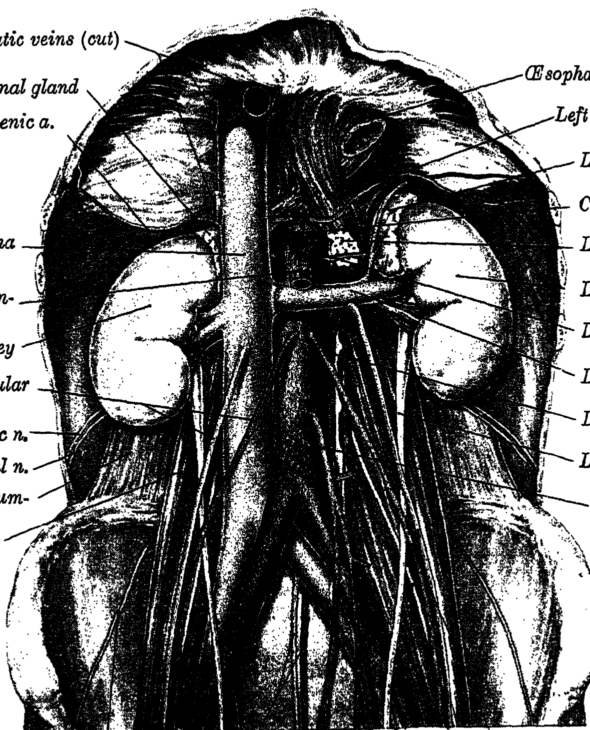
The Abdominal Aorta (fig. 738)

The **abdominal aorta** begins at the aortic opening of the Diaphragm, in front of the lower border of the body of the last thoracic vertebra, and, descending in front of the vertebral column, ends on the body of the fourth lumbar vertebra, a little to the left of the median plane, by dividing into the two common iliac arteries. It diminishes rapidly in size, in consequence of the large branches which arise from it.

Relations.—*Anteriorly* the abdominal aorta is at first related to the cœliac artery and its branches, the cœliac plexus of nerves and the lesser sac of

peritoneum (omental bursa), which intervene between it and the papillary process of the liver and the lesser omentum. Immediately below this level the aorta gives origin to the superior mesenteric artery, and is crossed by the left renal vein. The body of the pancreas, with the splenic vein closely applied to its posterior aspect, extends obliquely upwards and to the left across the abdominal aorta, but is separated from it by the vessels already mentioned. Below the pancreas the aorta is related to the proximal parts of its testicular (or ovarian) branches, and is crossed by the third part of the duodenum. In its lowest part the aorta comes into intimate relationship with the posterior parietal peritoneum and is crossed by the root of the mesentery and its contents. The

Fig. 738.—The abdominal aorta and its branches.



large nerves of the aortic plexus, the inferior mesenteric ganglion, and the commencement of the inferior mesenteric artery all intervene between the vessel and the peritoneum.

Posteriorly the abdominal aorta lies on the upper four lumbar vertebræ, the corresponding intervertebral discs and the anterior longitudinal ligament. The lumbar arteries; which arise from its dorsal aspect, and the third and fourth and sometimes the second left lumbar veins, which cross behind it to reach the inferior vena cava, intervene between the vessel and the ligament. The vessel may overlap the anterior border of the left Psoas major muscle to a slight extent.

On the *right side*, it is related above to the cisterna chyli and the thoracic duct, the azygos vein, and the right crus of the Diaphragm, which overlaps it and separates it from the inferior vena cava and the right cœliac ganglion. Below the level of the second lumbar vertebra it is in contact with the inferior vena cava.

On the *left side*, it is related to the left crus of the Diaphragm and the left cœliac ganglion, above. Opposite the second lumbar vertebra it comes into

relation with the duodeno-jejunal flexure and the sympathetic trunk, which continues downwards along the left side of the vessel. The fourth (ascending) part of the duodenum and the inferior mesenteric vessels constitute additional relations.

Applied Anatomy.—Aneurysm of the abdominal aorta occurs most frequently at its upper part, close to and often involving the cœliac artery, because in this situation the vessel rapidly narrows after giving off several large branches, and its walls have lost the support afforded higher up by the crura of the Diaphragm.

If the aneurysm enlarges forwards it forms a pulsating tumour in the left hypochondriac or epigastric regions; by pressure upwards at the same time it may interfere with the movements of the Diaphragm and embarrass respiration, or may compress the œsophagus and produce dysphagia; pressure on the stomach and cœliac plexus gives rise to dyspepsia, while jaundice may follow pressure on the bile duct and duodenum, or polyuria, albuminuria, hæmaturia and anuria pressure on the renal vessels and nerves; if the inferior vena cava is compressed there may be œdema of the lower limbs. This form of aneurysm may burst into the peritoneal cavity, behind the peritoneum, between the layers of the mesentery, or more rarely into the duodenum.

When an aneurysm of the abdominal aorta enlarges backwards it usually produces absorption of the bodies of the vertebræ. Pain is invariably present and is usually of two kinds—a fixed and constant pain in the back, caused by the tumour eroding the bones, and a sharp lancinating pain radiating to the loins, hypogastrium and buttocks along the branches of the lumbar nerves which are pressed on by the tumour.

The abdominal aorta has been tied in several cases, and although none of the patients permanently recovered, still, as one case lived forty-eight days, the possibility of the re-establishment of the circulation may be considered to be proved.

Collateral Circulation.—The collateral circulation would be carried on by the anastomoses between the internal mammary and the inferior epigastric arteries; by the free communication between the superior and inferior mesenteric arteries, if the ligature were placed between these vessels; or by the anastomosis between the inferior mesenteric and the internal pudendal arteries, when (as is more common) the point of ligature is below the origin of the inferior mesenteric artery; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac (hypogastric) artery.

The Branches of the Abdominal Aorta (fig. 738)

The branches of the abdominal aorta may be divided into four sets: ventral, lateral, dorsal and terminal. The ventral and lateral branches are distributed to viscera, while the dorsal branches supply the body wall.

Ventral branches.
Cœliac.
Superior mesenteric.
Inferior mesenteric.

Lateral branches.
Phrenic.
Middle suprarenal.
Renal.
Testicular (in the male).
Ovarian (in the female).

Dorsal branches.
Lumbar.
Median sacral.

Terminal branches.
Common iliac.

The ventral branches, which supply the alimentary canal and its derivatives, represent fused ventral branches of the two dorsal aortæ and are therefore unpaired. The lateral branches, which supply the derivatives from the mesonephric ridges, are all paired vessels. Of the dorsal branches, the lumbar arteries, which represent persistent intersegmental arteries (p. 150), are paired, but the median sacral is an unpaired vessel. The terminal branches are paired.

The Cœliac Artery (figs. 739, 740)

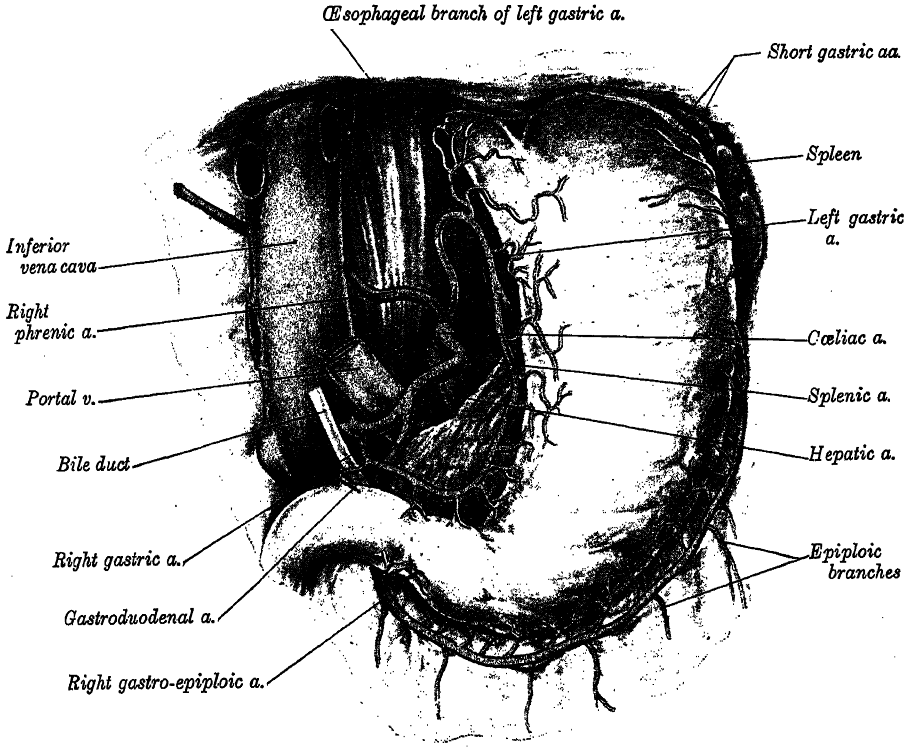
The cœliac artery is a thick trunk, about 1·25 cm. long, which arises from the front of the aorta, just below the aortic opening of the Diaphragm; it passes nearly horizontally forwards above the pancreas and the splenic vein,

and divides into three branches, (1) *left gastric*, (2) *hepatic*, and (3) *splenic*; it occasionally gives off one of the phrenic arteries.

Relations.—The cœliac artery lies behind the lesser sac of the peritoneum (omental bursa), and is surrounded by the cœliac plexus of nerves, which sends branches along the three divisions of the artery. On its *right side* it is related to the right cœliac ganglion, the right crus of the Diaphragm, and the caudate process of the liver: on its *left side* to the left cœliac ganglion, the left crus of the Diaphragm, and the cardiac end of the stomach. *Below* it is related to the upper border of the pancreas and the splenic vein.

1. The **left gastric artery** (fig. 739), which is the smallest branch of the cœliac artery, passes upwards and to the left, behind the lesser sac, to the cardiac

FIG. 739.—The cœliac artery and its branches.



The liver and the lesser omentum have been removed. The posterior wall of the lesser sac and the anterior layer of the greater omentum have been taken away.

end of the stomach. In its course, the left gastric artery lies close to the left phrenic artery and medial to or in front of the left suprarenal gland. At or near the cardiac end of the stomach it gives off two or three *œsophageal branches*, which ascend through the œsophageal opening of the Diaphragm and anastomose with the aortic œsophageal arteries; others supply the cardiac part of the stomach and anastomose with branches of the splenic artery. The artery then turns forwards and downwards in the left gastropancreatic fold, and runs (frequently as two branches) along the lesser curvature of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the stomach and anastomoses with the right gastric artery.

2. The **hepatic artery** (figs. 739, 741) is intermediate in size between the left gastric and splenic arteries. It is accompanied by the hepatic plexus of nerves, and is first directed forwards and to the right, to the upper margin of the first part of the duodenum, passing below the medial end of the opening into the lesser sac (epiploic foramen) (fig. 1162). It then crosses in front of the portal vein, and ascends between the layers of the lesser omentum and in

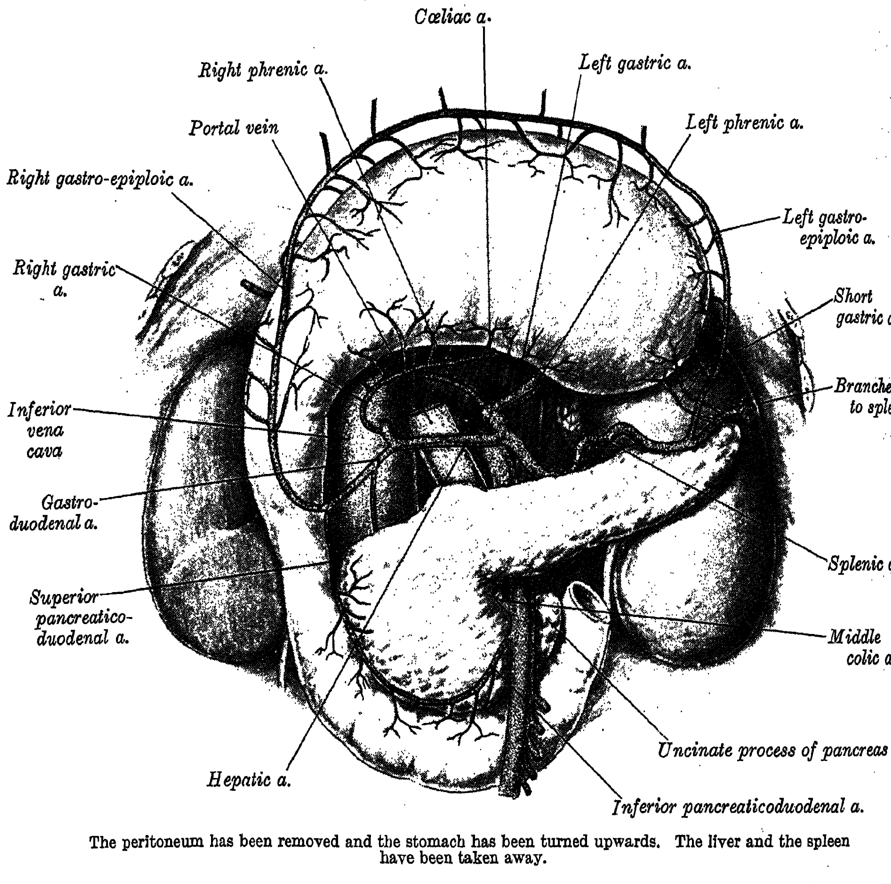
front of the opening into the lesser sac, to the porta hepatis, where it divides into right and left branches which supply the corresponding lobes of the liver, accompanying the ramifications of the portal vein and hepatic ducts. In the lesser omentum the hepatic artery lies in front of the portal vein, and on the left of the bile-duct and its right branch crosses behind the common hepatic duct (fig. 741). The distribution of the hepatic artery within the liver is described with the anatomy of the liver, in the section on Splanchnology.

Its branches are :

Right gastric. Gastroduodenal. Cystic.

The **right gastric artery** (fig. 739) arises from the hepatic artery above the first part of the duodenum ; it descends in the lesser omentum to the pyloric

FIG. 740.—The cœliac artery and its branches.



The peritoneum has been removed and the stomach has been turned upwards. The liver and the spleen have been taken away.

end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches, and anastomosing with the left gastric artery.

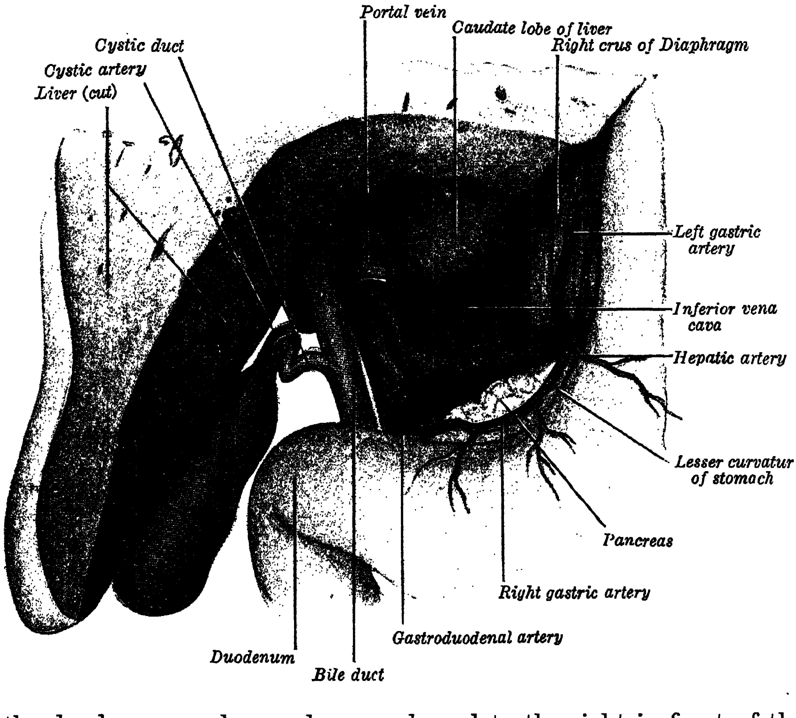
The **gastroduodenal artery** (figs. 739, 740) is a short but large branch, which descends between the first part of the duodenum and the neck of the pancreas, lying immediately to the right of the line along which the peritoneum is reflected from the posterior surface of the first half-inch of the duodenum (fig. 1161). At the lower border of the duodenum it divides into the *right gastro-epiploic* and the *superior pancreaticoduodenal* arteries. Previous to its division it gives off two or three small branches to the pyloric end of the stomach and to the pancreas.

The **right gastro-epiploic artery** (figs. 739, 740), which is the larger terminal branch of the gastroduodenal artery, skirts the right margin of the lesser sac and then runs from right to left along the greater curvature of the stomach, between the layers of the greater omentum. It ends by anastomosing with

the left gastro-epiploic branch of the splenic artery. Except at the pylorus, where it is in contact with the stomach, it lies about a finger's breadth from the greater curvature. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend to supply the greater omentum.

The **superior pancreaticoduodenal artery** (fig. 740) is usually represented by an anterior and a posterior vessel. The *anterior* descends on the front of the groove between the duodenum and the head of the pancreas. It supplies both of these organs, and anastomoses with the anterior division of the inferior pancreaticoduodenal branch of the superior mesenteric artery, and with the pancreatic branches of the splenic artery. The *posterior superior pancreatico-duodenal artery* arises from the gastroduodenal at the upper border of the first

FIG. 741.—Drawing of a dissection to show the relations of the hepatic artery, bile duct and portal vein in the lesser omentum.



part of the duodenum, and runs downwards and to the right in front of the portal vein and the bile duct. It then passes downwards on the back of the head of the pancreas, supplying branches to the gland and to the duodenum, and crosses behind the bile duct, just before that structure pierces the duodenal wall. It ends by anastomosing with the posterior division of the inferior pancreaticoduodenal artery.

The **cystic artery** (fig. 741), usually arises from the right branch of the hepatic artery, and passes behind the common hepatic and cystic ducts to gain the upper surface of the neck of the gall-bladder, on which it runs downwards and forwards before dividing into *superficial* and *deep* branches. The former ramifies on the free, and the latter on the attached, surface of the gall-bladder. Occasionally the cystic artery arises from the trunk of the hepatic artery or, rarely, from the gastroduodenal artery, and crosses in front of the bile duct to reach its destination.

3. The **splenic artery** (figs. 739, 740), which is the largest branch of the cœliac artery, is remarkable for the tortuosity of its course. Surrounded by the splenic plexus of nerves, and accompanied by the splenic vein, which lies behind the pancreas, it passes horizontally to the left, behind the stomach and the lesser sac of the peritoneum (omental bursa), and along the upper border of the pancreas; it crosses in front of the left suprarenal gland and the upper

part of the left kidney, and enters the lienorenal ligament. On arriving near the spleen it gives origin to five or six branches which enter the hilum of the spleen.

Its branches are :

Pancreatic.	Left gastro-epiploic.
Short gastric.	Splenic.

The **pancreatic branches** (fig. 740) are numerous small vessels supplying the body and tail of the pancreas ; they are derived from the splenic artery as it runs along the upper border of the pancreas. One branch, larger than the rest, is sometimes given off near the tail of the pancreas ; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is sometimes called the *arteria pancreatica magna*. These vessels anastomose with the pancreatic branches of the superior and inferior pancreaticoduodenal arteries.

The **short gastric arteries** (fig. 740) consist of from five to seven small branches which arise from the end of the splenic artery, and from its terminal divisions. They pass between the layers of the gastrosplenic ligament, and are distributed to the fundus of the stomach, anastomosing with branches of the left gastric and left gastro-epiploic arteries.

The **left gastro-epiploic artery** (figs. 739, 740), the largest branch of the splenic artery, runs from left to right about a finger's breadth from the greater curvature of the stomach, between the layers of the greater omentum, and anastomoses with the right gastro-epiploic artery. It distributes several ascending branches to both surfaces of the stomach ; others descend to supply the greater omentum. It should be observed that the splenic artery and its gastric branches pass round the left border of the lesser sac of the peritoneum (omental bursa) (fig. 1162).

The **splenic branches** enter the hilum of the spleen between the two layers of the lienorenal ligament. Their distribution within the spleen is described with the anatomy of that organ (p. 1424).

Peculiarities.—Although the arrangement of the cœliac artery and its branches is fairly constant, three variations are worthy of mention. (1) An *accessory right hepatic artery* sometimes arises from the superior mesenteric artery and runs upwards and to the right, passing behind the portal vein to gain the right extremity of the porta hepatis. (2) An *accessory left hepatic artery* not infrequently arises from the left gastric artery and courses to the right between the two layers of the lesser omentum. It enters the lower part of the fissure for the ligamentum venosum to gain the left extremity of the porta hepatis. (3) An *accessory left gastric artery* may arise from the left branch of the hepatic artery and traverse the lesser omentum to gain the lesser curvature of the stomach.

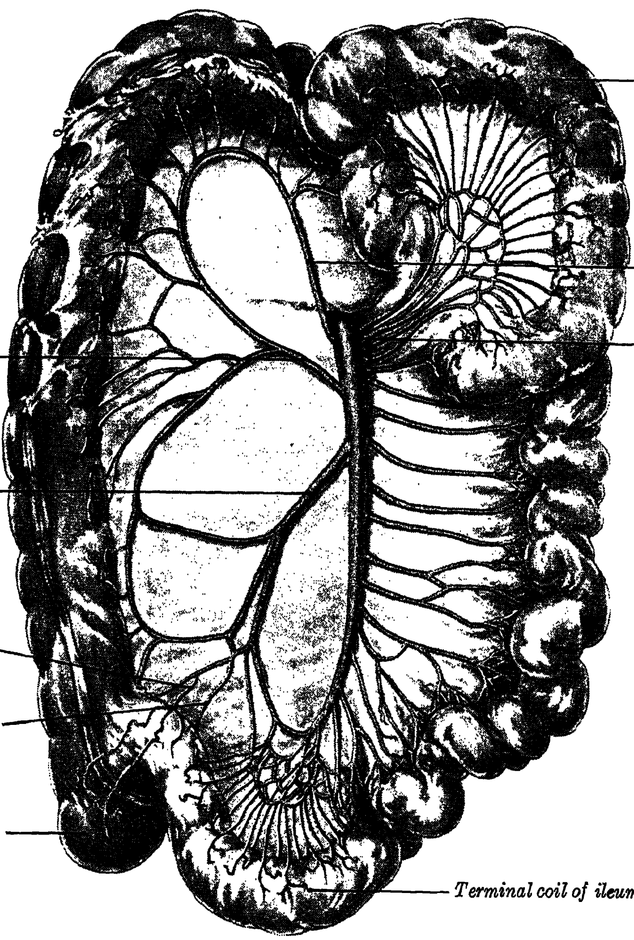
The Superior Mesenteric Artery (fig. 742)

The **superior mesenteric artery** supplies the whole of the small intestine except the first part of the duodenum ; it also supplies the cæcum and the ascending colon and most of the transverse colon. It arises from the front of the aorta about 1 cm. below the cœliac artery, and is crossed at its origin by the splenic vein and the body of the pancreas. Near its origin it is separated from the front of the aorta by the left renal vein. Thereafter it passes downwards and forwards, anterior to the uncinate process of the head of the pancreas and the third part of the duodenum, and descends between the layers of the mesentery and near its root until it reaches the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches, viz. the ileocolic artery. In its course it crosses in front of the inferior vena cava, the right ureter, and Psoas major, and forms an arch, the convexity of which is directed forwards, downwards, and to the left side. It is accompanied by the superior mesenteric vein, which lies to its right side, and is surrounded by the superior mesenteric plexus of nerves. Its branches are :

Inferior pancreaticoduodenal.	Ileocolic.
Jejunal and ileal.	Right colic.
Middle colic.	

The **inferior pancreaticoduodenal artery** (fig. 740) springs from the superior mesenteric artery or from its first jejunal branch, opposite the upper border of the third part of the duodenum. Usually it divides at once into an anterior and a posterior branch. The *anterior branch* courses to the right in front of the head of the pancreas and then ascends to anastomose with the anterior superior pancreaticoduodenal artery. The *posterior branch* passes upwards and to the right behind the head of the pancreas, which it sometimes pierces, to anastomose with the posterior superior pancreaticoduodenal artery. Both branches supply

FIG. 742.—The superior mesenteric artery and its branches.

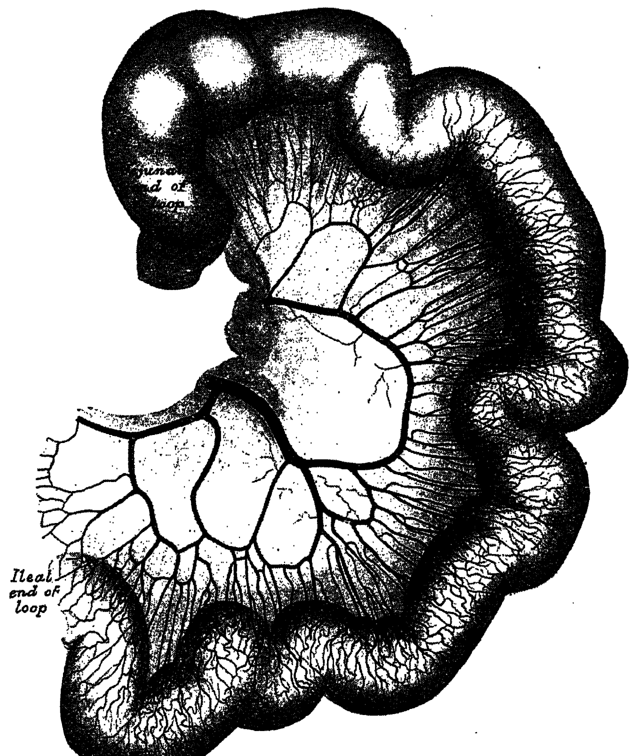


The first coil of the jejunum and the terminal coil of the ileum have been spread out to show the arrangement of their arteries.

the head of the pancreas, including its uncinate process, and the second, third and fourth parts of the duodenum.

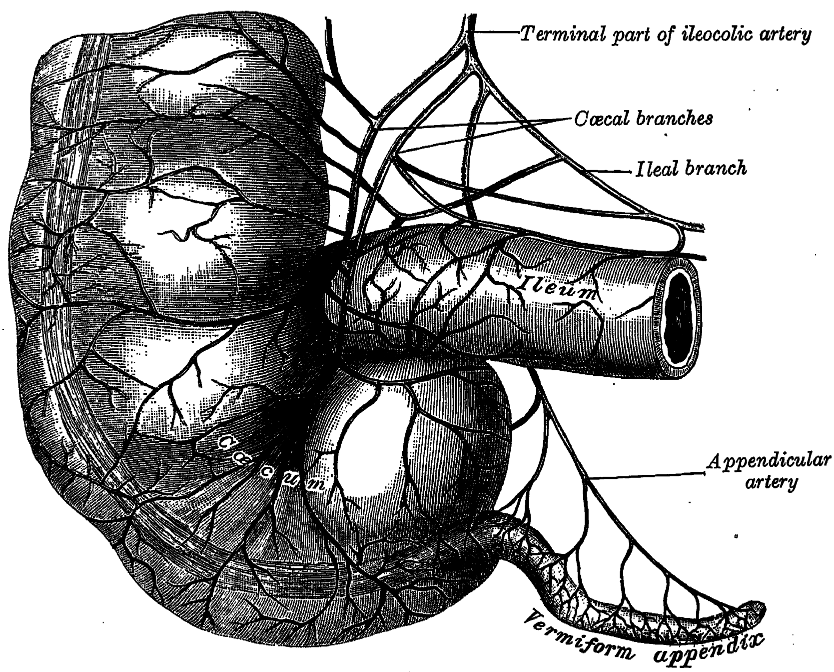
The **jejunal and ileal branches** (fig. 742) arise from the left side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum, with the exception of the terminal part of the latter, which is supplied by the ileocolic artery. They run nearly parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with adjacent branches, to form a series of arches (fig. 743). The branches which arise from the arches unite to form a second series of arches, and the process may be repeated three or four times. In the short, upper part of the mesentery only one set of arches exists, but as the mesentery increases in depth, second, third, fourth, and even fifth groups are present. From the terminal arches numerous small straight vessels arise which

FIG. 743.—A loop of the small intestine showing the distribution of the intestinal arteries. (From a preparation by Hamilton Drummond.)



The vessels were injected while the gut was *in situ*; the gut was then removed, and an x-ray photograph taken.

FIG. 744.—The arteries of the cæcum and vermiform appendix.



supply the intestine. These terminal branches are distributed, roughly alternately, to the right and left surfaces of the gut, and neighbouring vessels do not anastomose with one another.* As a rule the jejunal arteries are longer and less numerous than the ileal arteries. From both groups small branches are given off to the lymph glands and other structures between the layers of the mesentery.

The **ileocolic artery** (fig. 742) is the lowest of the branches arising from the concavity of the superior mesenteric artery. It passes downwards and to the right behind the peritoneum, towards the right iliac fossa, where it divides into a superior and an inferior branch ; the superior branch anastomoses with the right colic artery, the inferior with the end of the superior mesenteric artery. In its course, the ileocolic artery crosses in front of the right ureter, testicular (or ovarian) vessels and Psoas major muscle.

The inferior branch of the ileocolic runs towards the upper border of the ileocolic junction and supplies the following branches (fig. 744) : (*a*) *colic*, which passes upwards on the ascending colon ; (*b*) *anterior* and *posterior cæcal*, which are distributed to the front and back of the cæcum ; (*c*) an *appendicular artery*, which descends behind the termination of the ileum and enters the mesentery of the vermiform appendix ; it runs near the free margin of this mesentery and ends in branches which supply the vermiform appendix ; and (*d*) *ileal*, which runs upwards and to the left on the lower part of the ileum, and anastomoses with the termination of the superior mesenteric artery.

The **right colic artery** (fig. 742) arises from near the middle of the concavity of the superior mesenteric artery, or from a stem common to it and the ileocolic artery. It passes to the right behind the peritoneum, and in front of the right testicular (or ovarian) artery and vein, the right ureter, and the Psoas major, towards the ascending colon. Sometimes the vessel lies at a higher level, and crosses the second part of the duodenum and the lower end of the right kidney. At the colon it divides into a descending branch, which anastomoses with the ileocolic artery, and an ascending branch, which anastomoses with the middle colic artery. These branches form arches, from the convexity of which vessels are distributed to the ascending colon.

The **middle colic artery** (fig. 742) arises from the superior mesenteric artery just below the pancreas and, passing downwards and forwards between the layers of the transverse mesocolon, divides into a right and a left branch ; the former anastomoses with the right colic artery ; the latter with the superior left colic artery, a branch of the inferior mesenteric artery. The arches thus formed are placed about two fingers' breadth from the transverse colon, to which they distribute branches.

The Inferior Mesenteric Artery (fig. 745)

The **inferior mesenteric artery** supplies the terminal part of the transverse colon, the whole of the descending colon, the pelvic colon and the greater part of the rectum. It is smaller than the superior mesenteric artery, and arises from the aorta, about 3 or 4 cm. above its division into the common iliac arteries, and close to the lower border of the third part of the duodenum. It descends behind the peritoneum, lying at first in front of the aorta, and then on its left side. It crosses the left common iliac artery on the medial side of the left ureter, and is continued between the two layers of the pelvic mesocolon into the true pelvis as the *superior rectal* (*superior hæmorrhoidal*) *artery*, and ends on the upper part of the rectum. In the lower part of its course, the inferior mesenteric vein lies on its lateral side. Its branches are :

Superior left colic. Inferior left colic. Superior rectal.

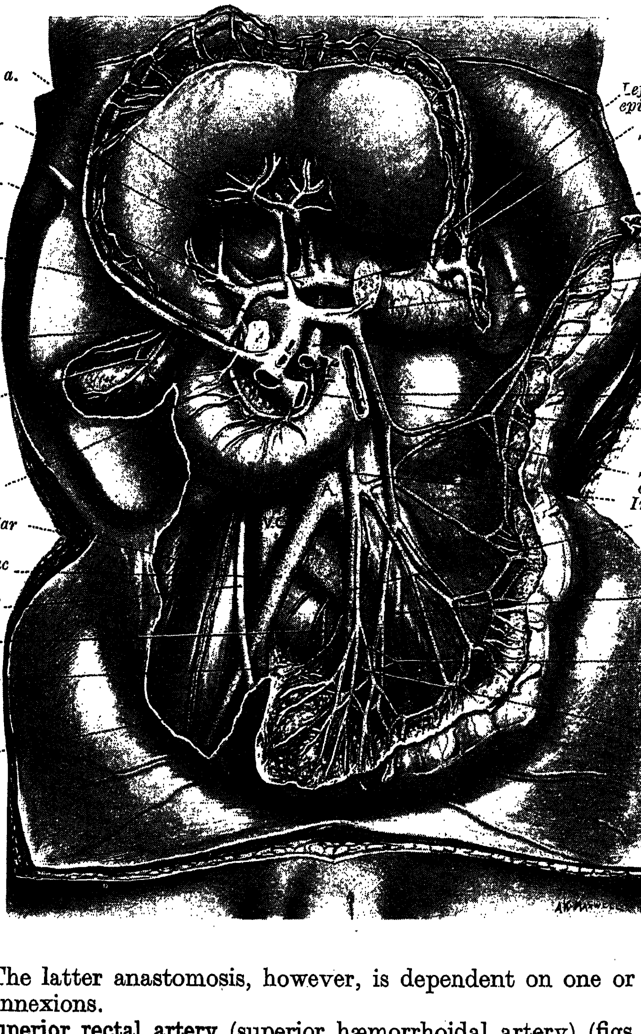
The **superior left colic artery** (fig. 745) runs upwards and to the left behind the peritoneum and in front of the Psoas major, and, after a short but variable course, divides into an ascending and a descending branch ; the trunk or the branches of the artery cross the left ureter and left testicular vessels. The ascending branch passes in front of the left kidney and then between the two layers of the transverse mesocolon, where it anastomoses with the middle colic

* A. J. Cokkinis, *Journal of Anatomy*, vol. lxiv. 1930.

artery ; the descending branch anastomoses with the highest inferior left colic (sigmoid) artery. From the arches formed by these anastomoses branches are distributed to the left half of the transverse colon, and to the descending colon.

The **inferior left colic arteries** (sigmoid arteries) (figs. 745, 746), two or three in number, run obliquely downwards and to the left behind the peritoneum and in front of the left Psoas major, ureter, and testicular vessels. Their branches supply the lower part of the descending colon and the pelvic colon, anastomosing above with the superior left colic artery, and below with the superior rectal

FIG. 745.—The inferior mesenteric vessels and their branches.



artery. The latter anastomosis, however, is dependent on one or more very slender connexions.

The **superior rectal artery** (superior hæmorrhoidal artery) (figs. 745, 746), which is the continuation of the inferior mesenteric artery, descends into the pelvis between the layers of the pelvic mesocolon, crossing, in its course, the left common iliac vessels. It divides, opposite the third sacral vertebra, into two branches ; these descend one on each side of the rectum, and supply its mucous membrane as far as the anal canal, and the upper part of its muscular coat ; about halfway down the rectum the two arteries break up into several small branches. These pierce the muscular coat of the bowel and run straight downwards in the wall of the gut between its muscular and mucous coats, to the level of the Sphincter ani internus ; here by anastomoses with one another they form a system of loops around the lower end of the rectum, and communicate with the middle rectal branches of the hypogastric (internal iliac) artery, and with the inferior rectal branches of the internal pudendal artery.

Applied Anatomy.—As a result of the free anastomoses between the left colic arteries a continuous 'marginal artery' descends near the gut from the left colic flexure to the distal end of the pelvic colon, where it stops, because the superior rectal artery does not divide into arch-forming branches. The point where the lowest left colic artery anastomoses with the superior rectal artery is therefore sometimes named the 'critical point.' Ligature of these two arteries will almost certainly result in gangrene of the part of the rectum which is supplied by them. If, however, the inferior mesenteric artery be tied proximal to the origin of its lowest colic branch, blood can pass through the latter branch into the superior rectal artery.

The Middle Suprarenal Arteries

The **middle suprarenal arteries** are two small vessels which arise, one from each side of the aorta, opposite the superior mesenteric artery. Each artery passes laterally and slightly upwards, over the crus of the Diaphragm, to the suprarenal gland, where it anastomoses with suprarenal branches of the phrenic and renal arteries. On the right side the artery passes behind the inferior vena cava and is closely related to the cœliac ganglion. On the left side it comes into relation with the cœliac ganglion, the splenic artery and the upper border of the pancreas. The distribution of the suprarenal arteries is described on p. 1418.

The Renal Arteries (fig. 738)

The **renal arteries** are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed across the corresponding crus of the Diaphragm, nearly at right angles to the aorta. The *right* is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava, the right renal vein, the head of the pancreas, and the second part of the duodenum. The *left* is a little higher than the right; it lies behind the left renal vein, the body of the pancreas and the splenic vein, and may be crossed by the inferior mesenteric vein. Just before reaching the hilum of the kidney, each artery divides into four or five branches; most of these lie between the renal vein and the pelvis of the ureter, the vein being in front, and the pelvis behind, but one or more branches are usually situated behind the pelvis. Each vessel gives off some small *inferior suprarenal branches* (p. 150) to the suprarenal gland, and supplies twigs to the ureter and the surrounding cellular tissue and muscles.

One or two accessory renal arteries are frequently found, more especially on the left side: they usually arise from the aorta, and may come off above or below the main artery, the former being slightly the more common position. Instead of entering the kidney at the hilum, they usually pierce the upper or lower part of the kidney; an accessory artery to the lower part of the kidney crosses in front of the ureter and, on the right side, usually in front of the inferior vena cava.

The Testicular Arteries (fig. 738)

The **testicular arteries** are two long, slender vessels, which arise from the front of the aorta a little below the renal arteries and are distributed to the testes. Each passes obliquely downwards and laterally behind the peritoneum, resting on the Psoas major; the right artery lies in front of the inferior vena cava and behind the third portion of the duodenum, the right colic and ileocolic arteries, and the terminal part of the ileum; the left artery passes behind the left colic artery, and the lower part of the descending colon. Each artery passes in front of the genitofemoral nerve, the ureter and the lower part of the external iliac artery on its way to reach the deep inguinal ring (abdominal inguinal ring), where it enters the spermatic cord. Accompanied by the other constituents of the spermatic cord, it traverses the inguinal canal and enters the scrotum. At the upper end of the testis it divides into several branches; two or three of these accompany the vas deferens (ductus deferens) and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce

the posterior part of the tunica albuginea, and supply the substance of the testis. In the abdomen the testicular artery supplies small branches to the fat around the kidney, the ureter and the iliac lymph glands ; in the inguinal canal it gives one or two twigs to the Cremaster.

Not infrequently the right testicular artery passes behind the inferior vena cava. It should be remembered that the testicular arteries represent persistent lateral splanchnic branches of the aorta (p. 150) and that as these vessels enter the mesonephros they cross ventral to the supracardinal vein but dorsal to the subcardinal vein. Under normal conditions of development the lateral splanchnic artery which persists as the right testicular artery passes below (caudal to) the particular supra-subcardinal anastomosis which persists to take part in the formation of the inferior vena cava. When it passes above (cranial to) this anastomoses the right testicular artery will lie behind the inferior vena cava in the adult.

The Ovarian Arteries

The **ovarian arteries** in the female correspond to the testicular arteries in the male, but they enter the pelvis and supply the ovaries (fig. 749). The origin and course of the first part of each artery are the same as those of the testicular artery, but on arriving at the brim of the true pelvis the artery crosses the upper parts of the external iliac artery and vein, and enters the pelvic cavity. It then runs medially between the two layers of the infundibulopelvic ligament (suspensory ligament of the ovary) and gains the broad ligament of the uterus, where it lies below the uterine tube. At the level of the ovary it passes backwards in the mesovarium and breaks up into branches which are distributed to the ovary. Small branches are given to the ureter and the uterine tube, and one passes to the side of the uterus, and unites with the uterine artery. Other offsets are continued on the round ligament of the uterus, through the inguinal canal, to the skin of the labium majus and the groin.

At an early period of fœtal life, when the testes or ovaries lie by the side of the vertebral column, below the kidneys, the testicular and ovarian arteries are short ; but with the descent of the testicles into the scrotum, and of the ovaries into the pelvis, the arteries are gradually lengthened.

The Phrenic Arteries (fig. 738)

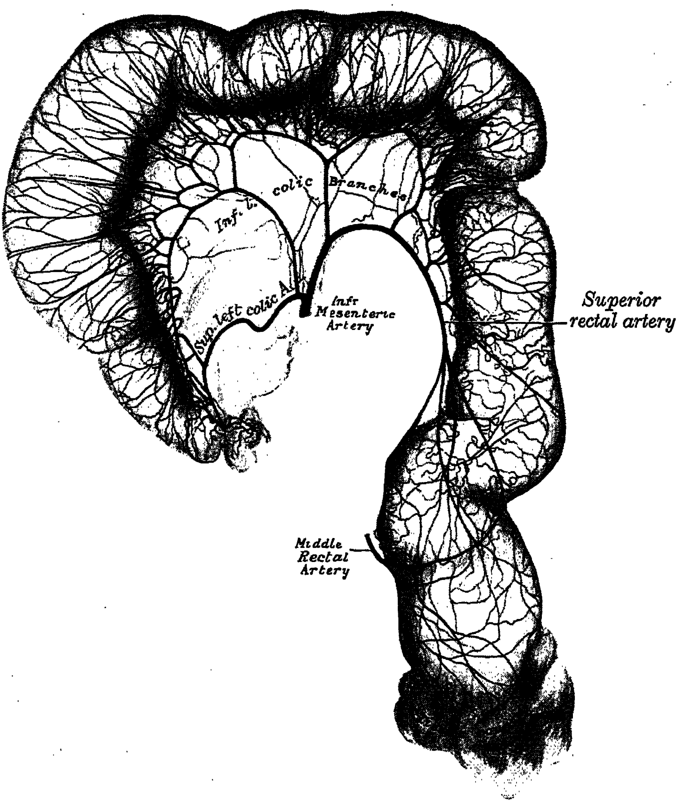
The **phrenic arteries** (inferior phrenic arteries) are two small vessels which supply the Diaphragm. They present much variety in their origins ; they may arise separately from the front of the aorta, immediately above the cœliac artery, or by a common trunk, which may spring either from the aorta or from the cœliac artery ; sometimes one artery is derived from the aorta, and the other from one of the renal arteries. From its origin the artery runs upwards and laterally in front of the crus of the Diaphragm and close to the medial border of the suprarenal gland. The left phrenic passes behind the œsophagus, and runs forwards on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and along the right side of the opening which transmits that vein. Near the posterior border of the central tendon of the Diaphragm each vessel divides into an internal and an external branch. The internal branch curves forwards, and anastomoses with its fellow of the opposite side in front of the central tendon, and with the musculophrenic and pericardiacophrenic arteries. The external branch passes towards the side of the thorax, and anastomoses with the lower posterior intercostal arteries, and with the musculophrenic artery. The external branch of the right artery gives off a few twigs to the inferior vena cava ; and the left artery sends some branches to the œsophagus. Each vessel gives off two or three small *superior suprarenal branches* to the suprarenal gland of its own side. The liver and the spleen also receive a few twigs from the right and left vessels respectively.

The Lumbar Arteries

The **lumbar arteries** are in series with the posterior (aortic) intercostal arteries and represent persistent intersegmental somatic branches of the aorta

in the embryo (p. 150). Usually four in number on each side, they arise from the back of the aorta, opposite the bodies of the upper four lumbar vertebræ. A fifth pair, small in size, occasionally arises from the median sacral artery; but the lumbar branches of the iliolumbar arteries usually take the place of the fifth pair. The lumbar arteries run laterally and backwards on the bodies of the lumbar vertebræ, deep to the sympathetic trunks, to reach the intervals between the adjacent transverse processes, and are then continued into the abdominal wall. The arteries of the right side pass deep to the inferior vena cava, and the upper two on the right side (the first only on the left side) run deep to the corresponding crus of the Diaphragm. The arteries of both sides

FIG. 746.—The pelvic colon and rectum, showing the distribution of the branches of the inferior mesenteric artery, and their anastomoses. (From a preparation by Hamilton Drummond.)



pass under cover of the tendinous arches which give origin to the Psoas major, and are continued behind this muscle and the lumbar plexus. They then cross the Quadratus lumborum, the upper three arteries running behind, the last usually in front of that muscle. At the lateral border of the Quadratus lumborum they pierce the posterior aponeurosis of the Transversus abdominis, and are carried forwards between this muscle and the Internal oblique. They anastomose with one another and with the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

Branches.—Each lumbar artery gives off a *posterior ramus* which, passing backwards between the transverse processes, is distributed to the muscles and skin of the back. The posterior ramus also furnishes a *spinal branch,* which enters the vertebral canal and supplies its contents, anastomosing with the arteries above and below it, and with the artery of the opposite side. Branches are also given by the lumbar arteries and their posterior rami to the neighbouring muscles.

The Median Sacral Artery (fig. 738)

The **median sacral artery** (middle sacral artery) is a small vessel which arises from the back of the aorta a little above its bifurcation. It descends in the median plane in front of the fourth and fifth lumbar vertebræ, the sacrum and coccyx, and ends in the coccygeal body. At the level of the fifth lumbar vertebra it is crossed by the left common iliac vein, and it frequently gives off on each side a small lumbar artery (*arteria lumbalis ima*). Minute branches are said to pass from it to the posterior surface of the rectum. On the last lumbar vertebra it anastomoses with the lumbar branch of the iliolumbar artery; in front of the sacrum it anastomoses with the lateral sacral arteries, and sends offsets into the anterior sacral foramina.

The Common Iliac Arteries (figs. 738, 747)

The abdominal aorta divides, on the left side of the body of the fourth lumbar vertebra, into the right and left **common iliac arteries.** Each artery passes downwards and laterally, and divides opposite the intervertebral disc between the last lumbar vertebra and the sacrum, into two branches, termed the *external iliac* and *internal iliac* (hypogastric) *arteries*: the former supplies the greater part of the lower limb; the latter, the viscera and parietes of the pelvis, the perineum and the gluteal region.

The **right common iliac artery** (figs. 738, 747), about 5 cm. long, passes obliquely across the body of the last lumbar vertebra. *In front,* it is crossed by sympathetic nerves passing to the hypogastric plexus, and, at its point of division, by the ureter; throughout its course it is covered with the parietal peritoneum, by which it is separated from the coils of the small intestine. *Behind,* it is separated from the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral disc by the sympathetic trunk, the terminal parts of the two common iliac veins and the commencement of the inferior vena cava. The obturator nerve, the lumbosacral trunk and the iliolumbar artery are situated more deeply and traverse the fatty tissue which occupies the interval between the last lumbar vertebra and the Psoas major muscle. *Laterally* it is in relation above with the inferior vena cava and the right common iliac vein; below, with the Psoas major. *Medially* its upper part is related to the left common iliac vein.

The **left common iliac artery** (fig. 738), about 4 cm. long, is in relation, *in front,* with the peritoneum, the small intestine, sympathetic nerves passing to the hypogastric plexus, and the superior rectal (superior hæmorrhoidal) artery, and is crossed at its point of bifurcation by the ureter. It rests on the sympathetic trunk and the bodies of the fourth and fifth lumbar vertebræ, and the intervening intervertebral disc. The obturator nerve, the lumbosacral trunk and the iliolumbar artery are placed more deeply. The left common iliac vein lies partly *medial* to, and partly *behind,* the artery; *laterally* the artery is in relation with the Psoas major.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas major, ureters, and the surrounding areolar tissue; occasionally they give origin to the iliolumbar or to accessory renal arteries.

Peculiarities.—The points of origin of the common iliac arteries vary according to the bifurcation of the aorta, which in most cases occurs either upon the fourth lumbar vertebra, or upon the disc between it and the fifth.

The common iliac arteries may divide above or below the usual level, and they often make an abrupt downward curve.

The length of the arteries varies from 3·5 to 7·5 cm. In rare instances, the right common iliac has been found wanting, the external and internal iliac arteries arising directly from the aorta.

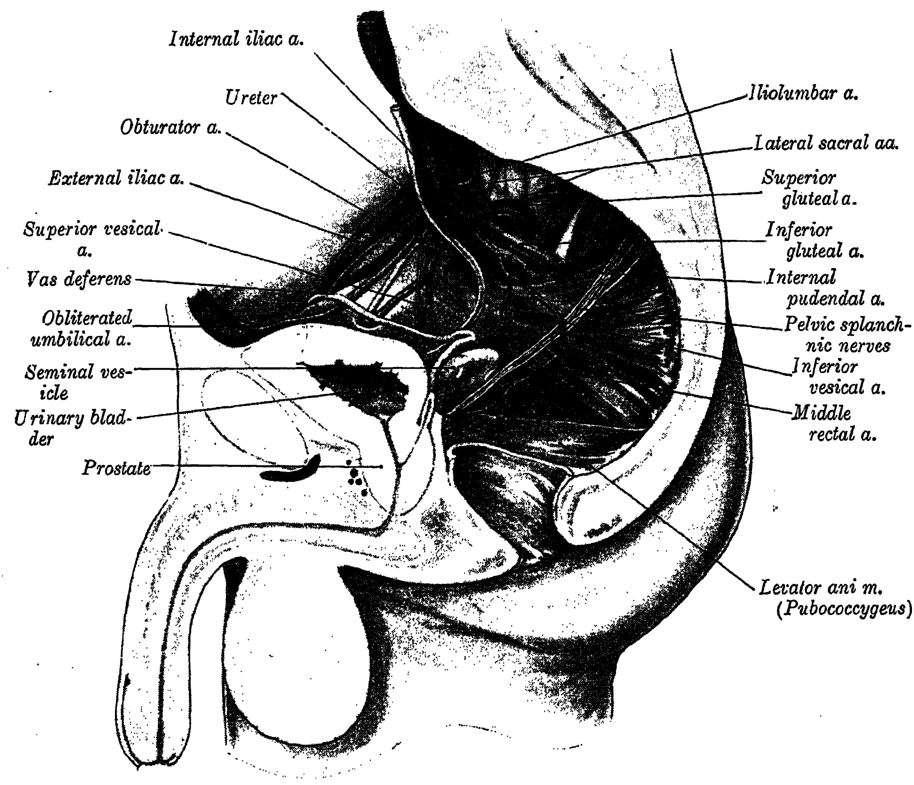
Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are: the anastomoses of the rectal branches of the internal iliac artery with the superior rectal branches from the inferior mesenteric artery; of the uterine, ovarian and vesical arteries of the opposite sides; of the lateral sacral arteries with the median sacral artery; of the inferior epigastric artery

with the internal mammary, lower posterior intercostal and lumbar arteries; of the deep circumflex iliac artery with the lumbar arteries; of the iliolumbar artery with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the inferior epigastric artery.

The Internal Iliac Artery (fig. 747)

The **internal iliac artery** (hypogastric), about 4 cm. long, arises at the bifurcation of the common iliac artery, opposite the sacro-iliac joint; it descends to the upper margin of the greater sciatic foramen, where it divides into an *anterior* trunk, which continues in the line of the parent vessel towards

Fig. 747.—The arteries of the pelvis. Right side.



The internal iliac vein and its tributaries have been removed; the rectum has been divided just above the anal canal and its upper part has been taken away.

the spine of the ischium, and a *posterior* trunk, which passes backwards towards the foramen.

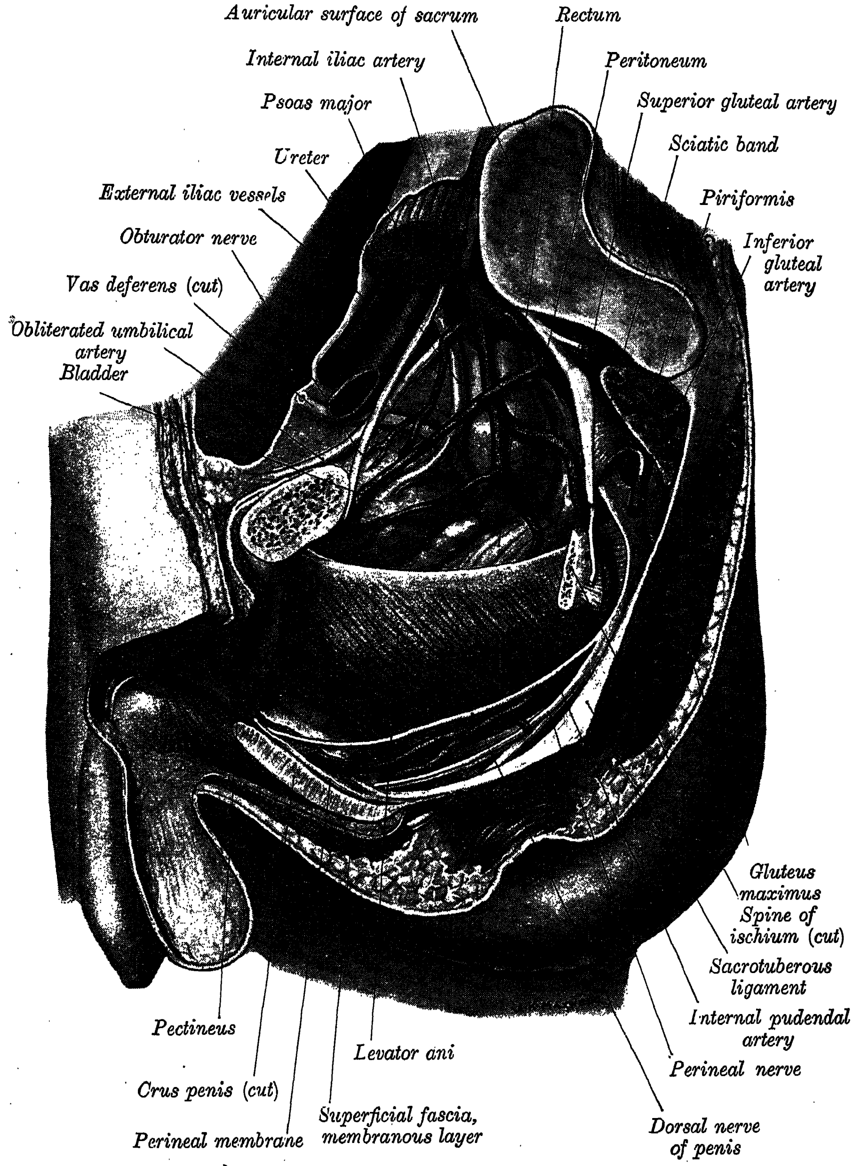
Relations.—It is in relation *in front* with the ureter and, in the female, with the ovary and the fimbriated end of the uterine tube; *behind*, with the internal iliac vein, the lumbosacral nerve-trunk and the sacro-iliac joint; *laterally*, near its origin, with the external iliac vein, which lies between it and the Psoas major; lower down, with the obturator nerve; and *medially* with the peritoneum, which separates it from the terminal part of the ileum, on the right side, and the pelvic colon, on the left side, and with some of the tributaries of the internal iliac vein.

In the fœtus, the internal iliac artery is twice as large as the external iliac artery, and is the direct continuation of the common iliac artery. It ascends on the back of the anterior wall of the abdomen to the umbilicus, converging on its fellow of the opposite side. Having passed through the umbilical

opening, the two arteries, now termed *umbilical*, enter the umbilical cord, where they are coiled round the umbilical vein, and ultimately ramify in the placenta.

At birth, when the placental circulation ceases, only the pelvic portion of the artery remains patent and constitutes the internal iliac artery and the first

FIG. 748.—A dissection of the pelvic contents from the left side.



NOTE.—Most of the left hip-bone has been removed together with the Obturator internus muscle. The Sciatic nerve has been cut away close to its origin from the sacral plexus.

part of the superior vesical artery of the adult; the remainder of the vessel is converted into a fibrous cord, termed the *lateral umbilical ligament*, which extends from the pelvis to the umbilicus.

Peculiarities.—The lengths of the internal and common iliac arteries bear an inverse proportion to each other.

The place of division of the internal iliac artery varies between the upper margin of the sacrum and the upper border of the greater sciatic foramen.

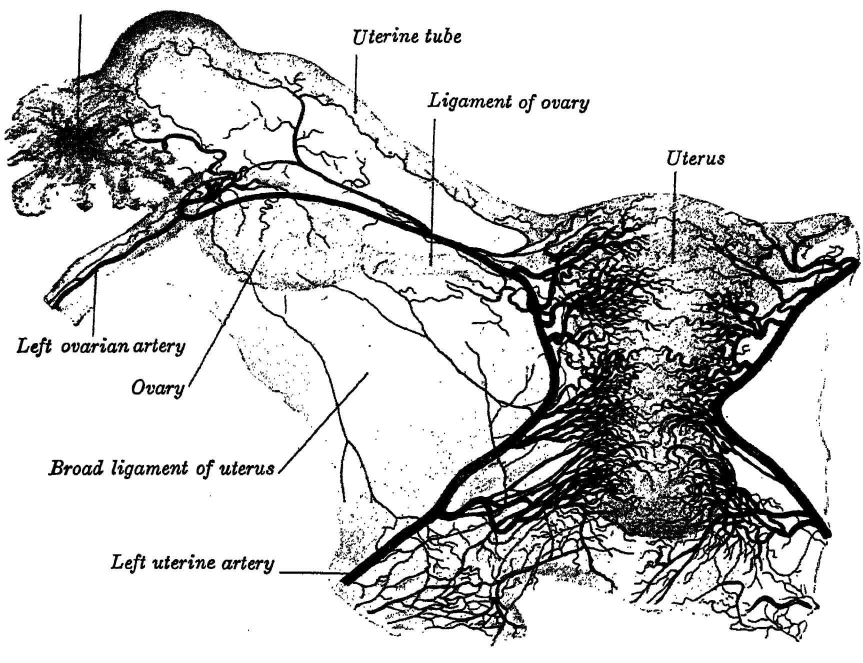
The branches of the internal iliac artery are :

From the Anterior Trunk.
- Superior vesical.
- Inferior vesical.
- Middle rectal.
- Uterine } *In the female.*
- Vaginal }
- Obturator.
- Internal pudendal.
- Inferior gluteal.

From the Posterior Trunk.
- Iliolumbar.
- Lateral sacral.
- Superior gluteal.

The **superior vesical artery** (fig. 747) supplies numerous branches to the upper part of the bladder. From one of these a slender vessel, named the *artery to the vas deferens*, frequently takes origin and accompanies the vas deferens (ductus deferens) in its course to the testis, where it anastomoses with the testicular

FIG. 749.—The left uterine and ovarian arteries of an unmarried girl aged 17½ years. Posterior aspect. (From a preparation by Hamilton Drummond.)



artery. Other branches supply the ureter. The first part of the superior vesical artery is the proximal, patent portion of the fœtal umbilical artery.

The **inferior vesical artery** (fig. 747) frequently arises in common with the middle rectal artery, and is distributed to the fundus of the bladder, the prostate, the seminal vesicles and the lower part of the ureter. The branches to the prostate communicate with the corresponding vessels of the opposite side. The inferior vesical artery gives origin to the artery to the vas deferens when that vessel does not arise from one of the superior vesical branches.

The **middle rectal artery** (middle hæmorrhoidal artery) (figs. 746, 747) usually arises with the preceding vessel. It is distributed to the muscular coats of the rectum, anastomosing with the superior and inferior rectal arteries. It gives offsets to the seminal vesicles and prostate, which anastomose with branches of the inferior vesical artery.

The **uterine artery** (fig. 749) runs medially on the Levator ani and towards the cervix uteri ; about 2 cm. from the cervix *it crosses above and in front of the ureter*—to which it supplies a small branch—and above the lateral fornix of the

vagina. Reaching the side of the uterus it ascends in a tortuous manner between the two layers of the broad ligament to the junction of the uterine tube and uterus. It then runs laterally towards the hilum of the ovary, and ends by joining with the ovarian artery. It supplies branches to the cervix uteri and others which descend on the vagina; the latter anastomose with branches of the vaginal arteries and form with them two median longitudinal vessels—the *azygos arteries of the vagina*—one of which descends in front of, and the other behind, the vagina. It supplies numerous branches to the body of the uterus, and from its terminal portion twigs are distributed to the uterine tube and the round ligament of the uterus.

The **vaginal artery** usually corresponds to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sends branches to the bulb of the vestibule, the fundus of the bladder and the contiguous part of the rectum. It assists in forming the azygos arteries of the vagina, and is frequently represented by two or three branches.

The **obturator artery** (fig. 747) passes forwards and downwards on the lateral wall of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through the obturator canal, divides into an anterior and a posterior branch. In the pelvic cavity this vessel is in relation, laterally, with the obturator fascia, which separates it from the Obturator internus muscle; medially, it is crossed by the ureter and the vas deferens, which separate it from the parietal pelvic peritoneum; in the nullipara the ovary is a medial relation. The obturator nerve is above the vessel, and the obturator vein below it.

Branches.—Inside the pelvis, the obturator artery gives off (*a*) **iliac branches** to the iliac fossa; these supply the bone and the Iliacus, and anastomose with the iliolumbar artery; (*b*) a **vesical branch** which runs medially to the bladder, and may replace the inferior vesical branch of the internal iliac artery; and (*c*) a **pubic branch** which springs from the vessel just before it leaves the pelvic cavity; this branch ascends upon the back of the pubis and anastomoses with the corresponding vessel of the opposite side, and with the pubic branch of the inferior epigastric artery.

Outside the pelvis, the obturator artery divides, at the upper margin of the obturator foramen, into an anterior and a posterior branch, which encircle the foramen under cover of the Obturator externus.

The **anterior branch** runs forwards on the outer surface of the obturator membrane and then curves downwards along the anterior margin of the foramen. It supplies branches to the Obturator externus, Pectineus, Adductores and Gracilis, and anastomoses with the posterior branch and with the medial circumflex femoral artery.

The **posterior branch** follows the posterior margin of the foramen and turns forwards on the ramus of the ischium where it anastomoses with the anterior branch. It gives twigs to the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. It also supplies an *acetabular branch* which enters the hip-joint through the acetabular notch, ramifies in the fat of the acetabular fossa, and sends a twig along the ligamentum capitis femoris to the head of the femur.

Peculiarities.—In about 28 per cent. of subjects the place of the obturator artery is taken by an enlarged pubic branch of the inferior epigastric artery (p. 784); this branch descends almost vertically to the upper part of the obturator foramen. The artery usually lies in contact with the external iliac vein, and on the lateral side of the femoral ring (fig. 750A); in such cases it would not be endangered in the operation for strangulated femoral hernia. Occasionally, however, it curves along the free margin of the pectineal part of the inguinal ligament (fig. 750B), and if in such circumstances a femoral hernia occurred, the vessel would almost completely encircle, and might constrict, the neck of the hernial sac; moreover, it would be in great danger of being wounded if an operation were performed for strangulation. It sometimes arises from the main stem or from the posterior trunk of the internal iliac artery, or it may spring from the superior gluteal artery: occasionally it arises from the external iliac artery.

The **internal pudendal artery** (figs. 747, 748, 751), the smaller of the two terminal branches of the anterior trunk of the internal iliac artery, supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is smaller in the female than in the male, and the distribution of its branches somewhat different.

The **internal pudendal artery in the male** runs downwards and laterally to the lower border of the greater sciatic foramen, and, passing from the pelvis

between the Piriformis and Coccygeus, enters the gluteal region through the lower part of the greater sciatic foramen ; it then crosses the back of the tip of the ischial spine, and enters the perineum through the lesser sciatic foramen. The artery then traverses the pudendal canal in the lateral wall of the ischiorectal fossa, and so crosses the Obturator internus, being situated about 4 cm. above the lower margin of the ischial tuberosity. It gradually approaches the margin of the ramus of the ischium and passes forwards deep to the perineal membrane (inferior fascia of the urogenital diaphragm) ; it then runs forwards along the medial margin of the inferior ramus of the pubis, and at a distance of about 1·25 cm. behind the inferior pubic ligament it divides into the *dorsal* and *deep arteries of the penis*, but it may pierce the perineal membrane before doing so.

Relations.—Within the pelvis, it lies in front of the Piriformis, the sacral plexus of nerves, and the inferior gluteal artery. As it crosses the ischial spine,

Fig. 750.—Variations in the course of an abnormal obturator artery.

it is covered by the Gluteus maximus ; here the pudendal nerve lies medial, and the nerve to the Obturator internus lateral, to the vessel. In the perineum it lies on the lateral wall of the ischiorectal fossa in the pudendal canal (p. 573) ; it is accompanied by a pair of venæ comitantes and by the pudendal nerve, at first, and then by its terminal branches, viz. the dorsal nerve of the penis, which lies above it, and the perineal nerve, which lies below it.

Branches.—The branches of the internal pudendal artery (figs. 751, 752) are :

Muscular.	Artery of the bulb of the penis.
Inferior rectal.	Urethral.
Scrotal.	Deep artery of the penis.
Transverse perineal.	Dorsal artery of the penis.

The **muscular branches** consist of two sets ; one to the muscles in the pelvis ; the other, as the vessel crosses the ischial spine, to the muscles of the gluteal region.

The **inferior rectal artery** (inferior hæmorrhoidal artery) arises from the internal pudendal as it passes above the ischial tuberosity. Piercing the wall of the pudendal canal (p. 573) it divides into two or three branches which cross the ischiorectal fossa, and are distributed to the muscles and skin of the anal region. In addition they supply the anal canal and send offshoots round the lower edge of the Gluteus maximus to the skin of the buttock. They anastomose with the corresponding vessels of the opposite side, with the superior and middle rectal arteries, and with the transverse perineal artery.

The **scrotal branches** arise from the internal pudendal artery, in front of the preceding branches, cross either superficial, or deep to the Transversus perinei superficialis, and run forwards in the interspace between the Bulbospongiosus and Ischiocavernosus, to both of which they supply branches, and finally are distributed to the skin and Dartos muscle of the scrotum. They often spring from the succeeding artery.

The **transverse perineal artery** arises from the internal pudendal artery, just before it passes deep to the perineal membrane. It runs transversely on the cutaneous surface of the Transversus perinei superficialis, and anastomoses with the corresponding vessel of the opposite side and with the scrotal and inferior rectal arteries. It supplies the Transversus perinei superficialis and the structures between the anus and the bulb of the penis.

The **artery of the bulb of the penis** is a short vessel of relatively large calibre which arises from the internal pudendal artery as it lies deep to the perineal membrane; it passes medially, pierces the membrane, and gives off branches which ramify in the bulb of the penis and in the posterior part of the corpus spongiosum penis (corpus cavernosum urethra). It supplies a small branch to the bulbo-urethral gland.

Fig. 751.—The superficial branches of the internal pudendal artery, in the male.

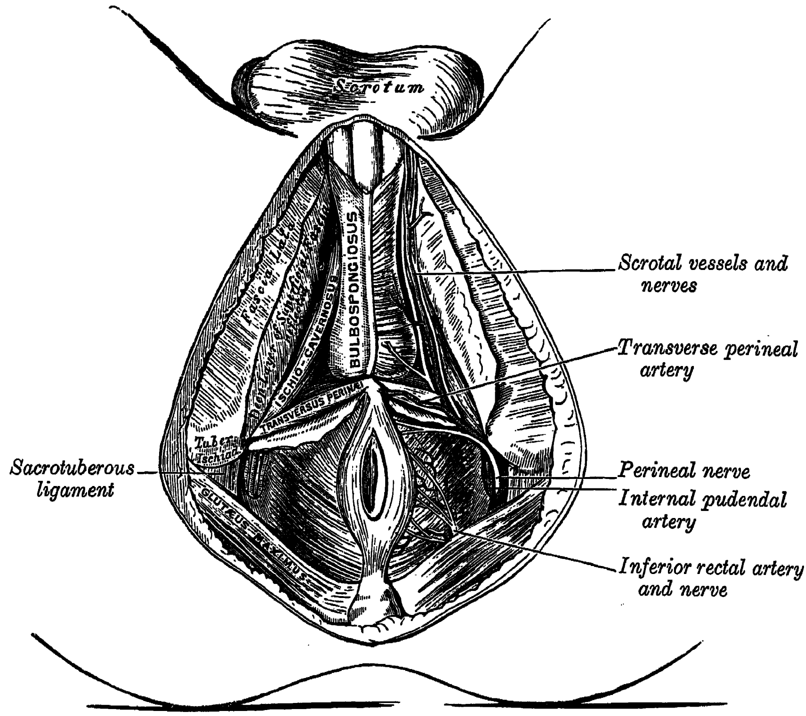


Fig. 752.—The deeper branches of the internal pudendal artery, in the male.

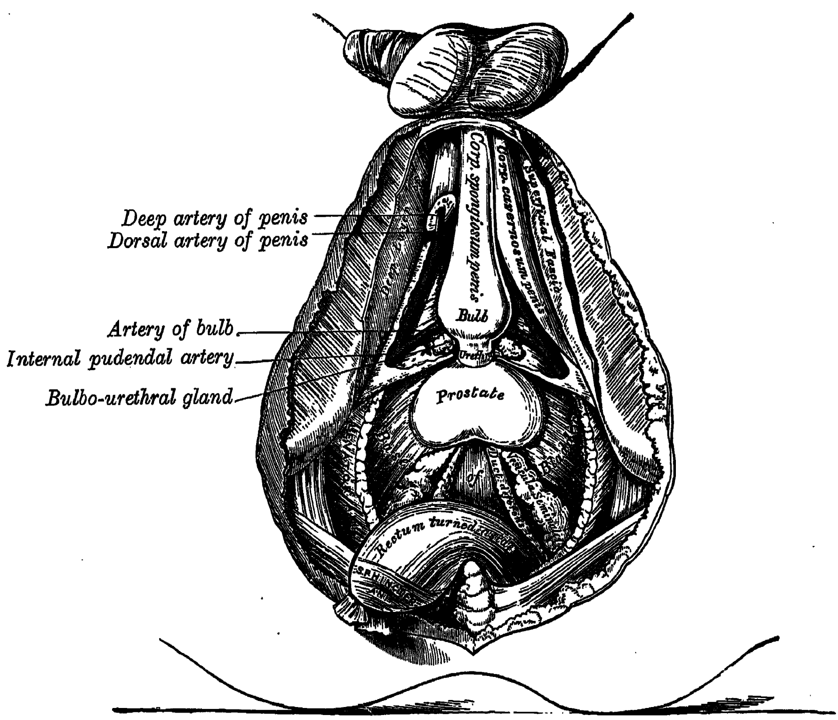


The **urethral artery** arises a short distance in front of the artery of the bulb. It runs forwards and medially, pierces the perineal membrane and enters the corpus spongiosum penis (corpus cavernosum urethræ), in which it is continued forwards to the glans penis.

The **deep artery of the penis**, one of the terminal branches of the internal pudendal artery, arises from that vessel while it is situated deep to the perineal membrane; it pierces the membrane, and, entering the crus penis obliquely, runs forwards in the centre of the corpus cavernosum penis, and supplies its erectile tissue.

The **dorsal artery of the penis** pierces the perineal membrane, and ascends between the crus penis and the pubic symphysis. It then passes between the two layers of the suspensory ligament of the penis, and runs forwards on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the penis, it lies between the dorsal nerve and deep dorsal vein, the former being on its lateral side. It supplies the skin and the fibrous sheath of the corpus cavernosum penis, sending branches through the sheath to anastomose with the deep artery of the penis.

The **internal pudendal artery in the female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The labial branches supply the labia pudendi; the artery of the bulb is distributed to the bulb of the vestibule and the erectile tissue of the vagina; the deep artery of the clitoris supplies the corpus cavernosum clitoridis; the dorsal artery of the clitoris gives branches to the dorsum of that organ, and ends in the glans and prepuce of the clitoris.

Peculiarities.—The internal pudendal artery is sometimes relatively small, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, named the *accessory pudendal*, which generally arises from the internal pudendal artery before its exit from the greater sciatic foramen. It passes forwards along the lower part of the bladder and across the side of the prostate to the root of the penis, where it perforates the perineal membrane, and gives off the branches usually derived from the internal pudendal artery. The commonest deficiency is that in which the internal pudendal artery ends as the artery of the bulb, the dorsal and deep arteries of the penis being derived from the accessory pudendal artery. The internal pudendal artery may also end as the transverse perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudendal artery is derived from one of the other branches of the internal iliac artery, most frequently the inferior vesical or the obturator.

The **inferior gluteal artery** (figs. 748, 753), the larger of the two terminal branches of the anterior trunk of the internal iliac artery (hypogastric artery), is distributed chiefly to the buttock and the back of the thigh. It runs down on the sacral plexus of nerves and the Piriformis, behind the internal pudendal artery, and, passing between the first and second, or second and third, sacral nerves, and then between the Piriformis and Coccygeus it reaches the lower part of the greater sciatic foramen, through which it leaves the pelvis to gain the gluteal region. It then descends in the interval between the greater trochanter of the femur and the tuberosity of the ischium, accompanied by the sciatic and posterior femoral cutaneous nerves, and covered by the Gluteus maximus; it is continued down the back of the thigh, supplying the skin, and anastomosing with branches of the perforating arteries.

Branches.—*Inside the pelvis.* It distributes (*a*) branches to the Piriformis, Coccygeus and Levator ani; (*b*) branches which supply the fat around the rectum, and occasionally take the place of the middle rectal artery; and (*c*) vesical branches to the fundus of the bladder, seminal vesicles and prostate.

Outside the pelvis.—**Muscular branches** supply the Gluteus maximus, the lateral rotators of the thigh, and the muscles attached to the tuberosity of the ischium; they anastomose with the superior gluteal, internal pudendal, obturator and medial circumflex femoral arteries.

Coccygeal branches (fig. 748) run medially, pierce the sacrotuberous ligament, and supply the Gluteus maximus and the structures on the back of the coccyx.

The **arteria comitans nervi ischiadici**, a long slender vessel, accompanies the sciatic nerve for a short distance; it then penetrates it, and runs in its substance to the lower part of the thigh.

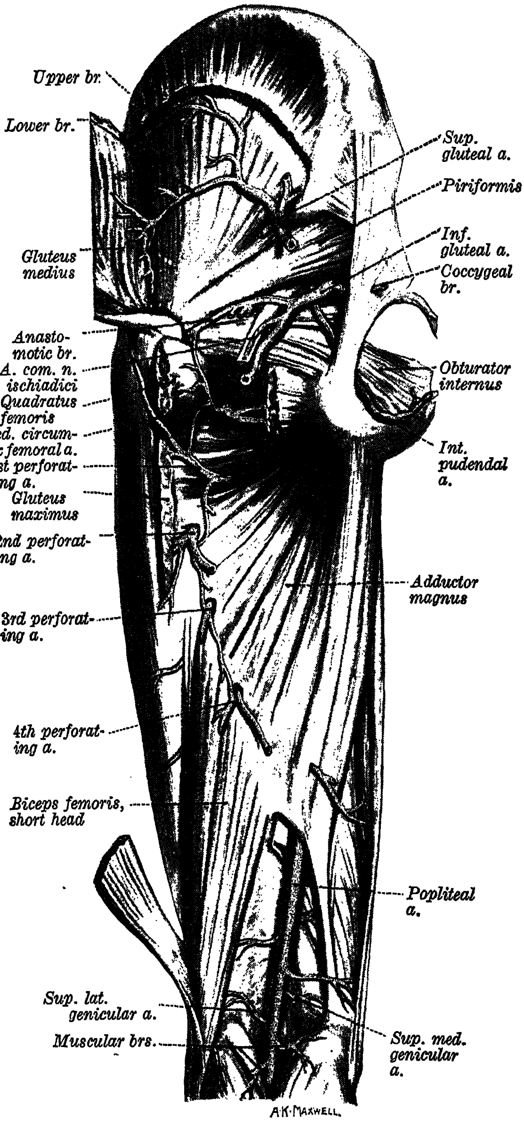
An anastomotic branch, directed obliquely downwards across the lateral rotator muscles of the thigh, assists in forming the so-called *cruciate anastomosis* (p. 791) by joining with the first perforating and the medial and lateral circumflex femoral arteries.

An articular branch, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

Cutaneous branches are distributed to the skin of the buttock and back of the thigh.

The **iliolumbar artery** (fig. 747), a branch of the posterior trunk of the internal iliac artery, runs upwards and laterally, in front of the sacro-iliac joint and the lumbosacral trunk, and behind the obturator nerve and the external iliac vessels, to the medial border of the Psoas major, behind which it divides into a lumbar and an iliac branch.

FIG. 753.—The arteries of the left gluteal and posterior femoral region.



The **lumbar branch** supplies the Psoas major and Quadratus lumborum, anastomoses with the fourth lumbar artery, and sends a small *spinal branch* through the intervertebral foramen between the fifth lumbar vertebra and the base of the sacrum, into the vertebral canal to supply the cauda equina.

The **iliac branch** supplies the Iliacus; some offsets run between the muscle and the bone, and anastomose with the iliac branches of the obturator artery; one of these enters an oblique canal to supply the bone, while others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomosing in their course with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.

The **lateral sacral arteries** (fig. 747) arise from the posterior division of the internal iliac (hypogastric) artery; there are usually two, a superior and an inferior. The *superior*, and larger, passes medially, and enters the first or second anterior sacral foramen, supplies branches to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the superior gluteal artery. The *inferior* runs obliquely across the front of the Piriformis and the sacral nerves, descends on the front of the sacrum lateral to the sympathetic trunk, and anastomoses over the coccyx with the median sacral artery and the opposite lateral sacral artery. Branches from this vessel enter the anterior sacral foramina, and, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal arteries.

The **superior gluteal artery** (figs. 747, 753) is the largest branch of the internal iliac (hypogastric) artery, and appears to be the continuation of the posterior division of that vessel. It is a short artery which runs backwards between the lumbosacral trunk and the first sacral nerve, or between the first and second sacral nerves, and, passing out of the pelvis through the upper part of the greater sciatic foramen above the upper border of the piriformis, divides into a *superficial* and a *deep branch*. Within the pelvis it gives off a few twigs

to the Piriformis and Obturator internus, and a nutrient artery to the hip-bone.

The *superficial branch* enters the deep surface of the Gluteus maximus, and divides into numerous branches; some of these supply the muscle and anastomose with the inferior gluteal artery; others perforate the tendinous origin of the muscle, supply the skin covering the posterior surface of the sacrum, and anastomose with the posterior branches of the lateral sacral arteries.

The *deep branch* lies under the Gluteus medius and soon splits into a superior and an inferior division. The *superior division* runs along the upper border of the Gluteus minimus to the anterior superior iliac spine, anastomosing with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The *inferior division* crosses the Gluteus minimus obliquely, distributes branches to this muscle and to the Gluteus medius, and anastomoses with the lateral circumflex femoral artery; one branch enters the trochanteric fossa, where it anastomoses with the inferior gluteal and the ascending branch of the medial circumflex femoral artery; other branches pierce the Gluteus minimus and supply the hip-joint.

Collateral Circulation.—The circulation after ligature of the internal iliac artery is carried on by the anastomoses of the uterine and ovarian arteries; of the vesical arteries of the two sides; of the rectal branches of the internal iliac artery with those from the inferior mesenteric artery; of the pubic branch of the obturator artery with the vessel of the opposite side, and with the inferior epigastric and medial circumflex femoral arteries; of the circumflex and perforating branches of the arteria profunda femoris with the inferior gluteal artery; of the superior gluteal artery with the posterior branches of the lateral sacral arteries; of the iliolumbar with the last lumbar artery; of the median sacral artery with the lateral sacral arteries; and of the circumflex iliac with the iliolumbar and superior gluteal arteries.*

THE EXTERNAL ILIAC ARTERY (figs. 747, 754)

The **external iliac artery** is larger than the internal iliac (hypogastric) artery, and runs obliquely downwards and laterally, along the medial border of the Psoas major. It extends from the bifurcation of the common iliac artery to a point behind the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis, where it enters the thigh as the femoral artery.

Relations.—*In front and medially* the external iliac artery is in relation with the peritoneum and extraperitoneal tissue, which separate the right artery from the termination of the ileum and frequently the vermiform appendix, and the left artery from the pelvic colon and some coils of the small intestine. The beginning of the artery may be crossed by the ureter; in the female it is crossed by the ovarian vessels. The testicular vessels lie for some distance upon it near its termination, and it is crossed in this situation by the genital (external spermatic) branch of the genitofemoral nerve, the deep circumflex iliac vein, the vas deferens in the male, and the round ligament of the uterus in the female. *Posteriorly* it is separated from the medial border of the Psoas major by the iliac fascia. The external iliac vein lies partly behind the upper part of the artery, but is on the medial side of its lower part. *Laterally* it is related to the Psoas major, from which it is separated by the iliac fascia. Numerous lymphatic vessels and lymph glands lie on the front and sides of the vessel.

Branches.—Besides supplying several small branches to the Psoas major and the neighbouring lymph glands, the external iliac artery gives off the inferior epigastric and deep circumflex iliac branches.

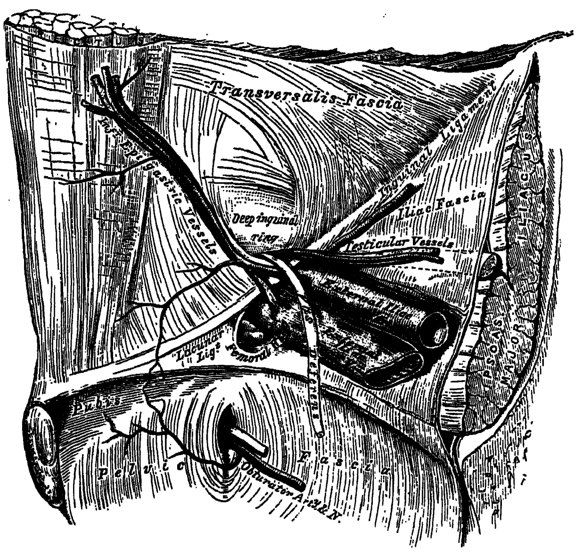
The **inferior epigastric artery** (figs. 604, 754) arises from the external iliac artery, immediately above the inguinal ligament. It curves forwards in the extraperitoneal tissue, and then ascends obliquely along the medial margin of the deep inguinal ring (abdominal inguinal ring); continuing its upward course, it pierces the transversalis fascia, passes in front of the arcuate line (linea semicircularis), and ascends between the Rectus abdominis and the

* For a description of a case in which Owen made a dissection ten years after ligature of the internal iliac artery, see *Med. Chir. Trans.* vol. xvi.

posterior lamella of its sheath. It finally divides into numerous branches, which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary artery and with the lower posterior intercostal arteries. As the inferior epigastric artery passes obliquely upwards from its origin it lies along the lower and medial margins of the deep inguinal ring, and behind the commencement of the spermatic cord, separated from it by the transversalis fascia. In the male the vas deferens (ductus deferens), and in the female the round ligament of the uterus, winds round the lateral and posterior surfaces of the artery. The inferior epigastric artery supplies the following branches :

The **cremasteric artery** (external spermatic artery) accompanies the spermatic cord, supplies the Cremaster and other coverings of the cord, and anastomoses with the testicular

FIG. 754.—The right inferior epigastric artery, and the relations of the right femoral and deep inguinal rings. Seen from within the abdomen.



artery. In the female the artery is very small and accompanies the round ligament of the uterus.

A **pubic branch** descends along the medial margin of the femoral ring to the back of the pubis, and there anastomoses with the pubic branch of the obturator artery. In about 28 per cent. of subjects the pubic branch is large, and takes the place of the obturator artery (p. 778).

Branches are distributed to the abdominal muscles and the peritoneum, and anastomose with the circumflex iliac and lumbar arteries.

Cutaneous branches perforate the aponeurosis of the External oblique muscle, supply the skin and anastomose with branches of the superficial epigastric artery.

Peculiarities.—The inferior epigastric artery may spring from any part of the external iliac artery between the inguinal ligament and a point 6 cm. above it ; or it may arise below this ligament, from the femoral artery. In the latter case, it ascends in front of the femoral vein. It frequently springs from the external iliac artery, by a common trunk with the abnormal obturator artery. Sometimes it arises from the obturator artery.

Applied Anatomy.—The inferior epigastric artery has important surgical relations, and is one of the principal means, through its anastomosis with the internal mammary, of establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the deep inguinal ring (abdominal inguinal ring), and is therefore *medial* to an oblique inguinal hernia, but *lateral* to a direct inguinal hernia, as these emerge from the abdomen.

The **deep circumflex iliac artery** arises from the lateral side of the external iliac artery nearly opposite the inferior epigastric artery. It ascends obliquely

to the anterior superior iliac spine and behind the inguinal ligament, in a sheath formed by the junction of the transversalis and iliac fasciæ. There it anastomoses with the ascending branch of the lateral circumflex femoral artery. It then pierces the transversalis fascia and passes along the inner lip of the crest of the ilium to about its middle, where it perforates the Transversus abdominis and runs backwards between that muscle and the Internal oblique, to anastomose with the iliolumbar and superior gluteal arteries. Opposite the anterior superior iliac spine it gives off a large *ascending branch* (fig. 602), which runs between the Internal oblique and Transversus, supplying them, and anastomosing with the lumbar and inferior epigastric arteries.

Collateral Circulation.—The principal anastomoses by which the collateral circulation is established, after ligature of the external iliac artery, are: the iliolumbar with the circumflex iliac arteries; the superior gluteal with the lateral circumflex femoral artery; the obturator with the medial circumflex femoral artery; the inferior gluteal with the circumflex and first perforating branches of the arteria profunda femoris; and the internal pudendal with the external pudendal arteries. When the obturator artery arises from the inferior epigastric artery, it is supplied with blood by branches from either the internal iliac, the lateral sacral or the internal pudendal arteries. The inferior epigastric artery receives its supply from the internal mammary and lower posterior intercostal arteries, and from the internal iliac artery by the anastomoses of its branches with the obturator artery.*

THE ARTERIES OF THE LOWER LIMB

The chief artery of the lower limb is a direct continuation of the external iliac. It extends from the level of the inguinal ligament to the lower border of the Popliteus, where it divides into the anterior and posterior tibial arteries. Its upper part is named the femoral artery; its lower, the popliteal artery.

The Femoral Artery (figs. 758, 759)

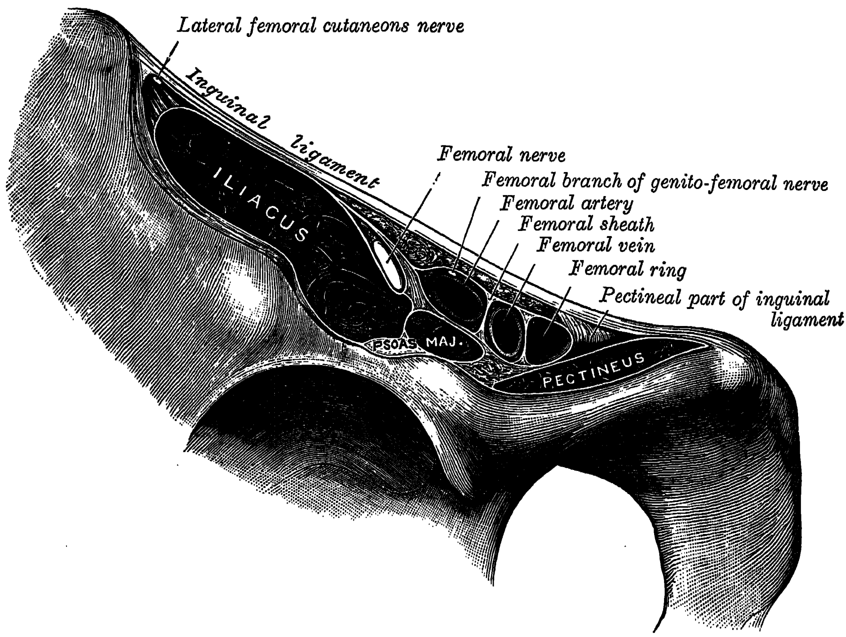
The **femoral artery** is the continuation of the external iliac artery. It begins behind the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis, and passes down the front and medial side of the thigh. It ends at the junction of the middle with the lower one-third of the thigh, where it passes through an opening in the Adductor magnus to become the popliteal artery. The upper part of the femoral artery is contained in the *femoral triangle*, the lower part in the *subsartorial canal* (adductor canal). The first 3 cm. or 4 cm. of the vessel are enclosed, together with the femoral vein, in the *femoral sheath.*

The **femoral sheath** (fig. 755) is formed by a prolongation downwards, behind the inguinal ligament, of the fasciæ lining the abdomen, the transversalis fascia being continued down in front of the femoral vessels and the iliopectineal fascia behind them. The sheath has the form of a short funnel, the wide end of which is directed upwards, while the lower, narrow end fuses with the fascial investment of the vessels, about 3 or 4 cm. below the inguinal ligament. The lateral wall of the sheath is vertical and is perforated by the femoral branch of the genitofemoral nerve; the medial wall is directed obliquely downwards and laterally, and is pierced by the long saphenous vein and by some lymphatic vessels. Like the carotid sheath (p. 537) in structure, the femoral sheath consists of a mass of connective tissue in which the femoral vessels are imbedded. It is customary to describe three compartments; of these, the lateral contains the femoral artery, the intermediate the femoral vein, while the medial and smallest compartment is named the *femoral canal*, and contains some lymph vessels and a lymph gland, imbedded in a small amount of areolar tissue. The femoral canal is conical and measures 1·25 cm. in length; its base, directed upwards and named the *femoral ring*, is oval in form, its long or transverse

* Sir Astley Cooper described in vol. i. of the *Guy's Hospital Reports* the dissection of a limb eighteen years after successful ligature of the external iliac artery.

diameter measuring 1·25 cm. The femoral ring (fig. 755) is bounded in front by the inguinal ligament, behind by the Pectineus covered by its fascia, medially by the crescentic base of the pectineal part of the inguinal ligament (lacunar ligament), and laterally by the femoral vein. The spermatic cord in the male, and the round ligament of the uterus in the female, lie immediately above the anterior margin of the ring, while the inferior epigastric vessels are close to its upper and lateral angle. The ring is larger in women than in men. This difference is accounted for partly by the greater breadth of the female pelvis and partly by the smaller size of the femoral vessels. The femoral ring is closed by a somewhat condensed portion of the extraperitoneal tissue, named the *femoral septum,* which contains a small lymph gland and is covered

Fig. 755.—The structures passing behind the inguinal ligament. Seen from below.



by the parietal layer of the peritoneum. The femoral septum is pierced by numerous lymph vessels passing from the deep inguinal to the external iliac lymph glands, and the parietal peritoneum immediately above it presents a slight depression named the *femoral fossa.*

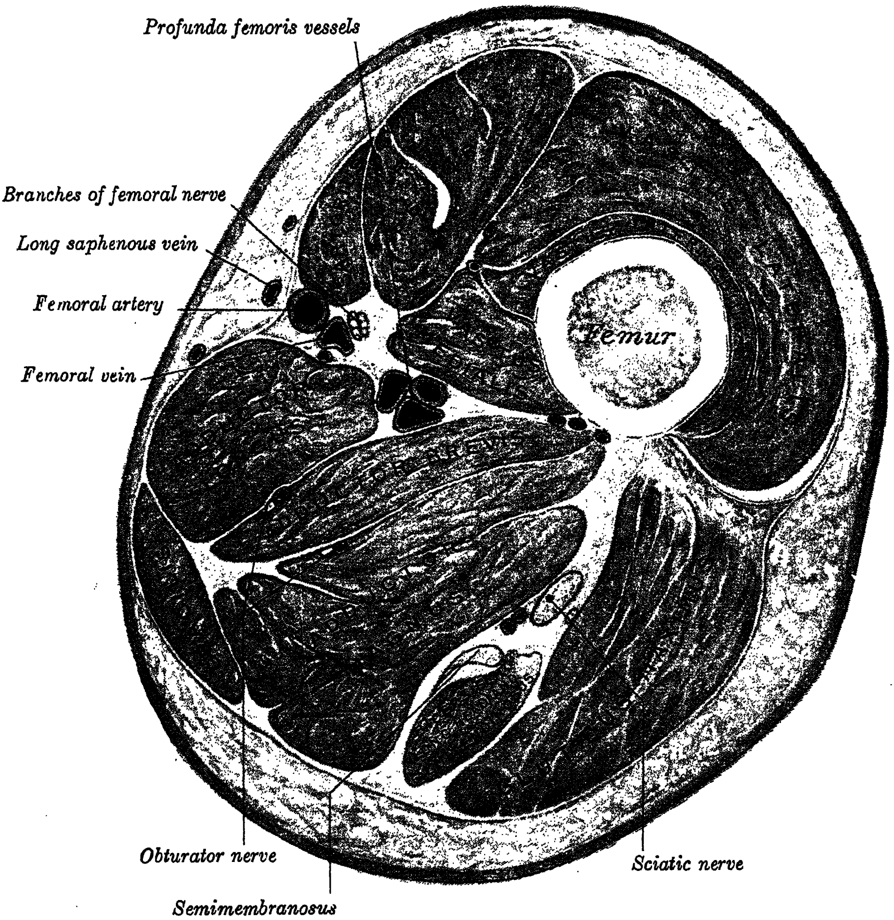
The **femoral triangle** (fig. 758) corresponds to the depression seen immediately below the fold of the groin. Its apex is directed downwards, and the sides are formed, laterally by the medial margin of the Sartorius, medially by the medial margin of the Adductor longus, above by the inguinal ligament. The floor of the triangle is gutter-like and is formed laterally by the Iliacus and Psoas major, and medially by the Pectineus and Adductor longus. The femoral vessels, which extend from near the middle of its base to its apex, lie in the deepest part of the gutter. On the lateral side of the femoral artery the femoral nerve divides into its branches. Besides the vessels and nerves, this triangle contains some fat and lymph glands.

The **subsartorial canal** (adductor canal) (fig. 757) is an aponeurotic tunnel in the middle one-third of the thigh, extending from the apex of the femoral triangle to the opening in the Adductor magnus through which the femoral vessels pass from the front of the thigh to the popliteal fossa. It is triangular on transverse section, and is bounded, in front and laterally, by the Vastus medialis; behind, by the Adductor longus above, and Adductor magnus below; and is roofed by a strong aponeurosis which extends from these muscles, across

the femoral vessels, to the Vastus medialis. The Sartorius lies on the aponeurotic roof. The canal contains the femoral artery and vein, and the saphenous nerve; the nerve to the Vastus medialis traverses the proximal part of the adductor canal, and then enters its muscle.

The relations of the femoral artery.—In the *femoral triangle* (fig. 758) the artery is covered with the skin and superficial fascia, the superficial inguinal lymph glands, the superficial layer of the fascia lata and the anterior part of the femoral sheath, and is crossed by the superficial circumflex iliac vein, which runs in the superficial fascia. The femoral branch of the genitofemoral nerve

FIG. 756.—A transverse section through the thigh at the level of the apex of the femoral triangle. About four-fifths of the natural size.



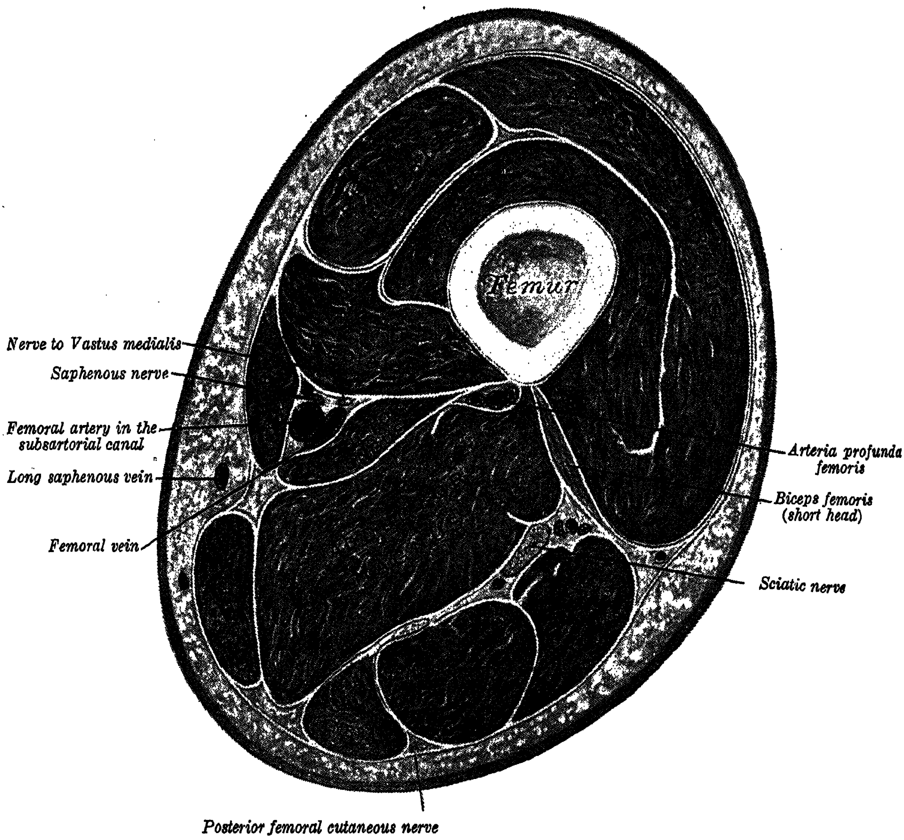
courses for a short distance within the lateral compartment of the femoral sheath, and lies at first in front of and then lateral to the artery. Near the apex of the femoral triangle the medial cutaneous nerve of the thigh crosses the artery from its lateral to its medial side.

Behind, the artery lies in contact with the posterior part of the femoral sheath, by which it is separated from the tendon of the Psoas major, the Pectineus and the Adductor longus, in that order from above downwards. The artery is separated from the capsule of the hip-joint by the tendon of the Psoas major, from the Pectineus by the femoral vein and profunda vessels, and from the Adductor longus by the femoral vein—the profunda vessels having passed posterior to the Adductor longus. The nerve to the Pectineus passes medially behind the upper end of the artery. *Laterally* the artery is

related to the femoral nerve. The femoral vein is medial to the artery in the upper part of the femoral triangle, and posterior to the artery in the lower part.

In the *subsartorial canal* (figs. 757, 759) the femoral artery is more deeply situated, being covered with the skin, the superficial and deep fasciæ, the Sartorius and the fibrous roof of the canal. The saphenous nerve is at first on the lateral side of the artery; it then lies in front of it, and below is placed on its medial side. Behind, the artery is related to the Adductor longus above, and Adductor magnus below; in front and lateral to it is the Vastus medialis.

Fig. 757.—A transverse section through the middle of the thigh. Four-fifths of natural size.



The femoral vein lies posterior to the upper, and lateral to the lower, part of the artery.

Peculiarities.—Several instances are recorded where the femoral artery divided, below the origin of the arteria profunda femoris, into two trunks, which reunited near the opening in the Adductor magnus; a few have been reported where the femoral artery was absent, its place being supplied by the inferior gluteal artery, which accompanied the sciatic nerve to the popliteal fossa; in these the external iliac artery was small, and ended as the arteria profunda femoris. The femoral vein is occasionally placed along the medial side of the artery throughout the entire extent of the femoral triangle; or it may be duplicated so that a large vein is placed on each side of the artery for a greater or lesser distance.

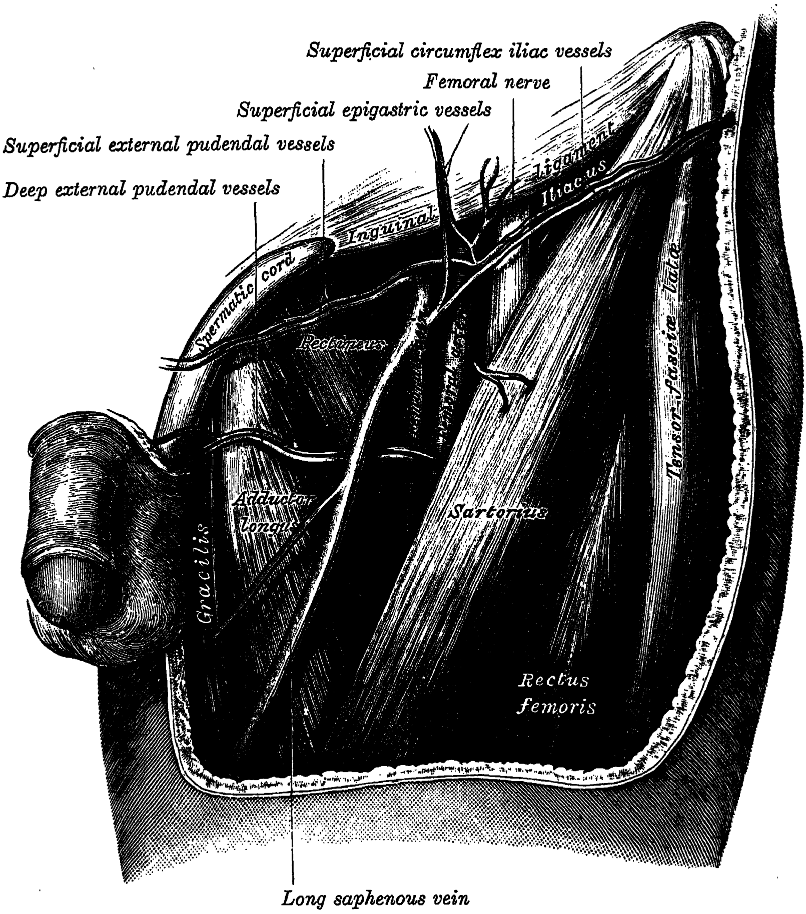
Applied Anatomy.—Compression of the femoral artery is most effectually made immediately below the inguinal ligament. In this situation the artery is superficial, and is separated from the superior ramus of the pubis by the Psoas major; here digital compression will effectually control the circulation through it. The vessel may also be controlled in the middle third of the thigh by a tourniquet which presses the vessel against the medial side of the femur.

Branches.—The branches of the femoral artery are :

1. Superficial epigastric.
2. Superficial circumflex iliac.
3. Superficial external pudendal.
4. Deep external pudendal.
5. Muscular.
6. Profunda femoris.
7. Descending genicular.

1. The **superficial epigastric artery** (fig. 758) arises from the front of the femoral artery about 1 cm. below the inguinal ligament, and, piercing the

FIG. 758.—The left femoral triangle.



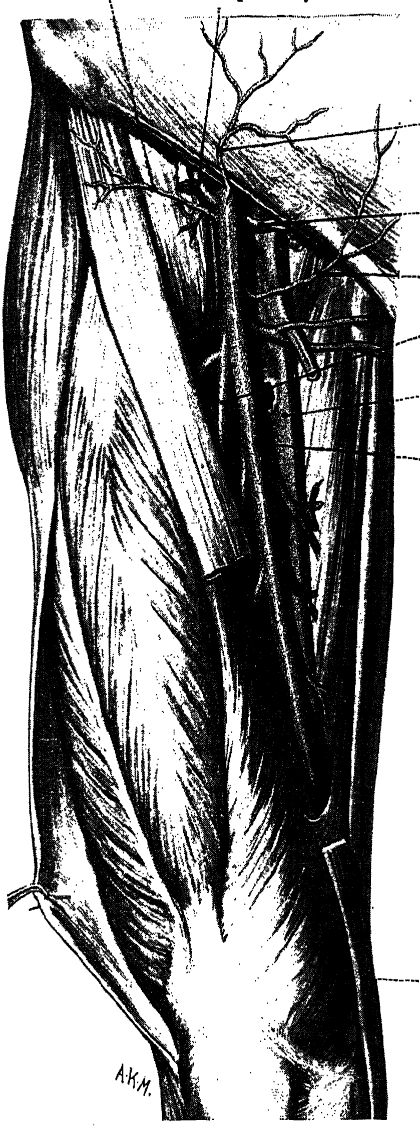
femoral sheath and the cribriform fascia, ascends in front of the inguinal ligament, and between the two layers of the superficial fascia of the abdominal wall nearly as far as the umbilicus. It distributes branches to the superficial inguinal lymph glands, the superficial fascia and the skin ; it anastomoses with branches of the inferior epigastric artery, and with its fellow of the opposite side.

2. The **superficial circumflex iliac artery** (fig. 758), the smallest of the superficial branches of the femoral artery, arises close to the preceding vessel, and running laterally, parallel with the inguinal ligament, pierces the fascia lata near the anterior superior iliac spine ; it gives branches to the skin, superficial fascia and superficial inguinal lymph glands, and anastomoses with the deep circumflex iliac, the superior gluteal and the lateral circumflex femoral arteries.

3. The **superficial external pudendal artery** (fig. 758) arises from the

medial side of the femoral artery, close to the preceding vessels. After piercing the femoral sheath and the cribriform fascia, it courses medially, across the spermatic cord (or round ligament of the uterus in the female), to be distributed to the skin on the lower part of the abdomen, the penis and scrotum in the male, and the labium majus in the female, anastomosing with branches of the internal pudendal artery.

Fig. 759.—The right femoral vessels.



4. The **deep external pudendal artery** (fig. 758) passes medially across the Pectineus and either in front of or behind the Adductor longus; it is covered by the fascia lata, which it pierces at the medial side of the thigh, and thereafter it is distributed, in the male, to the skin of the scrotum and perineum, in the female to the labium majus; its branches anastomose with the scrotal (or labial) branches of the internal pudendal artery.

5. **Muscular branches** are supplied by the femoral artery to the Sartorius, Vastus medialis and the Adductor muscles.

6. The **arteria profunda femoris** (figs 757, 759) is a large vessel arising from the lateral side of the femoral artery, about 3·5 cm. below the inguinal ligament. At first lateral to the femoral artery the profunda then runs behind it and the femoral vein to the medial side of the femur, and is continued downwards behind the Adductor longus. It ends at the lower one-third of the thigh in a small branch which pierces the Adductor magnus and anastomoses with the superior muscular branches of the popliteal artery. The terminal part of the profunda is sometimes named the *fourth perforating artery*.

Relations. — *Behind*, from above downwards, it is related to the Iliacus, Pectineus, Adductor brevis, and Adductor magnus. *In front*, it is separated from the femoral artery by the femoral and profunda veins above, and by the Adductor longus below. *Laterally*, the origin of the Vastus medialis intervenes between it and the femur.

Peculiarities.—This vessel sometimes arises from the medial side, more rarely from the back of the femoral artery. When it arises from the medial side, it may cross in front of the femoral vein and then pass backwards round its medial side. In most cases it arises between 2·25 cm. and 5 cm. below the inguinal ligament; in a few cases the distance is less than 2·25 cm.; more rarely it arises opposite the ligament. Occasionally the distance between the origin of the vessel and the inguinal ligament exceeds 5 cm.

The arteria profunda femoris gives off the following branches :

Lateral circumflex femoral.	Perforating.
Medial circumflex femoral.	Muscular.

The **lateral circumflex femoral artery** (fig. 759) arises from the lateral side of the profunda artery, passes laterally between the divisions of the femoral nerve and behind the Sartorius and Rectus femoris, and divides into ascending, transverse and descending branches. Occasionally it arises from the femoral artery.

The *ascending branch* passes upwards along the trochanteric line, under cover of the Tensor fasciæ latæ, to the lateral part of the hip ; it anastomoses with the terminal branches of the superior gluteal and deep circumflex iliac arteries, and sends a twig to the hip-joint between the medial and lateral parts of the iliofemoral ligament.

The *descending branch*, which may arise as an independent branch direct from the profunda femoris or, sometimes, from the femoral artery, runs downwards, behind the Rectus femoris, along the anterior border of the Vastus lateralis, to which it gives offsets ; one long branch descends in the latter muscle as far as the knee, and anastomoses with the lateral superior genicular branch of the popliteal artery. It is accompanied by the nerve to the Vastus lateralis.

The *transverse branch*, the smallest, passes laterally over the Vastus intermedius, pierces the Vastus lateralis, and winds round the femur, just below the greater trochanter, anastomosing on the back of the thigh with the medial circumflex femoral, inferior gluteal, and first perforating arteries (*cruciate anastomosis*).

The **medial circumflex femoral artery** usually arises from the posteromedial aspect of the profunda artery, but frequently springs from the femoral artery. It gives off *muscular branches* to the adductor muscles and then winds round the medial side of the femur, passing first between the Pectineus and Psoas major, and then between the Obturator externus and Adductor brevis, and finally appears between the Quadratus femoris and the upper border of the Adductor magnus, where it divides into transverse and ascending branches. The *transverse branch* takes part in the formation of the cruciate anastomoses. The *ascending branch* runs obliquely upwards upon the tendon of the Obturator externus and in front of the Quadratus femoris towards the trochanteric fossa, where it anastomoses with twigs from the gluteal arteries. An *acetabular branch* arises from the medial circumflex femoral artery at the upper border of Adductor brevis and enters the hip-joint below the transverse acetabular ligament, in company with the acetabular branch from the obturator artery; it supplies the fat in the acetabular fossa, and is continued along the ligamentum capitis femoris to the head of the femur.

The **perforating arteries** (fig. 753), usually three in number, are so named because they perforate the insertion of the Adductor magnus to reach the back of the thigh. They pass backwards close to the linea aspera of the femur under cover of small tendinous arches in the insertion of the muscle, and give off muscular, cutaneous and anastomosing branches. Reduced in size, they pass deep to the short head of the Biceps femoris (the first usually pierces the insertion of the Gluteus maximus), pierce the lateral intermuscular septum and enter the Vastus lateralis. The first perforating artery is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The *first perforating artery* passes backwards between the Pectineus and Adductor brevis (sometimes it perforates the latter muscle); it then pierces the Adductor magnus close to the linea aspera. It gives branches to the Adductor brevis, Adductor magnus, Biceps femoris and Gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral, and second perforating arteries.

The *second perforating artery*, larger than the first, but frequently arising in common with it, pierces the insertions of the Adductor brevis and Adductor magnus, and divides into ascending and descending branches, which supply the posterior femoral muscles, anastomosing with the first and third perforating arteries. The *nutrient artery* of the femur is usually given off from this artery; when two nutrient arteries exist, they usually spring from the first and third perforating vessels.

The *third perforating artery* is given off below the Adductor brevis; it pierces the insertion of the Adductor magnus, and divides into branches which supply the posterior

femoral muscles, and anastomose above with the higher perforating arteries, and below with the termination of the profunda and the muscular branches of the popliteal. The nutrient artery of the femur may arise from this branch.

The termination of the profunda artery, already described, is sometimes called the *fourth perforating artery.*

The perforating arteries form a double chain of anastomosing vessels, (*a*) in the muscles and (*b*) close to the linea aspera.

Numerous **muscular branches** arise from the arteria profunda femoris ; some of these end in the Adductors, others pierce the Adductor magnus, give branches to the hamstrings, and anastomose with the medial circumflex femoral artery and with the superior muscular branches of the popliteal artery.

The anastomosis on the back of the thigh. An important chain of anastomoses stretches from the gluteal region to the popliteal fossa, and is formed from above downwards, as follows : (*a*) the gluteal arteries anastomose with the terminal branches of the medial circumflex femoral artery, (*b*) the circumflex femoral arteries with the first perforating artery, (*c*) the perforating arteries with each other, and (*d*) the fourth perforating artery with the superior muscular branches of the popliteal artery.

7. **The descending genicular artery** (highest genicular artery) (figs. 759, 762) arises from the femoral just before it passes through the opening in the Adductor magnus, and immediately gives off a saphenous branch, and then descends in the substance of the Vastus medialis, and in front of the tendon of the Adductor magnus, to the medial side of the knee, where it anastomoses with the medial superior genicular artery. It supplies *muscular branches* to the Vastus medialis and Adductor magnus, and gives off *articular branches*, which take part in the anastomosis round the knee-joint. One of the articular branches crosses above the patellar surface of the femur, forming an anastomotic arch with the lateral superior genicular artery, and supplying branches to the knee-joint.

The *saphenous branch* pierces the lower part of the roof of the subsartorial canal and accompanies the saphenous nerve to the medial side of the knee. It passes between the Sartorius and Gracilis, and is distributed to the skin of the upper and medial part of the leg, anastomosing with the medial inferior genicular artery.

Collateral Circulation.—After ligature of the femoral artery above the origin of the profunda femoris artery, the main channels for carrying on the circulation are the following anastomoses : (1) the superior and inferior gluteal branches of the internal iliac (hypogastric) artery with the medial and lateral circumflex femoral and first perforating branches of the arteria profunda femoris ; (2) the obturator branch of the internal iliac artery with the medial circumflex femoral of the arteria profunda femoris ; (3) the internal pudendal branch of the internal iliac artery with the superficial and deep external pudendal branches of the femoral artery ; (4) the deep circumflex iliac branch of the external iliac artery with the lateral circumflex femoral branch of the arteria profunda femoris and the superficial circumflex iliac branch of the femoral artery ; and (5) the inferior gluteal branch of the internal iliac artery with the perforating branches of the arteria profunda femoris.

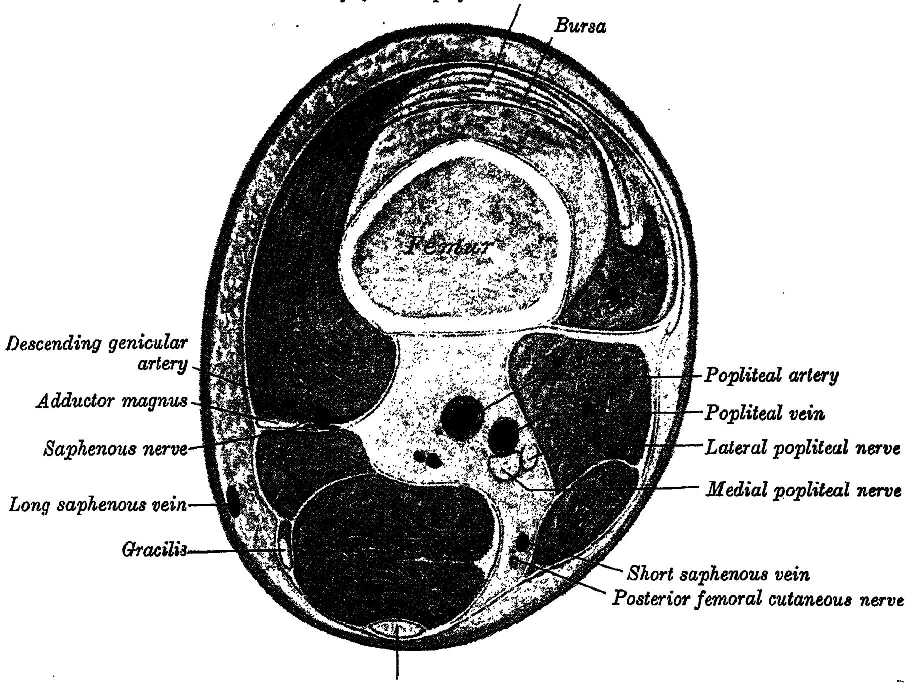
The Popliteal Fossa (figs. 760, 761)

Boundaries.—The **popliteal fossa,** or **space,** is a lozenge-shaped space at the back of the knee-joint. Laterally, it is bounded by the Biceps femoris above, and by the Plantaris and the lateral head of the Gastrocnemius below ; medially it is limited by the Semitendinosus and Semimembranosus above, and by the medial head of the Gastrocnemius below. The floor is formed by the popliteal surface of the femur, the oblique posterior ligament of the knee-joint, the back of the upper end of the tibia and the fascia covering the Popliteus ; the fossa is covered by the popliteal fascia.

Contents (figs. 760, 761).—When its boundaries are undisturbed, the popliteal fossa is only about 2·5 cm. wide, and very little can be seen of its contents. This is especially the case in the lower part of the space where the two heads of the Gastrocnemius lie in contact with each other. If, however, the boundaries be drawn apart the fossa is seen to contain the popliteal vessels, the

medial and lateral popliteal (tibial and the common peroneal) nerves, the termination of the short saphenous vein, the lower part of the posterior femoral cutaneous nerve, the articular branch from the obturator nerve, a few small lymph glands and a considerable quantity of fat. The medial popliteal (tibial) nerve descends through the middle of the fossa, lying under the popliteal fascia, and crossing the vessels posteriorly from the lateral to the medial side. The lateral popliteal (common peroneal) nerve descends on the lateral side of the upper part of the fossa, close to the tendon of the Biceps femoris. The popliteal vessels are on the floor of the fossa, the vein being superficial to the artery and united to it by dense areolar tissue; the vein is a thick-walled vessel, and lies lateral to the artery above, and then crosses it posteriorly to gain its medial side below; sometimes it is double, the artery lying between the two veins,

FIG. 760.—A transverse section through the thigh, 4 cm. above the adductor tubercle of the femur. Four-fifths of natural size.



which are usually connected by short transverse branches. The articular branch from the obturator nerve descends upon the artery to the knee-joint. The popliteal lymph glands, six or seven in number, are imbedded in the fat; one lies beneath the popliteal fascia near the termination of the short saphenous vein, another between the popliteal artery and the back of the knee-joint, while the others are placed at the sides of the popliteal vessels.

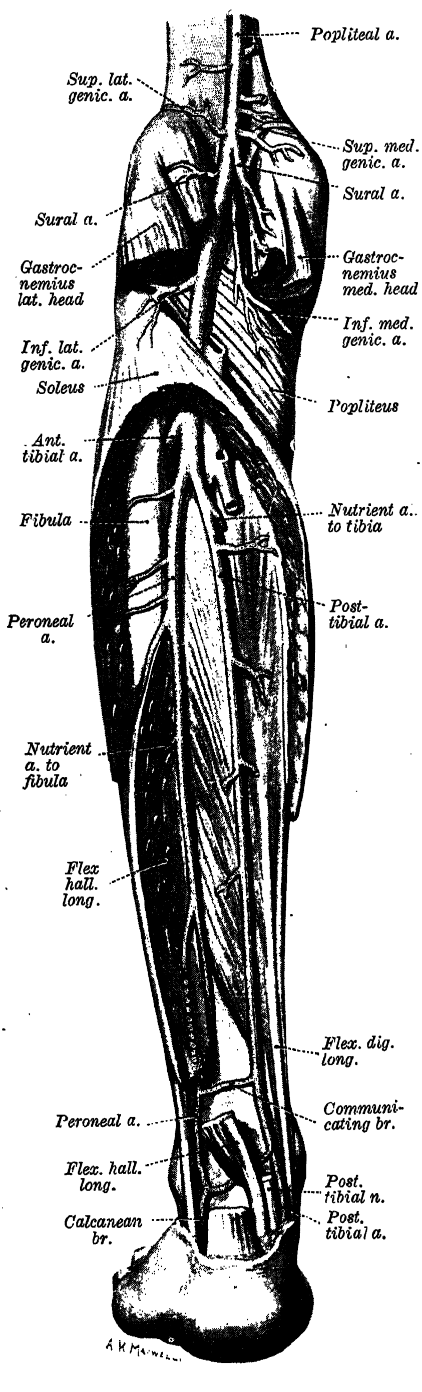
THE POPLITEAL ARTERY (figs. 760, 761)

The **popliteal artery** is the continuation of the femoral artery, and courses through the popliteal fossa. It commences at the opening in the Adductor magnus, at the junction of the middle with the lower one-third of the thigh, and extends downwards and slightly laterally to the intercondylar fossa of the femur. It then runs vertically downwards to the lower border of the Popliteus, where it divides into *anterior* and *posterior tibial arteries*.

Relations.—In *front*, from above downwards, the artery lies on the popliteal surface of the femur (separated from the vessel by some fat), the back of the knee-joint, and the fascia covering the Popliteus. *Behind*, it is overlapped by

the Semimembranosus above, and is covered by the Gastrocnemius and Plantaris below. In the middle part of its course the artery is separated from the skin and fasciæ by a quantity of fat, and is crossed from the lateral to the medial side by the medial popliteal nerve and the popliteal vein, the vein being between the nerve and the artery and closely adherent to the latter. On its *lateral side*, above, are the Biceps femoris, the medial popliteal nerve, the popliteal vein and the lateral condyle of the femur; below, the Plantaris and the lateral head of the Gastrocnemius. On its *medial* side, above, are the Semimembranosus and the medial condyle of the femur; below, the medial popliteal nerve, the popliteal vein and the medial head of the Gastrocnemius. The relations of the popliteal lymph glands to the artery are described above.

FIG. 761.—The left popliteal, posterior tibial and peroneal arteries.



Peculiarities.—Occasionally the popliteal artery divides into its terminal branches opposite the knee-joint; when this occurs the anterior tibial artery usually descends in front of the Popliteus (p. 152). The popliteal artery sometimes divides into the anterior tibial and peroneal arteries, the posterior tibial artery being wanting or rudimentary; occasionally it divides into three branches, the anterior and posterior tibial, and peroneal arteries.

Applied Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee, or by hyperextension of the knee. It may also be lacerated by fracture of the lower part of the femur, or by anteroposterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. It is more frequently the seat of aneurysm than any other artery except the thoracic aorta. No doubt this is due in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries. When the knee is acutely flexed, the popliteal artery becomes bent on itself to such an extent as entirely to arrest the circulation through it.

Branches.—The branches of the popliteal artery are:

Cutaneous. Muscular { Superior. Sural.

Genicular { Superior { medial. lateral. ; Middle ; Inferior { medial. lateral.

The cutaneous branches arise either from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius,

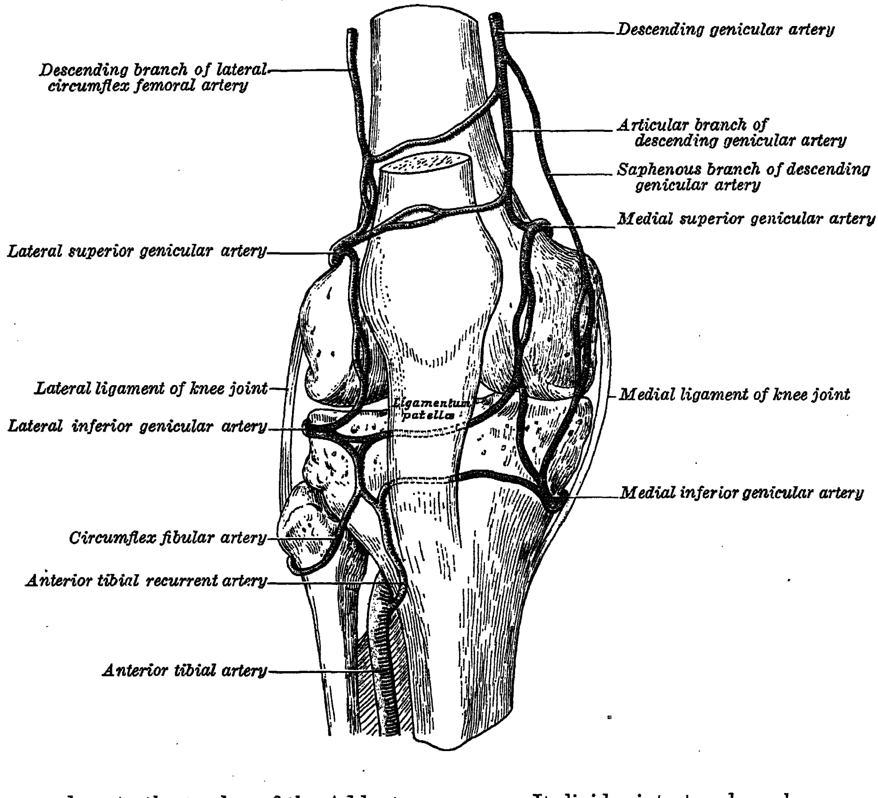
and, piercing the deep fascia, are distributed to the skin of the back of the leg ; one usually accompanies the short saphenous vein.

The **superior muscular branches**, two or three in number, arise from the upper part of the artery, and pass to the Adductor magnus and the hamstring muscles, anastomosing with the terminal part of the arteria profunda femoris.

The **sural arteries** are two large branches which arise opposite the knee-joint and are distributed to the Gastrocnemius, Soleus and Plantaris.

The **superior genicular arteries** (figs. 761, 762), two in number, arise one from each side of the popliteal artery, and wind round the femur immediately above its condyles to gain the front of the knee-joint. The *medial superior genicular artery* runs under cover of the Semimembranosus and Semitendinosus, above the medial head of the Gastrocnemius, and

FIG. 762.—The arterial anastomosis around the knee-joint.



passes deep to the tendon of the Adductor magnus. It divides into two branches, one of which supplies the Vastus medialis and anastomoses with the descending genicular (highest genicular) and medial inferior genicular arteries; the other ramifies close to the surface of the femur, and anastomoses with the lateral superior genicular artery. The size of the medial superior genicular artery varies inversely with that of the descending genicular. The *lateral superior genicular artery* passes under cover of the tendon of the Biceps femoris, and divides into a superficial and a deep branch ; the superficial branch supplies the Vastus lateralis, and anastomoses with the descending branch of the lateral circumflex femoral artery and with the lateral inferior genicular artery; the deep branch anastomoses with the medial superior genicular artery, and forms an arch across the front of the femur with the descending genicular artery.

The **middle genicular artery**, a small branch, arises from the popliteal artery opposite the back of the knee-joint; it pierces the oblique posterior ligament, and supplies the cruciate ligaments and the synovial membrane of the knee-joint.

The **inferior genicular arteries** (figs. 761, 762), two in number, arise from the popliteal artery under cover of the Gastrocnemius. The *medial inferior genicular artery* lies deep to the medial head of the Gastrocnemius and descends along the upper margin of the Popliteus, to which it gives branches; it then passes below the medial condyle of the tibia

and under cover of the medial (tibial collateral) ligament of the knee; at the anterior border of this ligament it ascends to the front and medial side of the joint, supplies the joint and the upper end of the tibia, and anastomoses with the lateral inferior and medial superior genicular arteries. The *lateral inferior genicular artery* runs laterally across the Popliteus, and then forwards above the head of the fibula to the front of the knee-joint, passing in its course under cover of the lateral head of the Gastrocnemius, the lateral (fibular collateral) ligament of the knee, and the tendon of the Biceps femoris. It divides into branches which anastomose with the medial inferior genicular, lateral superior genicular and anterior tibial recurrent arteries.

The **anastomosis around the knee-joint** (fig. 762).—Around and above the patella, and on the contiguous ends of the femur and tibia, an intricate arterial anastomosis forms a superficial and a deep network. The *superficial network* is situated between the fascia and skin round about the patella, and forms three well-defined arches; one above the patella in the loose connective tissue over the Quadriceps femoris, and two below the patella in the fat behind the ligamentum patellæ. The *deep network* lies on the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The vessels forming the anastomosis are the medial and lateral genicular, the descending genicular, the descending branch of the lateral circumflex femoral, the circumflex fibular, and the anterior tibial recurrent arteries.

The Anterior Tibial Artery (figs. 763, 765)

The **anterior tibial artery** is one of the two terminal branches of the popliteal artery and arises at the lower border of the Popliteus. Situated at first on the back of the leg, it passes forwards between the two heads of the Tibialis posterior and through the upper part of the interosseous membrane to the front of the leg, lying medial to the neck of the fibula. It next descends on the anterior surface of the interosseous membrane, gradually approaching the tibia: at the lower part of the leg it lies on this bone (fig. 766), and then on the front of the ankle-joint midway between the two malleoli, and is continued on the dorsum of the foot under the name of the *dorsalis pedis* artery.

Relations.—In the upper two-thirds of its extent, the anterior tibial artery rests upon the interosseous membrane of the leg; in the lower one-third, upon the front of the tibia and the ankle-joint. In the upper one-third of its course, it lies between the Tibialis anterior and Extensor digitorum longus; in the middle one-third between the Tibialis anterior and Extensor hallucis longus. At the ankle it is crossed from the lateral to the medial side by the tendon of the Extensor hallucis longus, and then lies between it and the first tendon of the Extensor digitorum longus. Its upper two-thirds are covered by the muscles which lie on each side of it, and by the deep fascia; its lower one-third, by the skin and fasciæ, and the extensor retinacula (transverse and cruciate crural ligaments).

A pair of venæ comitantes lie one on each side of the artery. The anterior tibial (deep peroneal) nerve, coursing round the lateral side of the neck of the fibula, comes into relation with the lateral side of the artery shortly after the latter reaches the front of the leg; about the middle of the leg the nerve is in front of the artery; at the lower part it is generally on its lateral side.

Peculiarities.—This vessel may be smaller than usual, or may be absent, its place being supplied by perforating branches from the posterior tibial, or by the perforating branch of the peroneal artery. The artery occasionally deviates towards the fibular side of the leg, regaining its usual position at the front of the ankle. Very occasionally it approaches the surface at the middle of the leg, and is covered merely by the skin and fasciæ below that point.

Applied Anatomy.—The anterior tibial artery is liable to be injured in fractures of the lower third of the tibia, on account of its close proximity to the bone. Ligature of the anterior tibial artery in the upper half of the leg is difficult on account of the depth of the vessel from the surface.

Branches.—The branches of the anterior tibial artery are:

Posterior tibial recurrent.	Muscular.	Anterior medial malleolar.
Anterior tibial recurrent.		Anterior lateral malleolar.

The **posterior tibial recurrent artery**—an inconstant branch—is given off from the anterior tibial artery before that vessel reaches the front of the leg. It ascends in front of the Popliteus in company with the nerve to that muscle, anastomoses with the inferior genicular branches of the popliteal artery, and gives an offset to the superior tibiofibular joint.

The **anterior tibial recurrent artery** (fig. 763) arises from the anterior tibial artery, as soon as that vessel has reached the front of the limb; it ascends in the Tibialis anterior, ramifies on the front and sides of the knee-joint, and assists in the formation of the patellar network by anastomosing with the genicular branches of the popliteal artery, and with the descending genicular artery.

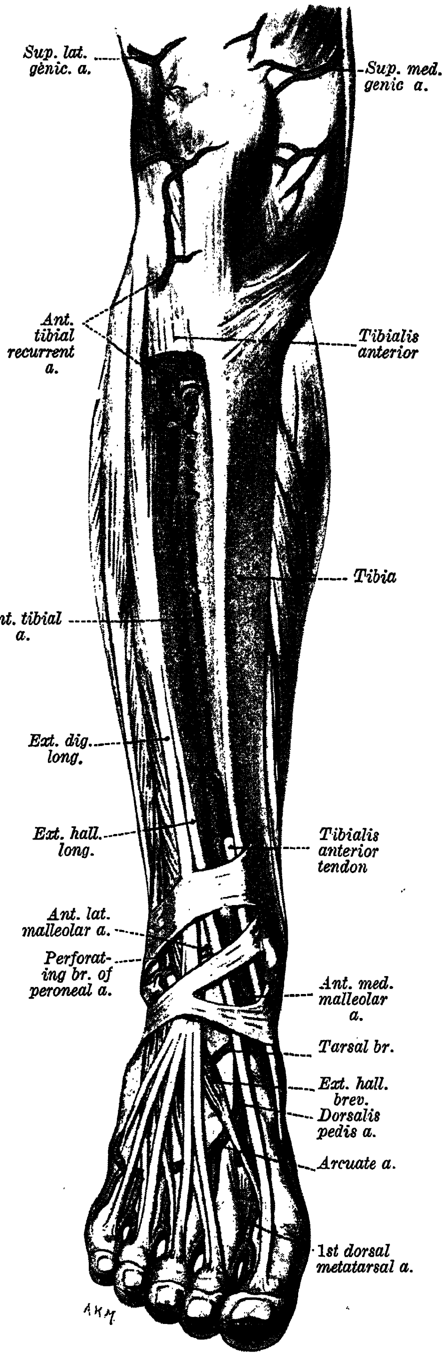
The **muscular branches** are numerous and are distributed to the muscles which lie on each side of the vessel; some pierce the deep fascia to supply the skin, others pass through the interosseous membrane of the leg, and anastomose with branches of the posterior tibial and peroneal arteries.

The **anterior medial malleolar artery** (fig. 763) arises about 5 cm. above the ankle-joint, and passes behind the tendons of the Extensor hallucis longus and Tibialis anterior, to the medial side of the ankle, where it anastomoses with branches of the posterior tibial and medial plantar arteries.

The **anterior lateral malleolar artery** (fig. 763) passes behind the tendons of the Extensor digitorum longus and Peroneus tertius; it supplies the lateral side of the ankle, and anastomoses with the perforating branch of the peroneal artery and with ascending twigs from the lateral tarsal artery.

The arteries around the ankle-joint anastomose freely with one another and form networks below the corresponding malleoli. The *medial malleolar network* is formed by the anterior medial malleolar branch of the anterior tibial artery, the medial tarsal branches of the dorsalis pedis artery, the malleolar and calcanean branches of the posterior tibial artery, and branches from the medial plantar artery. The *lateral malleolar network* is formed by the anterior lateral malleolar branch of the anterior tibial artery, the lateral tarsal branch of the dorsalis pedis artery, the perforating and the calcanean branches of the peroneal artery, and twigs from the lateral plantar artery.

FIG. 763.—The right anterior tibial and dorsalis pedis arteries.

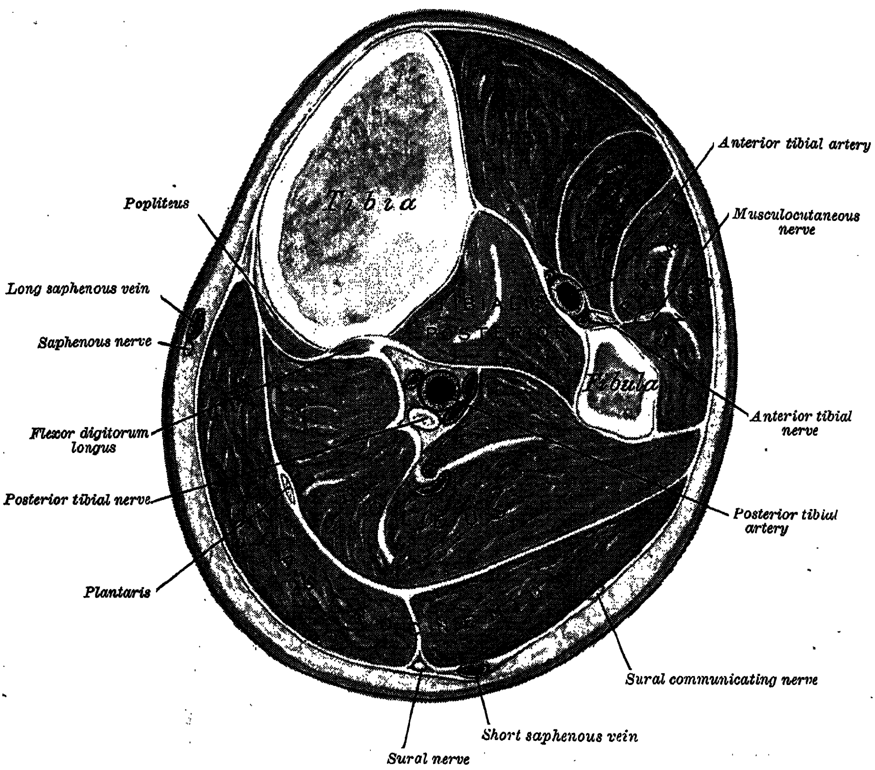


THE ARTERIA DORSALIS PEDIS (fig. 763)

The **arteria dorsalis pedis**, the continuation of the anterior tibial artery, passes forwards from the ankle-joint along the tibial side of the dorsum of the foot to the proximal part of the first intermetatarsal space, where it descends into the sole of the foot between the two heads of the first Dorsal interosseous muscle, and completes the plantar artery (fig. 768). At its junction with this artery it gives off the *first plantar metatarsal artery* (p. 802).

Relations.—The arteria dorsalis pedis is accompanied by two veins, and lies successively upon the front of the articular capsule of the ankle-joint, the talus, navicular, and intermediate cuneiform bones, and the ligaments connecting them. It is covered by the skin, fasciæ, and inferior extensor retinaculum (cruciate crural ligament), and crossed near its termination by the first tendon of the Extensor digitorum brevis. On its *tibial side* it is related to the tendon of the Extensor hallucis longus; on its *fibular side*, to the first tendon of the Extensor digitorum longus, and the medial terminal branch of the anterior tibial nerve.

FIG. 764.—A transverse section through the leg, 9 cm. below the knee-joint.



Peculiarities.—The arteria dorsalis pedis may be larger than usual, to compensate for a small lateral plantar artery; or its place may be taken by a large perforating branch of the peroneal artery. It frequently curves laterally, lying lateral to the line between the middle of the ankle and the proximal part of the first interosseous space.

Branches.—The branches of the arteria dorsalis pedis are:

Tarsal. Arcuate. First dorsal metatarsal.

The **tarsal arteries**, lateral and medial (fig. 763), arise from the arteria dorsalis pedis as the latter crosses the navicular bone. The lateral branch passes laterally under cover of the Extensor digitorum brevis; it supplies this muscle and the articulations of the tarsus, and anastomoses with branches of the arcuate, anterior lateral malleolar, and lateral plantar arteries, and with the perforating branch of the peroneal artery.

The *medial tarsal branches* are two or three small vessels which ramify on the medial border of the foot and join the medial malleolar network.

The **arcuate artery** (fig. 763) arises from the arteria dorsalis pedis opposite the medial cuneiform bone; it passes laterally over the bases of the metatarsal bones deep to the tendons of the Extensores digitorum longus et brevis, and anastomoses with the lateral tarsal and lateral plantar arteries. It gives off the *second, third* and *fourth dorsal metatarsal arteries*, which run forwards upon the corresponding Dorsal interosseous muscles; in the clefts between the toes each divides into two dorsal digital branches for the sides of the

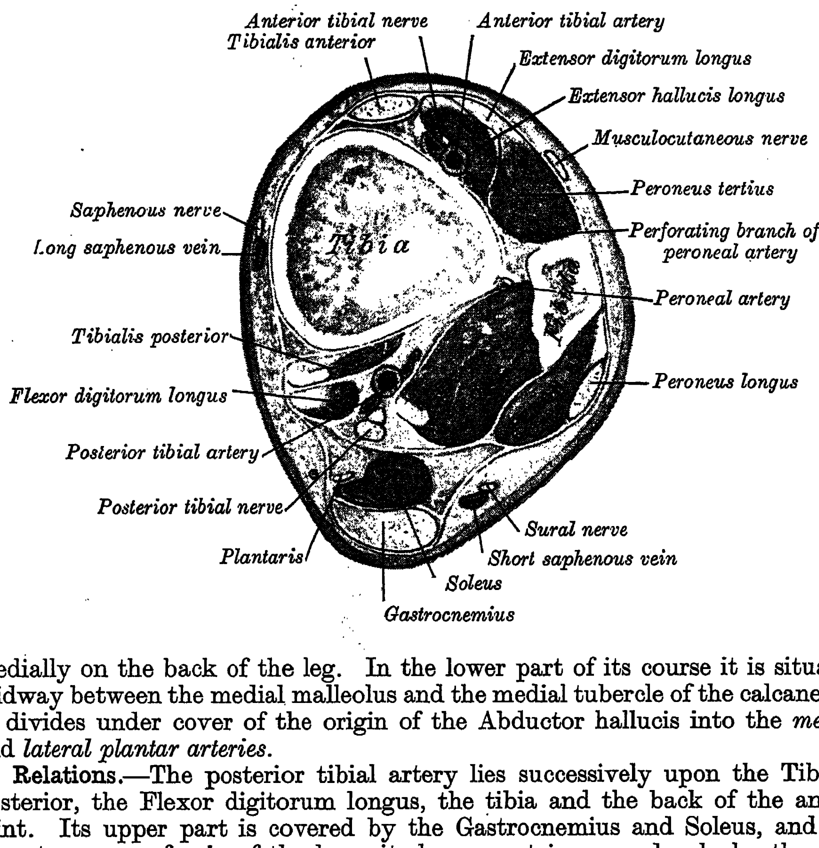
adjoining toes. At the proximal parts of the interosseous spaces the dorsal metatarsal arteries receive the posterior perforating branches from the plantar arch, and at the distal parts of the spaces they are joined by the anterior perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery gives off a branch which supplies the lateral side of the fifth toe.

The **first dorsal metatarsal artery** arises from the dorsalis pedis artery just before it descends into the sole; it runs forward on the first Dorsal interosseous muscle, and at the cleft between the first and second toes divides into two branches, one of which passes beneath the tendon of the Extensor hallucis longus, and is distributed to the medial border of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

The Posterior Tibial Artery (figs. 761, 765)

The **posterior tibial artery** begins at the lower border of the Popliteus, opposite the interval between the tibia and fibula, and passes downwards and

Fig. 765.—A transverse section through the leg, 6 cm. above the tip of the medial malleolus.



medially on the back of the leg. In the lower part of its course it is situated midway between the medial malleolus and the medial tubercle of the calcaneum. It divides under cover of the origin of the Abductor hallucis into the *medial* and *lateral plantar arteries.*

Relations.—The posterior tibial artery lies successively upon the Tibialis posterior, the Flexor digitorum longus, the tibia and the back of the ankle-joint. Its upper part is covered by the Gastrocnemius and Soleus, and the deep transverse fascia of the leg; its lower part is covered only by the skin and fascia, and runs parallel with, and about 2·5 cm. in front of, the medial border of the tendo calcaneus; its terminal part is deep to the flexor retinaculum (laciniate ligament) and the Abductor hallucis. It is accompanied by two veins, and by the posterior tibial nerve, which lies at first on its medial side, but soon crosses it posteriorly, and is, in the greater part of its course, on its lateral side.

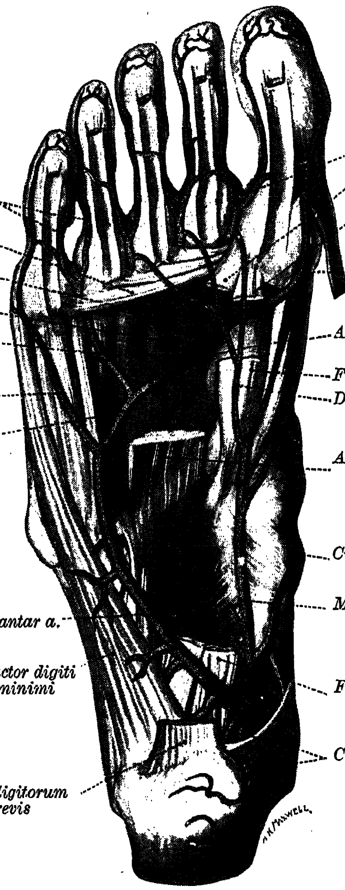
The structures which pass from the back of the leg to the sole of the foot under cover of the flexor retinaculum are arranged in the following order from the medial to the lateral side; first, the tendons of the Tibialis posterior and Flexor digitorum longus lying in the same groove behind the malleolus, the former being the more medial; then the posterior tibial artery, with a vein on each

side of it; lateral to the posterior tibial vessels is the posterior tibial nerve, and about 1·25 cm. nearer the heel, the tendon of the Flexor hallucis longus (fig. 761).

Peculiarities.—The posterior tibial artery may be small or absent, its place being supplied by a large peroneal artery, which either joins the small posterior tibial artery, or continues alone to the sole of the foot.

Applied Anatomy.—Ligature of the posterior tibial artery may be required in cases of wound of the sole of the foot, attended with great hæmorrhage; the vessel should then be tied at the ankle. In cases of wound of the posterior tibial, it will be necessary to enlarge

Fig. 766.—The arteries of the sole of the right foot.



the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg.

Branches.—The branches of the posterior tibial artery are:

1. Circumflex fibular.
2. Peroneal.
3. Nutrient.
4. Muscular.
5. Communicating.
6. Malleolar.
7. Calcanean.
8. Medial plantar.
9. Lateral plantar.

1. The **circumflex fibular artery,** sometimes a branch of the anterior tibial artery, passes laterally, round the neck of the fibula, through the Soleus, and anastomoses with the lateral inferior genicular artery.

2. The **peroneal artery** (fig. 761) arises from the posterior tibial, about 2·5 cm. below the lower border of the Popliteus. It passes obliquely towards the fibula, and descends along the medial crest of that bone, contained in a fibrous canal between the Tibialis posterior and the Flexor hallucis longus,

or in the substance of the latter muscle. It then runs behind the inferior tibiofibular joint, and divides into calcanean branches, which ramify on the lateral and posterior surfaces of the calcaneum. Its *upper* part is covered by the Soleus and the deep transverse fascia of the leg; its *lower* part, by the Flexor hallucis longus.

Peculiarities.—The peroneal artery may spring from the posterior tibial artery at a higher level than usual, or may even be a branch of the popliteal artery; sometimes it arises 7 or 8 cm. below the inferior border of the Popliteus. It is more frequently increased than diminished in size; and then it either joins and reinforces the posterior tibial artery, or takes the place of that artery in the lower part of the leg and foot. When the peroneal artery is smaller than usual, an additional branch from the posterior tibial artery takes its place; and a branch from the anterior tibial artery compensates for the diminished perforating artery.

Fig. 767.—The plantar arteries. Superficial dissection.

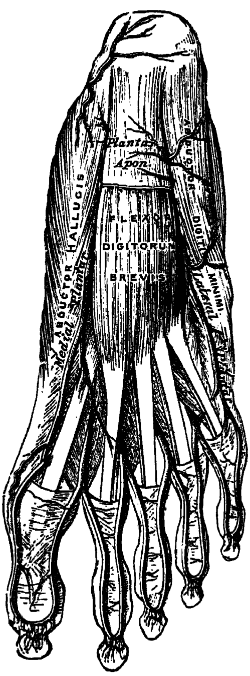


Fig. 768.—The plantar arteries. Deep dissection.

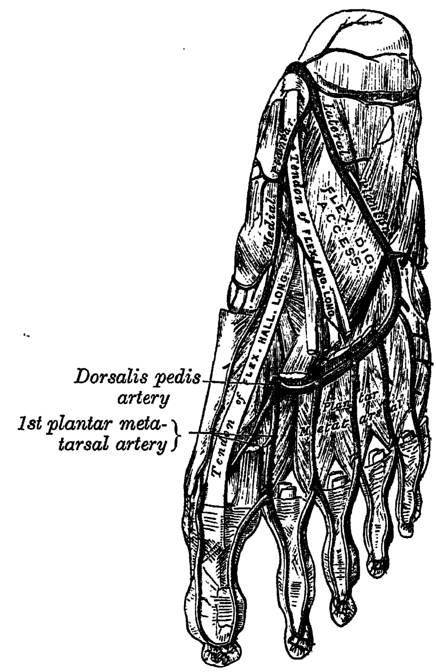


The peroneal artery gives off the following branches:

Muscular branches are supplied to the Soleus, Tibialis posterior, Flexor hallucis longus and Peronei.

A nutrient artery supplies the fibula, and is directed downwards.

A perforating branch pierces the interosseous membrane of the leg, about 5 cm. above the lateral malleolus, and reaches the front of the leg, where it anastomoses with the anterior lateral malleolar artery; it then descends in front of the inferior tibiofibular joint, gives branches to the tarsus, and anastomoses with the lateral tarsal artery. The perforating branch is sometimes enlarged, and may take the place of the dorsalis pedis artery.

A communicating branch arises from the peroneal artery about 5 cm. above the lower end of the tibia, and joins the communicating branch of the posterior tibial artery.

The **calcanean** or terminal branches of the peroneal artery pass to the lateral side of the heel, and communicate with the anterior lateral malleolar artery and, on the back of the heel, with the calcanean branches of the posterior tibial artery.

3. The **nutrient artery** of the tibia arises from the posterior tibial artery near its origin, and, after supplying a few minute muscular branches, runs downwards to enter the nutrient canal in the bone, at a point immediately below the soleal line (popliteal line).

4. **Muscular branches** are distributed to the Soleus and to the deep muscles on the back of the leg.

5. The **communicating branch** runs transversely across the back of the tibia about 5 cm. above its lower end, deep to the Flexor hallucis longus, and joins the communicating branch of the peroneal artery.

6. The **malleolar branch** is a small vessel which winds round the tibial malleolus and ends in the medial malleolar network.

7. The **calcanean branches** arise from the posterior tibial just before its division; they pierce the flexor retinaculum (laciniate ligament) and are distributed to the fat and skin behind the tendo calcaneus and about the heel, and to the muscles on the tibial side of the sole, anastomosing with the peroneal and medial malleolar arteries, and, on the back of the heel, with the calcanean branches of the peroneal artery.

8. The **medial plantar artery** (figs. 767, 768), the smaller terminal branch of the posterior tibial artery, passes forwards along the medial side of the foot in company with the medial plantar nerve, which lies to its lateral side. It is at first deep to the Abductor hallucis, and then runs forwards between it and the Flexor digitorum brevis, both of which it supplies. At the base of the first metatarsal bone, where it is much diminished in size, it passes along the medial border of the first toe and anastomoses with the first dorsal metatarsal artery. It supplies three small superficial digital branches which accompany the digital branches of the medial plantar nerve and join the first, second and third plantar metatarsal arteries.

9. The **lateral plantar artery** (fig. 768), the larger of the terminal branches of the posterior tibial artery, passes at first obliquely laterally and forwards to the base of the fifth metatarsal bone in company with the lateral plantar nerve, which lies on its medial side. It then turns medially with the deep branch of the nerve, to the interval between the bases of the first and second metatarsal bones, where it unites with the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes laterally, it is first placed between the calcaneum and Abductor hallucis, and then between the Flexor digitorum brevis and Flexor digitorum accessorius; as it runs forwards to the base of the fifth metatarsal bone it lies between the Flexor digitorum brevis and Abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

Branches.—The lateral plantar artery gives off muscular, superficial and anastomotic branches. The *muscular branches* supply the adjoining muscles; the *superficial branches* emerge along the line of the lateral intermuscular septum and supply the skin and subcutaneous tissue of the lateral part of the sole; the *anastomotic branches* run to the lateral border of the foot, where they anastomose with branches of the lateral tarsal and arcuate arteries. In addition, the lateral plantar artery sometimes gives off a *calcanean* branch, which pierces the origin of the abductor hallucis to supply the skin of the heel.

The **plantar arch** is deeply situated and extends from the base of the fifth metatarsal bone to the proximal part of the first interosseous space. It is convex forwards, lies below the bases of the second, third and fourth metatarsal bones and the corresponding Interossei, and above the oblique part of the Adductor hallucis.

Branches.—The plantar arch gives off three perforating and four plantar metatarsal branches, and distributes numerous twigs to the skin, fasciæ and muscles in the sole.

The three **perforating branches** ascend through the proximal parts of the second, third and fourth interosseous spaces, between the heads of the Dorsal interosseous muscles, and anastomose with the dorsal metatarsal arteries.

The four **plantar metatarsal arteries** (fig. 768) run forwards between the metatarsal bones and in contact with the Interossei. Each divides into a pair of plantar digital arteries, which supply the adjacent sides of the toes. Near their points of division each plantar metatarsal artery sends upwards an *anterior perforating branch* to join the corresponding dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and the dorsalis pedis arteries (p. 798), and sends a digital branch to the medial side of the first toe. The digital branch for the lateral side of the fifth toe arises from the lateral plantar artery near the base of the fifth metatarsal bone.

Applied Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. They must be treated on similar lines to those of wounds of the palmar arches (p. 756). Pressure locally, combined with elevation of the limb, may in some cases be sufficient to arrest the bleeding, but if this fails, an attempt should be made to find the bleeding point and ligature it. Should this prove unsuccessful, it may be necessary to ligature the femoral artery below the origin of the arteria profunda femoris, as ligature of the anterior and posterior tibial arteries may not be sufficient to control the hæmorrhage, and in the circumstances it is safer and quicker to tie the femoral artery.

THE VEINS

The veins convey the blood from the different parts of the body to the heart. They receive the blood from the capillaries, and unite with one another to form larger vessels which, in their passage towards the heart, increase in size as they receive tributaries, or join other veins. The veins are larger and more numerous than the arteries; hence, the capacity of the veins is greater than that of the arteries; the capacity of the pulmonary veins, however, exceeds that of the pulmonary arteries only to a slight extent. The veins are cylindrical like the arteries; their walls, however, are thin and they collapse when the vessels are empty, and the uniformity of their surfaces may be interrupted at intervals by slight constrictions, caused by the presence of valves in their interior (p. 666). They communicate very freely with one another, especially in certain regions of the body. Thus, between the venous sinuses of the cranium, and between the veins of the neck, where obstruction would be attended by imminent danger to the cerebral circulation, numerous anastomoses are found. Free communications also exist between the veins of the vertebral canal, and between the veins composing the various venous plexuses in the abdomen and pelvis.

The veins consist of two sets, viz. *pulmonary* and *systemic.*

The **pulmonary veins**, unlike other veins, contain oxygenated blood, which they return from the lungs to the left atrium of the heart.

The **systemic venous channels** return the venous blood from the body generally to the right atrium of the heart, and are subdivided into three sets, viz. superficial and deep veins, and venous sinuses.

The **superficial veins** lie in the superficial fascia, immediately under the skin; they return the blood from these structures, and eventually join the deep veins. In their mode of origin and termination the superficial veins are subject to considerable variation.

The **deep veins** accompany the arteries, and are usually enclosed in the same sheaths with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the artery, and are called *venæ comitantes.* The larger arteries—such as the axillary, subclavian, popliteal and femoral—have usually only one accompanying vein. In certain regions, however, the deep veins do not accompany the arteries; for instance, the cerebral veins, the veins of the skull and vertebral canal, the hepatic veins in the liver, and the larger veins returning blood from the bones.

Venous sinuses are found only in the interior of the skull, and are canals between the two layers of the dura mater. Their walls are devoid of muscular tissue and consist of endothelium only.

The **portal vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, and conveys the venous blood from the spleen and the viscera of digestion to the liver, where it breaks up into a network of capillary like vessels (sinusoids), from which the blood is drained by the hepatic veins to the inferior vena cava.

THE PULMONARY VEINS

The **pulmonary veins** return the oxygenated blood from the lungs to the left atrium of the heart. They are four in number, two from each lung, and are destitute of valves. They commence in the capillary network on the walls of the alveoli of the lungs, and, joining together, form one vessel from each lobule of the lung. These vessels, uniting successively, form a single trunk from each lobe, three from the right lung and two from the left. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, so that ultimately two veins, a superior and an inferior, leave each lung; they perforate the fibrous layer of the pericardium and open separately into the upper and posterior part of the left atrium (fig. 676). Occasionally the three veins on the right side remain separate. Sometimes the two left pulmonary veins unite to form a single trunk before entering the heart.

In the root of the lung, the superior pulmonary vein lies in front of and a little below the pulmonary artery; the inferior is situated at the lowest part of the hilum of the lung and on a plane posterior to that of the superior vein. The bronchus is behind the pulmonary artery.

On the right side the upper pulmonary vein passes behind the superior vena cava, and the lower behind the right atrium.

On the left side both pulmonary veins pass in front of the descending thoracic aorta.

Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane.

THE SYSTEMIC VEINS

The **systemic veins** may be arranged into three groups: 1. The veins of the heart. 2. The veins of the upper limbs, head, neck and thorax, all of which end in the superior vena cava. 3. The veins of the lower limbs, abdomen and pelvis, all of which end in the inferior vena cava.

THE VEINS OF THE HEART (fig. 769)

The **coronary sinus.**—Most of the veins of the heart open into the coronary sinus. This is a wide venous channel about 2 or 3 cm. long situated in the posterior part of the atrioventricular groove (coronary sulcus) of the heart (fig. 769), between the left atrium and left ventricle. It is completely surrounded by cardiac muscle, and some fibres from the left atrium may be carried over its posterior aspect. It ends in the right atrium between the opening of the inferior vena cava and the atrioventricular orifice, its aperture being guarded by a semilunar valve, named the *valve of the coronary sinus* (fig. 678).

Its tributaries are the great, small, and middle cardiac veins, the posterior vein of the left ventricle, and the oblique vein of the left atrium, all of which, except the last, are provided with valves at their orifices.

1. The **great cardiac vein** (fig. 769) begins at the apex of the heart and ascends in the anterior interventricular sulcus to reach the atrioventricular groove. It then curves to the left in this groove, and, reaching the back of the heart, opens into the left extremity of the coronary sinus. It receives tributaries from the left atrium and from both ventricles, including the *left marginal vein*, which ascends along the left margin of the heart and is of considerable size.

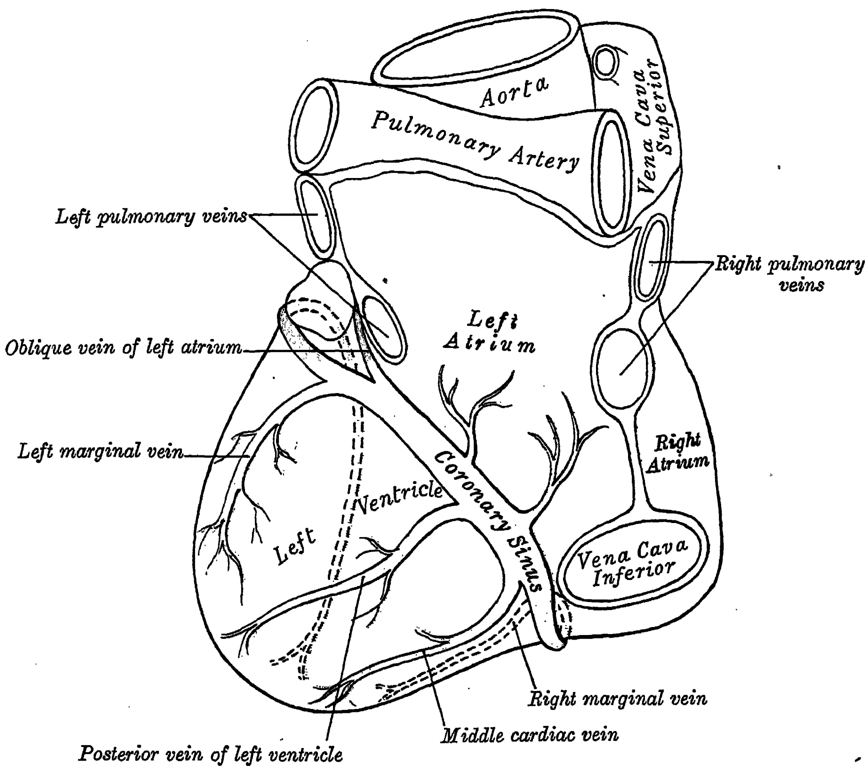
2. The **small cardiac vein** (fig. 769) runs in the atrioventricular groove between the right atrium and ventricle posteriorly, and opens into the right extremity of the coronary sinus. It receives blood from the back of the right atrium and ventricle; the *right marginal vein* ascends along the right margin of the heart and joins the small cardiac vein in the atrioventricular groove, or opens directly into the right atrium.

3. The **middle cardiac vein** (fig. 769) begins at the apex of the heart, runs backwards in the inferior interventricular groove, and ends in the coronary sinus near its right extremity.

4. The **posterior vein of the left ventricle** (fig. 769) runs on the diaphragmatic surface of the left ventricle a little to the left of the middle cardiac vein ; it usually opens into the coronary sinus, but may end in the great cardiac vein.

5. The **oblique vein of the left atrium** (fig. 769) is a small vessel which descends obliquely on the back of the left atrium and ends in the coronary sinus near its

FIG. 769.—A scheme showing the veins of the heart.



left extremity ; it is continuous above with the *ligament of the left vena cava* (p. 669), and the two structures are remnants of the left duct of Cuvier (p. 158).

The following cardiac veins do not end in the coronary sinus : (1) the **anterior cardiac veins,** comprising three or four small vessels which collect blood from the front of the right ventricle and open into the right atrium ; the right marginal vein frequently opens into the right atrium, and is therefore sometimes regarded as belonging to this group ; (2) the **venæ cordis minimæ,** comprising a number of minute veins, which lie in the muscular wall of the heart and open directly into its cavities, most of them into the atria, but a few into the ventricles.

THE VEINS OF THE HEAD AND NECK

The venous channels of the head and neck may be subdivided into : 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The diploic veins, the veins of the brain and the venous sinuses of the dura mater.

The Veins of the Exterior of the Head and Face (fig. 770)

Supratrochlear.	Maxillary.
Supra-orbital.	Posterior facial.
Anterior facial.	Posterior auricular.
Superficial temporal.	Occipital.

The **supratrochlear vein** (frontal vein) begins on the forehead in a venous network which communicates with the frontal tributaries of the superficial temporal vein. Veins converge from the network to form a single trunk, which descends on the forehead near the median plane parallel with the vein of the opposite side. At the root of the nose the two supratrochlear veins are joined by a transverse branch which is called the *nasal arch,* and receives small veins from the dorsum of the nose. The supratrochlear veins then diverge, and at the medial angle of the orbit, each joins with the *supra-orbital vein* to form the *anterior facial vein.* Occasionally the supratrochlear veins unite in a single trunk, which divides at the root of the nose into the two anterior facial veins.

The **supra-orbital vein** begins near the zygomatic process of the frontal bone, where it communicates with the superficial and middle temporal veins. It courses medially along the upper margin of the orbital opening under cover of the Orbicularis oculi, and, at the medial angle of the eye, pierces this muscle and unites with the supratrochlear vein to form the *anterior facial vein.* It sends a branch through the supra-orbital notch into the orbital cavity to join the superior ophthalmic vein; as this branch traverses the supra-orbital notch it is joined by the frontal diploic vein.

The **anterior facial vein,** formed by the junction of the supratrochlear and supra-orbital veins, runs obliquely downwards on the side of the root of the nose, to the level of the lower margin of the orbital opening. It then runs downwards and backwards behind the facial (external maxillary) artery, but follows a less tortuous course. It passes under cover of the Zygomaticus major, Risorius and Platysma, descends along the anterior border and then on the surface of the Masseter, crosses over the body of the mandible, and runs obliquely backwards, deep to the Platysma and superficial to the submandibular (submaxillary) gland, Digastric and Stylohyoid. A little below and in front of the angle of the mandible, it unites with the anterior branch of the posterior facial vein to form the *common facial vein,* which descends across the loop of the lingual artery, the hypoglossal nerve and the external and internal carotid arteries, and enters the internal jugular vein near the greater cornu of the hyoid bone. From near the termination of the common facial vein a branch of considerable size often runs down the anterior border of the Sternomastoid to join the lower part of the anterior jugular vein.

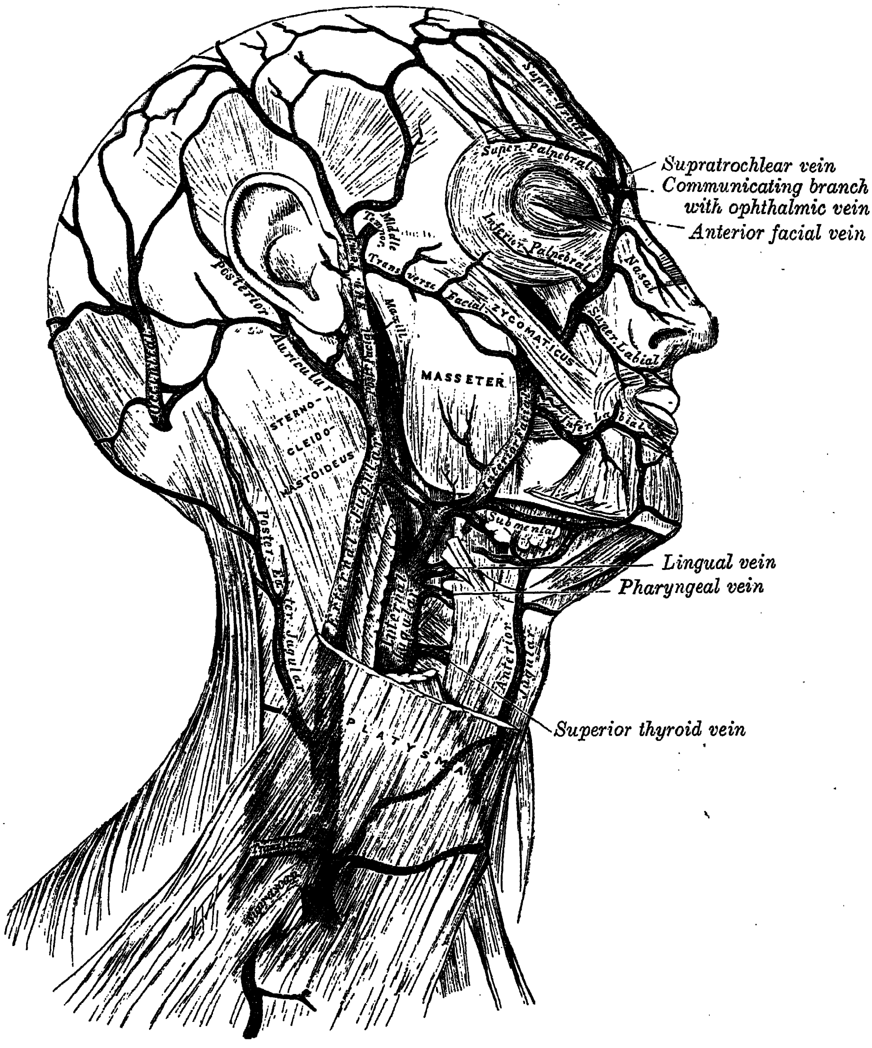
Tributaries.—The anterior facial vein receives the veins of the ala nasi, and communicates with the superior ophthalmic vein. Through this communication and the communication of the superior ophthalmic vein with the supra-orbital vein, an anastomosis is established between the anterior facial vein and the cavernous sinus. At a lower level the anterior facial vein receives a large branch, named the *deep facial vein,* from the pterygoid venous plexus. It is also joined by the inferior palpebral, the superior and inferior labial, the buccinator, the parotid and the masseteric veins. Below the mandible it receives the submental, external palatine and submandibular (submaxillary) veins. The common facial vein may be joined by the vena comitans of the hypoglossal nerve, and often receives the pharyngeal and superior thyroid veins.

Applied Anatomy.—The anterior facial vein is not so flaccid as most superficial veins, and, in consequence of this, shows less tendency to collapse when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement and by the supra-orbital veins, which are connected with the ophthalmic vein, a tributary of the cavernous sinus, but also by the deep facial vein, which communicates through the pterygoid plexus, with the cavernous sinus (p. 818). These facts have an important bearing upon the surgery of some diseases; any phlegmonous inflammation of the face following an infected wound is liable to set up thrombosis in the anterior facial

vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. These thrombi may extend upwards into the cranial sinuses, and so induce a fatal issue ; this has been known to follow in the case of ordinary carbuncle of the face. The position of the vein must be borne in mind when incisions are made for the relief of suppuration about the mandible.

The **superficial temporal vein** (fig. 770) begins on the side and vertex of the skull in a network which communicates with the corresponding vein of the opposite side, and with the supratrochlear, supra-orbital, posterior auricular

FIG. 770.—The veins of the right side of the head and neck.



and occipital veins. From this network, anterior and posterior tributaries arise, and unite above the zygomatic arch to form the superficial temporal vein, which is joined in this situation by the *middle temporal vein*. It then crosses the posterior root of the zygomatic arch, enters the substance of the parotid gland, and unites with the maxillary vein to form the posterior facial vein.

Tributaries.—The superficial temporal vein receives some veins from the parotid gland, articular veins from the mandibular joint, anterior auricular veins from the auricle, and the *transverse facial* from the side of the face. The middle temporal vein, after receiving the *orbital vein*, which is formed by some lateral palpebral branches, passes backwards between the layers of the temporal fascia and joins the superficial temporal vein.

The **pterygoid plexus** is of considerable size, and is situated partly between the Temporal and Lateral pterygoid muscles, and partly between the two Pterygoids. It receives the sphenopalatine, deep temporal, pterygoid, masseteric, buccal, dental, and greater palatine veins, and a branch or branches from the inferior ophthalmic vein. The pterygoid plexus anastomoses with the anterior facial vein, through the deep facial vein; it is also connected with the cavernous sinus by veins which pass through the emissary sphenoidal foramen (foramen Vesalii), foramen ovale and foramen lacerum.

The **maxillary vein** (internal maxillary vein) is a short trunk which accompanies the first part of the corresponding artery and is formed by a confluence of the veins of the pterygoid plexus. It passes backwards between the spheno-mandibular ligament and the neck of the mandible, and unites with the superficial temporal vein to form the posterior facial vein.

The **posterior facial vein,** formed by the union of the superficial temporal and maxillary veins, descends in the substance of the parotid gland, superficial to the external carotid artery but deep to the facial nerve. It divides into two branches, an anterior which passes forwards and unites with the anterior facial vein to form the common facial vein, and a posterior which is joined by the posterior auricular vein to form the external jugular vein.

The **posterior auricular vein** (fig. 770) begins on the posterior part of the side of the head, in a network which communicates with the tributaries of the occipital and superficial temporal veins. It descends behind the auricle, and joins the posterior division of the posterior facial vein in or just below the parotid gland to form the external jugular vein. It receives the stylomastoid vein and some tributaries from the cranial surface of the auricle.

The **occipital vein** (fig. 770) begins in a venous network at the posterior part of the skull. It pierces the cranial attachment of the Trapezius, dips into the suboccipital triangle and joins the deep cervical and vertebral veins. Occasionally it follows the course of the occipital artery and ends in the internal jugular vein; sometimes it joins the posterior auricular vein and, through it, opens into the external jugular vein. The parietal emissary vein connects it with the superior sagittal sinus, and the mastoid emissary vein with the transverse sinus. The occipital diploic vein sometimes joins it.

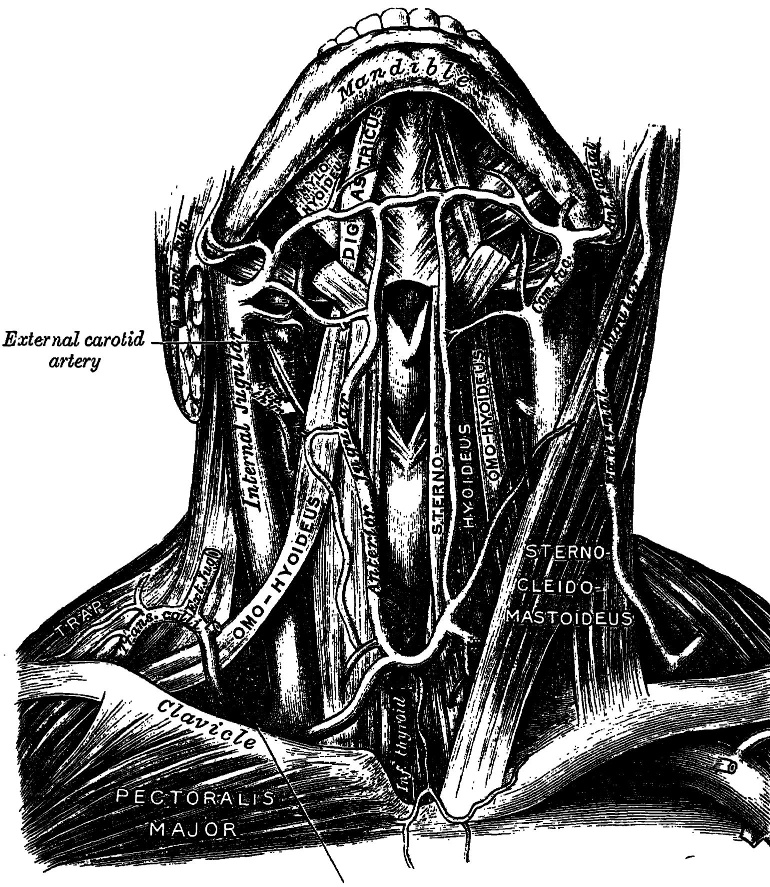
The Veins of the Neck (figs. 770, 772)

External jugular.	Anterior jugular.
Posterior external jugular.	Internal jugular.
Vertebral.	

The **external jugular vein** (fig. 770) receives the greater part of the blood from the exterior of the cranium and from the deep parts of the face, and is formed by the union of the posterior division of the posterior facial vein with the posterior auricular vein. It begins on a level with the angle of the mandible, just below the parotid gland, or, sometimes, in its substance, and runs down the neck, where its course is represented by a line drawn from the angle of the mandible to the middle of the clavicle. It crosses the Sternomastoid obliquely, and in the subclavian triangle perforates the deep fascia to end in the subclavian vein, lateral to, or in front of, the Scalenus anterior; the wall of the vein is adherent to the circumference of the opening in the deep fascia. It is covered by the Platysma, superficial fascia, and skin, and separated from the Sternomastoid by the investing layer of the deep cervical fascia; it crosses the anterior cutaneous nerve of the neck, and its upper half runs parallel with the great auricular nerve, which ascends behind it. The external jugular vein varies in size, bearing an inverse proportion to the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, a lower pair at its entrance into the subclavian vein, an upper about 4 cm. above the clavicle. The portion of the vein between the two sets of valves is often dilated, and is sometimes termed the *sinus*. These valves do not prevent regurgitation of the blood, or the passage of injection from below upwards.

Tributaries.—The external jugular vein receives the posterior external jugular, and, near its termination, the transverse cervical, suprascapular transverse scapular) and anterior jugular veins; in the parotid gland it is frequently joined by a branch from the internal jugular vein. The occipital vein occasionally opens into it.

FIG. 771.—The veins of the neck. Anterior aspect. (After Spalteholz.)



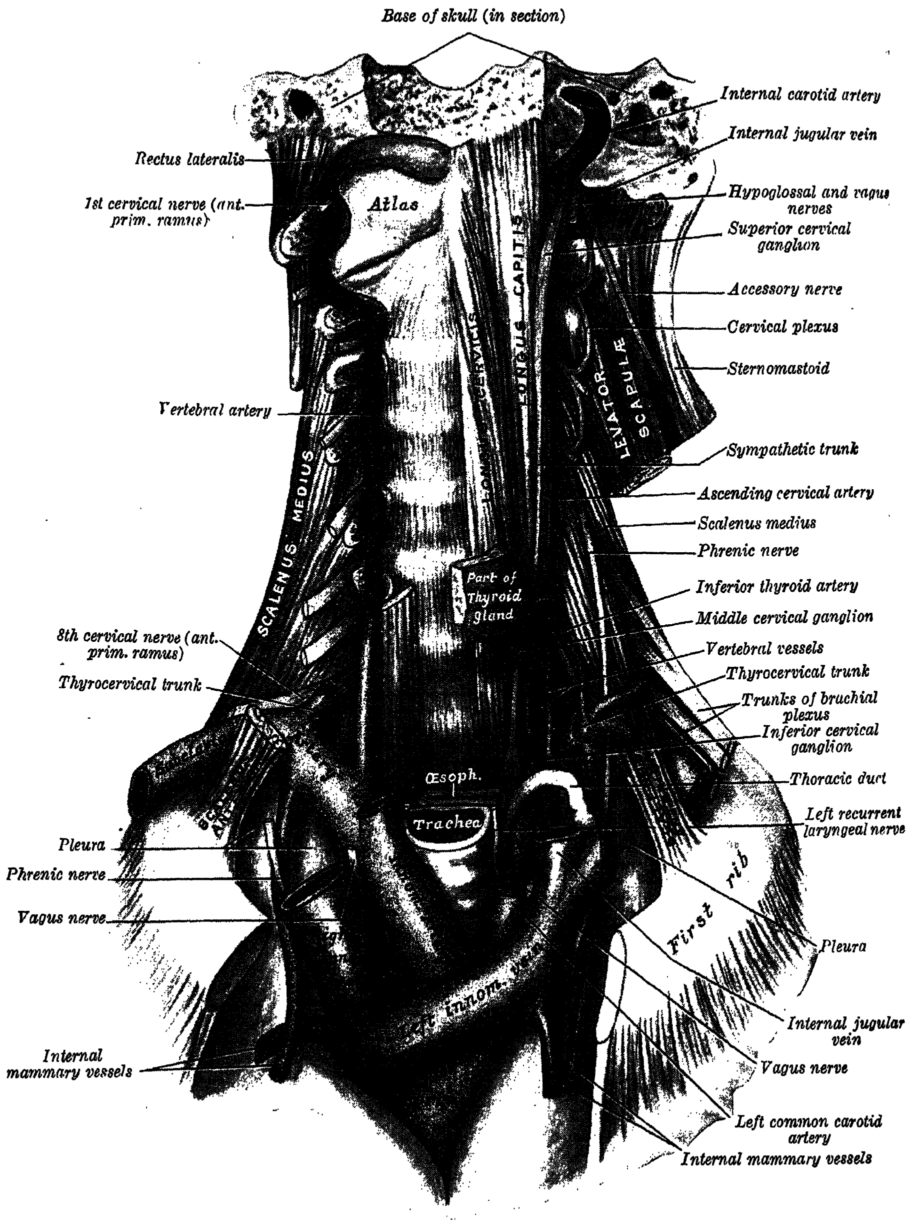
Applied Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. When the vein is cut there is some risk of air being drawn into it.

The **posterior external jugular vein** begins in the occipital region and returns the blood from the skin and superficial muscles in the upper and posterior part of the neck. It opens into the middle part of the external jugular vein.

The **anterior jugular vein** (figs. 770, 771) is devoid of valves and begins near the hyoid bone by the confluence of several superficial veins from the submandibular region. It descends between the anterior median line and the anterior border of the Sternomastoid; at the lower part of the neck it turns laterally under cover of that muscle, but superficial to the depressors of the hyoid bone, and opens into the termination of the external jugular vein, or into the subclavian vein. Its size varies considerably, and usually bears an inverse proportion to that of the external jugular vein. It communicates with the internal jugular vein and receives as tributaries some laryngeal veins, and occasionally a small thyroid vein. There are usually two anterior jugular veins, a right and a left; just above the sternum they are united by a large transverse

trunk, termed the *jugular arch,* which receives tributaries from the inferior thyroid veins. The anterior jugular veins may be replaced by a single trunk which descends in the anterior median line of the neck.

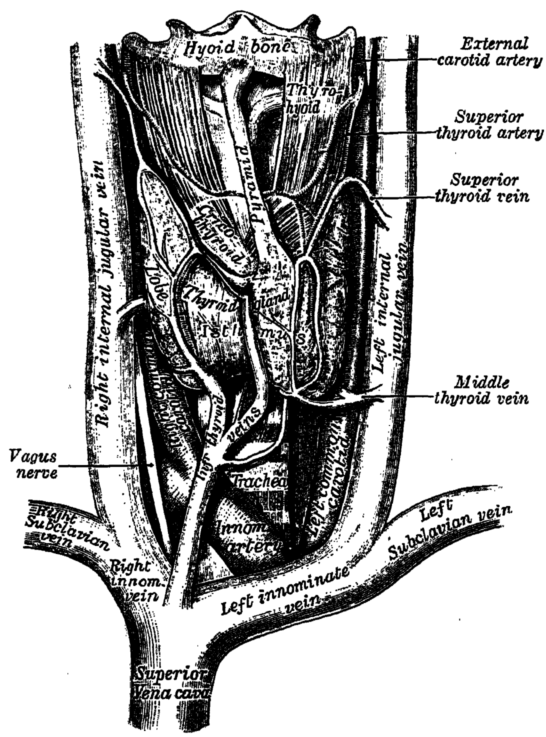
FIG. 772.—A drawing of a dissection of the prevertebral and upper thoracic regions showing the vessels, etc., near the root of the neck, the cervical course of the vertebral artery, and the structures which lie posterior to the internal jugular vein.



The **internal jugular vein** (fig. 771) collects the blood from the brain, from the superficial parts of the face, and from the neck. It begins at the base of the skull in the posterior compartment of the jugular foramen, where it is directly continuous with the sigmoid sinus. At its origin it is somewhat dilated; this dilatation, which is called the *superior bulb,* lies below the posterior part of the floor of the tympanic cavity. The vein runs downwards through the neck

within the carotid sheath (fig. 584), and, behind the sternal end of the clavicle, unites with the subclavian vein to form the innominate vein. The internal jugular vein is dilated near its termination to form what is known as the *inferior bulb*; directly above this bulb the vein contains a pair of valves. *Posteriorly* the internal jugular vein rests, from above downwards, on the Rectus capitis lateralis, the transverse process of the atlas, the Levator scapulæ, the Scalenus medius and the cervical plexus; then on the Scalenus anterior, the phrenic nerve, the thyrocervical trunk, the vertebral vein and the first part of the subclavian artery; on the left side it passes in front of the thoracic duct (fig. 772). *Medially* the vein is related to the internal and common carotid arteries, and to the vagus nerve, the last lying between the vein and the arteries but on a plane posterior to them. *Superficially* the vein is overlapped by the upper part, and covered by the lower part, of the Sternomastoid, and is crossed by the posterior belly of the Digastric and the superior belly of the Omohyoid. Above the Digastric it is covered by the parotid gland and the styloid process, and is crossed by the accessory nerve and the posterior auricular and occipital arteries. Between the Digastric and the Omohyoid the sternomastoid arteries and the nervus descendens cervicalis cross the vein, but the nerve often passes between it and the common carotid artery. Below the Omohyoid it is covered by the infrahyoid muscles, in addition to the Sternomastoid, and is crossed superficial to the infrahyoid muscles by the anterior jugular vein. The deep cervical lymph glands lie along the course of the vein, mainly on its superficial aspect. At the root of the neck the right internal jugular vein is placed at a little distance from the common carotid artery, while the left vein usually overlaps the artery. At the base of the skull the internal carotid artery is in front of the internal jugular vein, and is separated from it by the last four cranial nerves.

Fig. 773.—The veins of the thyroid gland.



Tributaries.—The internal jugular vein receives the inferior petrosal sinus, the common facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital vein. In the upper part of the neck it may communicate with the external jugular vein. The thoracic duct opens into the angle of union of the left subclavian and internal jugular veins, and the right lymphatic duct into the angle of union of the right subclavian and internal jugular veins.

The **inferior petrosal sinus** leaves the skull through the anterior part of the jugular foramen and, crossing either lateral or medial to the ninth, tenth and eleventh cranial nerves, joins the superior bulb of the internal jugular vein.

The **lingual veins** begin on the dorsum, sides, and under surface of the tongue, and, passing backwards along the course of the lingual artery, end in the internal jugular vein near the greater cornu of the hyoid bone. The **vena comitans hypoglossi**—a vein of considerable size—begins below the tip of the tongue, and may join the lingual veins; generally, however, it passes backwards superficial to the Hyoglossus, and opens into the common facial vein.

The **pharyngeal veins** begin in the *pharyngeal plexus* on the outer surface of the pharynx, and, after receiving some meningeal veins and the vein of the pterygoid canal, end in the internal jugular vein. They occasionally open into the facial, the lingual, or the superior thyroid vein.

The **superior thyroid vein** (fig. 773) begins in the substance and on the surface of the thyroid gland, by tributaries corresponding with the branches of the superior thyroid artery. It accompanies this artery, receives the superior laryngeal and cricothyroid veins, and ends in the internal jugular or in the common facial vein.

The **middle thyroid vein** (fig. 773) collects the blood from the lower part of the thyroid gland, and receives some veins from the larynx and trachea. It crosses in front of the common carotid artery, and ends in the lower part of the internal jugular vein under cover of the superior belly of the Omohyoid.

The inferior thyroid veins are described on p. 826.

The **common facial** and **occipital veins** have been described (pp. 806, 808).

Applied Anatomy.—The internal jugular vein requires ligature in cases of septic thrombosis of the sigmoid sinus, secondary to suppurative otitis media, in order to prevent septic emboli being carried into the general circulation. This operation has been performed in many cases, with the most satisfactory results. These cases are always extremely grave, for there is a danger of portions of the thrombus or clot being detached and causing septic embolism in the lungs. When the thrombosis involves the superior bulb of the internal jugular vein, the glossopharyngeal, vagus and accessory nerves may be paralysed. The hypoglossal nerve is sometimes paralysed by extension of the thrombus to the veins of the anterior condylar canal.

The internal jugular vein is also important surgically, because it is surrounded by a number of deep cervical lymph glands; and when these are enlarged in tuberculous or malignant disease, they are apt to adhere to the vessel, rendering their removal difficult and often dangerous.

Cardiac pulsation is often demonstrable in the internal jugular vein at the root of the neck. There are no valves in the innominate veins or superior vena cava; in consequence, the systole of the right atrium causes a wave to pass up these vessels, and when the conditions are favourable this wave appears as a somewhat feeble flicker over the internal jugular vein at the root of the neck, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to the ventricular systole. This atrial systolic venous impulse is much increased in conditions in which the right atrium is abnormally distended with blood or is hypertrophied, as is often the case in disease of the mitral valve. In the Adams-Stokes' syndrome it is this pulsation which gives evidence of the fact that the atria are beating faster—often two or three times faster—than the ventricles.

The **vertebral vein** is formed in the suboccipital triangle, from numerous small tributaries which spring from the internal vertebral plexuses and issue from the vertebral canal above the posterior arch of the atlas. They unite with small veins from the deep muscles at the upper part of the back of the neck, and form a vessel which enters the foramen in the transverse process of the atlas, and descends, forming a dense plexus around the vertebral artery, in the canal formed by the foramina transversaria of the cervical vertebræ. This plexus ends in the vertebral vein, which emerges from the foramen transversarium of the sixth cervical vertebra, and runs downwards, at first anterior and then anterolateral to the vertebral artery, to open into the upper and posterior part of the innominate vein, the opening being guarded by a pair of valves. In its course the vertebral vein descends behind the internal jugular vein and in front of the first part of the subclavian artery (fig. 772). A small vein usually descends from the plexus around the vertebral artery, passes through the foramen transversarium of the seventh cervical vertebra, and curves forwards between the subclavian artery and the cervical pleura to join the innominate vein.

Tributaries.—The vertebral vein communicates with the sigmoid sinus of the skull by a vein which passes through the posterior condylar canal, when that canal exists. It receives branches from the occipital vein, from the prevertebral muscles, and from the internal and external vertebral plexuses. It is joined by the anterior vertebral and the deep cervical veins; close to its termination it sometimes receives the first intercostal vein.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending

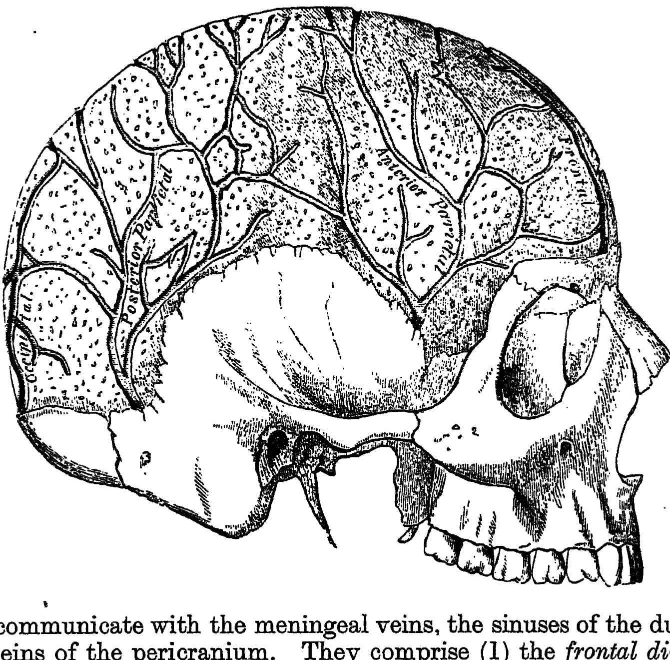
cervical artery between the Scalenus anterior and Longus capitis, and opens into the terminal part of the vertebral vein.

The **deep cervical vein** accompanies its artery between the Semispinales capitis et cervicis. It begins in the suboccipital region by communicating branches from the occipital vein and by small veins from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spines of the cervical vertebræ, and passes forwards between the transverse process of the seventh cervical vertebra and the neck of the first rib to end in the lower part of the vertebral vein.

The Diploic Veins (fig. 774)

The **diploic veins** occupy channels in the diploë of the cranial bones and are devoid of valves. They are large, and exhibit pouch-like dilatations at irregular intervals; their walls are thin, and formed of endothelium supported by a layer of elastic tissue.

Fig. 774.—The veins of the diploë. Displayed by the removal of the outer table of the skull.



They communicate with the meningeal veins, the sinuses of the dura mater, and the veins of the pericranium. They comprise (1) the *frontal diploic vein,* which emerges from the bone at the supra-orbital foramen and opens into the supra-orbital vein; (2) the *anterior parietal diploic vein,* which is confined chiefly to the frontal bone and pierces the greater wing of the sphenoid bone to end in the sphenoparietal sinus or in the anterior deep temporal vein; (3) the *posterior parietal diploic vein,* which is situated in the parietal bone; it descends to the posterior inferior angle of the parietal bone and joins the transverse sinus through an aperture placed at that angle or through the mastoid foramen; and (4) the *occipital diploic vein,* the largest of the four, which is confined to the occipital bone and opens into the occipital vein, or into the transverse sinus near the confluence of the sinuses. In addition, numerous small diploic veins pierce the inner table close to the margins of the superior sagittal sinus and terminate in the venous lacunæ (p. 815).

The Veins of the Brain

The veins of the brain possess no valves, and their walls, owing to the absence of muscular tissue, are extremely thin. They pierce the arachnoid mater and the inner or meningeal layer of the dura mater, and open into the cranial venous sinuses. They comprise two sets, cerebral and cerebellar.

The **cerebral veins** are divisible into external and internal groups, according as they drain the outer surfaces or the inner parts of the hemispheres.

The **external cerebral veins** are the superior, middle and inferior.

The *superior cerebral veins*, eight to twelve in number on each hemisphere, drain the superolateral and medial surfaces of the hemispheres, and are mainly lodged in the sulci between the gyri, but some run across the gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface of the hemisphere, and open into the superior sagittal sinus ; the anterior veins run nearly at right angles to the sinus ; the posterior and larger veins are directed obliquely forwards, and thus open into the sinus in a direction opposed to the current of the blood contained within it.

The *superficial middle cerebral vein* begins on the lateral surface of the hemisphere, and, following the posterior ramus and the stem of the lateral sulcus (lateral cerebral fissure), ends in the cavernous sinus. The *superior anastomotic vein* runs backwards and upwards between the middle cerebral vein and the superior sagittal sinus, and thus a communication is established between the superior sagittal and cavernous sinuses. A second vein, named the *inferior anastomotic vein*, courses over the temporal lobe, and connects the middle cerebral vein to the transverse sinus.

The *inferior cerebral veins* are of small size, and drain the under surface of the hemisphere. Those on the orbital surface of the frontal lobe join the superior cerebral veins, and through these open into the superior sagittal sinus ; those of the temporal lobe anastomose with the basal and middle cerebral veins, and join the cavernous, superior petrosal and transverse sinuses.

The *basal vein* begins at the anterior perforated substance by the union of (*a*) a small *anterior cerebral vein*, which accompanies the anterior cerebral artery, (*b*) the *deep middle cerebral vein*, which receives the tributaries from the insula and neighbouring gyri, and runs in the floor of the lateral cerebral sulcus, and (*c*) the *striate veins*, which pass through the anterior perforated substance. The basal vein passes backwards round the cerebral peduncle and ends in the great cerebral vein ; it receives tributaries from the interpeduncular fossa, the inferior horn of the lateral ventricle, the hippocampal gyrus and the mid-brain.

The **internal cerebral veins**, two in number, drain the deep parts of the hemisphere ; each is formed near the interventricular foramen by the union of the *thalamostriate* (terminal) and *choroid veins*. They run backwards parallel with each other, between the layers of the tela chorioidea of the third ventricle, and below the splenium of the corpus callosum, where they unite to form the *great cerebral vein*.

The *thalamostriate vein* (terminal vein) runs in the groove between the caudate nucleus and the thalamus, receives numerous veins from both of these structures, and unites behind the anterior column of the fornix with the choroid vein, to form the internal cerebral vein. The *choroid vein* runs along the whole length of the choroid plexus, and receives veins from the hippocampus, the fornix, and the corpus callosum.

The **great cerebral vein**, formed by the union of the two internal cerebral veins, is a short median trunk which curves sharply upwards around the splenium of the corpus callosum and opens into the anterior extremity of the straight sinus, after receiving the right and left basal veins.

The **cerebellar veins** are placed on the surface of the cerebellum, and consist of two sets, superior and inferior. Some of the *superior cerebellar veins* pass forwards and medially, across the superior vermis, to end in the straight sinus and in the internal cerebral veins ; others run laterally to the transverse and superior petrosal sinuses. The *inferior cerebellar veins*, of large size, end in the sigmoid, superior petrosal and occipital sinuses.

The Venous Sinuses of the Dura Mater (figs. 775 to 779)

The sinuses of the dura mater are venous channels which drain the blood from the brain ; they are situated between the two layers of the dura mater and are lined by endothelium continuous with that which lines the veins ; they contain no valves, and their walls are devoid of muscular tissue. They may be

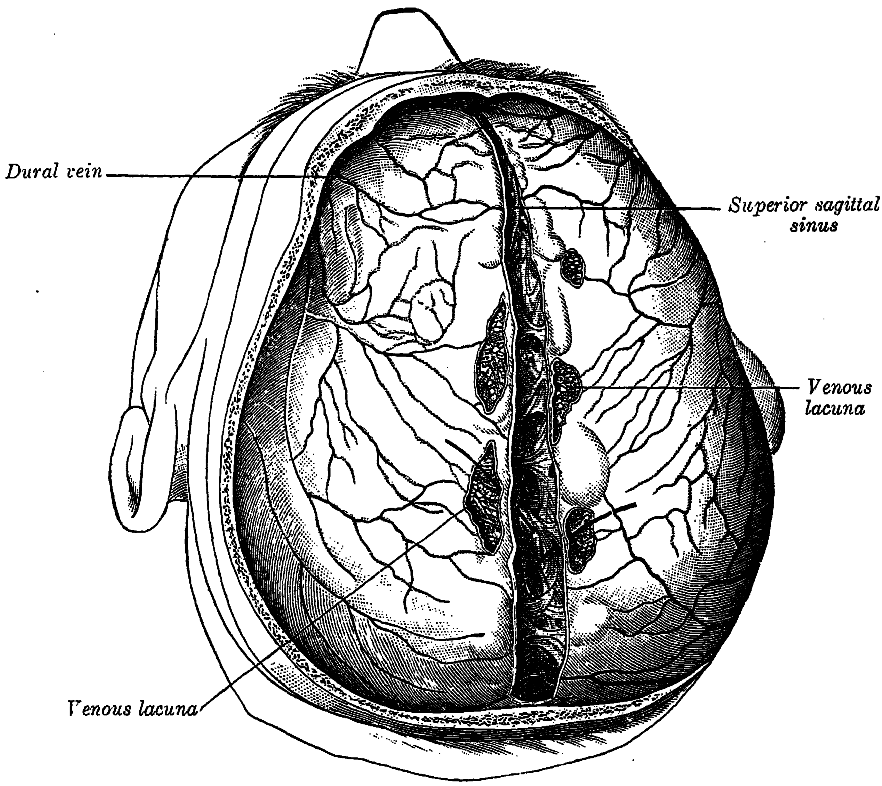
divided into two groups: (1) a posterosuperior, at the upper and posterior parts of the skull, and (2) an antero-inferior, at the base of the skull.

1. The posterosuperior group of venous sinuses:

Superior sagittal.	Two transverse.
Inferior sagittal.	Two sigmoid.
Straight.	Occipital.

The **superior sagittal sinus** (figs. 775, 776) occupies the attached, convex margin of the falx cerebri. It commences in front of the crista galli, where it receives a vein from the nasal cavity on the rare occasions when the foramen

FIG. 775.—The superior sagittal sinus laid open after the removal of the skull-cap. The fibrous bands which cross the sinus and the venous lacunæ are clearly seen; from two of the lacunæ bristles are passed into the sinus. (Poirier and Charpy.)



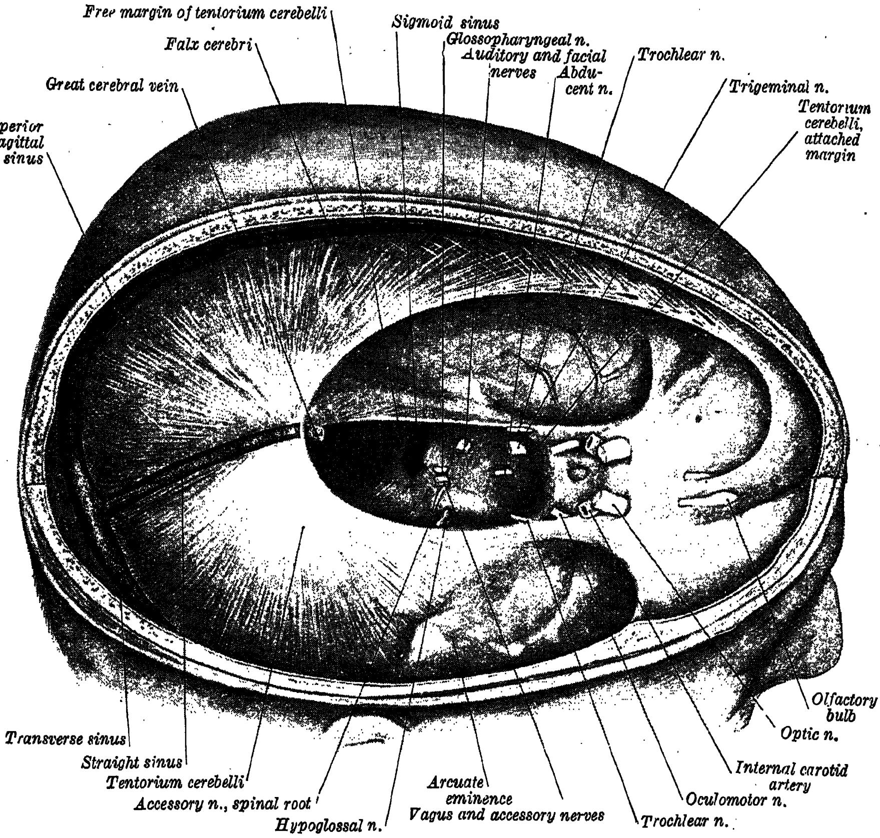
cæcum is patent; it runs backwards, grooving the inner surface of the frontal bone, the adjacent margins of the two parietal bones, and the squamous part of the occipital bone; near the internal occipital protuberance it deviates to one or other side (usually the right), and is continued as the corresponding transverse sinus. It is triangular in cross-section, and gradually increases in size as it passes backwards. Its inner surface presents the openings of the superior cerebral veins, projecting arachnoid granulations, and numerous fibrous bands which cross the inferior angle of the sinus; the sinus also communicates through small openings with irregularly-shaped *venous lacunæ* (lacunæ laterales), which are situated in the dura mater near the sinus. There are usually three lacunæ laterales on each side of the sinus: a small frontal, a large parietal, and an occipital, which is intermediate in size between the other two (Sargent *). Many fine fibrous bands cross the lacunæ, and numerous arachnoid granulations project into them from below. The superior sagittal sinus receives the superior

* Percy Sargent, *Journal of Anatomy and Physiology*, vol. xlv.

cerebral veins, and, near the posterior extremity of the sagittal suture, veins from the pericranium which pass through the parietal foramina ; the venous lacunæ receive the diploic and meningeal veins.

The *confluence of the sinuses* (fig. 777), is the term applied to the dilated posterior extremity of the superior sagittal sinus. It is lodged on one side (generally the right) of the internal occipital protuberance, and from it the transverse sinus of the same side is derived. It receives also the blood from the occipital sinus, and is connected by a channel with the commencement of the opposite transverse sinus.

FIG. 776.—The dura mater and its processes. Exposed by removing part of the right half of the skull, and the brain.



According to le Gros Clark * the lacunæ laterales should not be described as single well-defined cavities, but rather as a complicated meshwork of veins into which the diploic veins and the superior terminations of the meningeal veins open. He states that the superior cerebral veins never open into the lacunæ, but pass beneath them and open directly into the superior sagittal sinus.

Applied Anatomy.—The communications which take place between the superior sagittal sinus and the veins of the nose, scalp, and diploë, cause it to be at times the seat of infective thrombosis from suppurative processes in these parts.

The **inferior sagittal sinus** (fig. 776) is contained in the posterior one-half or two-third of the free margin of the falx cerebri. It increases in size as it passes backwards, and ends in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the medial surfaces of the hemispheres.

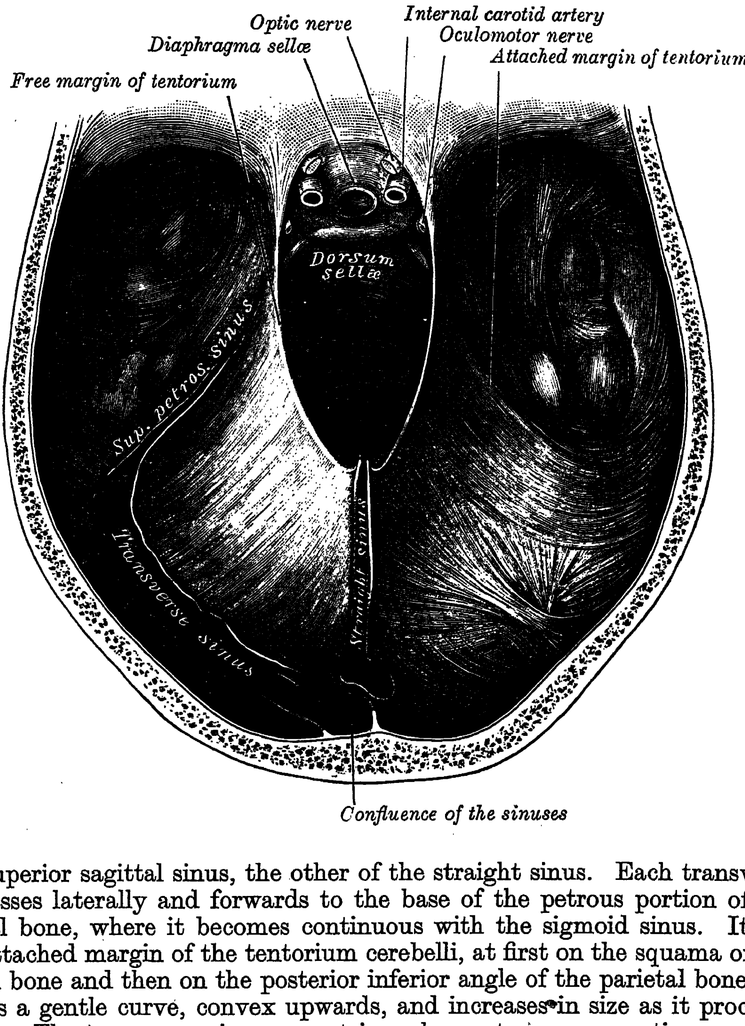
The **straight sinus** (figs. 776, 777) is situated in the line of junction of the falx cerebri with the tentorium cerebelli. It is triangular in cross-section and

* W. E. le Gros Clark, *Journal of Anatomy*, vol. lv.

is traversed by a few transverse bands. It runs backwards and downwards from the end of the inferior sagittal sinus to the transverse sinus of the side opposite to that into which the superior sagittal sinus is prolonged. Its terminal part communicates by a cross branch with the confluence of the sinuses. Besides the inferior sagittal sinus, it receives some of the superior cerebellar veins, and, at its commencement, the great cerebral vein, the site of the opening of this vein being marked by a dilatation.

The **transverse sinuses** (fig. 777, 778) are of large size, and begin at the internal occipital protuberance ; one, generally the right, being the direct continuation

Fig. 777.—The tentorium cerebelli. Superior aspect.

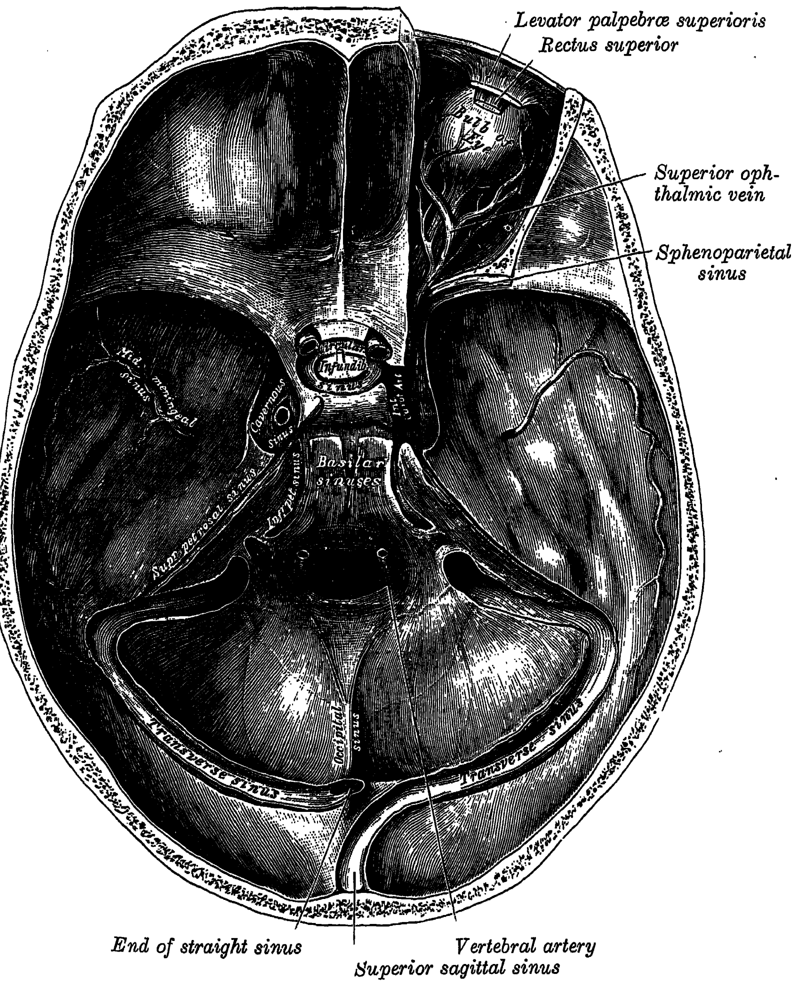


of the superior sagittal sinus, the other of the straight sinus. Each transverse sinus passes laterally and forwards to the base of the petrous portion of the temporal bone, where it becomes continuous with the sigmoid sinus. It lies in the attached margin of the tentorium cerebelli, at first on the squama of the occipital bone and then on the posterior inferior angle of the parietal bone. It describes a gentle curve, convex upwards, and increases in size as it proceeds forwards. The transverse sinuses are triangular on transverse section, and are frequently of unequal size, that formed by the superior sagittal sinus being the larger. At the point where they become continuous with the sigmoid sinuses, they are joined by the superior petrosal sinuses ; and in their course they receive some inferior cerebral, inferior cerebellar, and diploic veins, and the inferior anastomotic vein (p. 814). The *petrosquamous sinus*, when present, runs backwards along the junction of the squama and petrous portion of the temporal bone, and opens into the transverse sinus. Anteriorly, it communicates with the external jugular vein through a postglenoid (p. 296) or a squamosal foramen (p. 295).

The **sigmoid sinuses** (fig. 778) are directly continuous with the transverse sinuses at the point where the latter leave the tentorium cerebelli. Each

sigmoid sinus curves downwards and medially in a deep groove on the mastoid part of the temporal bone, crosses the jugular process of the occipital bone, and then turns forwards to become continuous with the superior bulb of the internal jugular vein in the posterior part of the jugular foramen. Anteriorly a very thin plate of bone separates the upper part of the sigmoid sinus from the tympanic antrum and mastoid air-cells. Each sinus communicates with the veins of the pericranium by means of the mastoid and condylar emissary veins.

FIG. 778.—The sinuses at the base of the skull.



The **occipital sinus** (fig. 778), the smallest of the cranial sinuses, is situated in the attached margin of the falx cerebelli, and is generally unpaired, but two may be present. It commences near the margin of the foramen magnum in several small venous channels, one of which joins the terminal part of the sigmoid sinus ; it communicates with the internal vertebral plexuses, and ends in the confluence of the sinuses.

2. The antero-inferior group of venous sinuses :

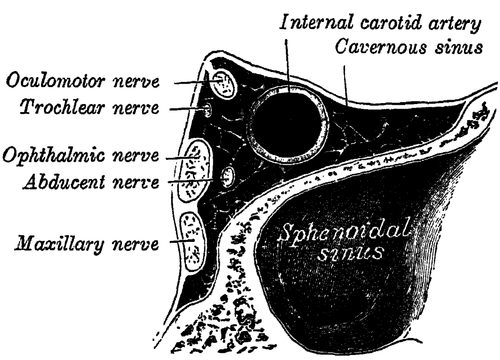
Cavernous.	Superior petrosal.	Basilar.
Sphenoparietal.	Inferior petrosal.	Middle meningeal.
Intercavernous.		

The **cavernous sinuses** (figs. 778, 779) are placed on the sides of the body of the sphenoid bone, and are so named because they present a spongy structure, due to their being traversed by numerous interlacing filaments. Each extends

from the superior orbital fissure in front, to the apex of the petrous part of the temporal bone behind, and has an average length of 2 cm. and a width of 1 cm. The internal carotid artery, surrounded by a plexus of sympathetic filaments, passes forwards through the sinus; the abducent nerve, in this part of its course, lies inferolateral to the artery; the oculomotor and trochlear nerves, and the ophthalmic and maxillary divisions of the trigeminal nerve (fig. 779) are placed in the lateral wall of the sinus. These structures are separated from the blood in the sinus by the lining membrane of the sinus. The sphenoidal sinus and the hypophysis cerebri are medial to the cavernous sinus. The cavum trigeminale (p. 1024) is closely related to the lower and posterior part of its lateral wall, and extends backwards beyond the sinus, enclosing the trigeminal (semilunar) ganglion. The uncus forms an additional relation of the lateral wall.

The tributaries of the cavernous sinus are the superior ophthalmic vein, a branch from the inferior ophthalmic vein, the superficial middle cerebral vein, some inferior cerebral veins, and the sphenoparietal sinus; the central vein of the retina and the anterior trunk of the middle meningeal sinus sometimes open into it. The cavernous sinus communicates with the transverse sinus through the superior petrosal sinus; with the internal jugular vein through the inferior petrosal sinus and a plexus of veins on the internal carotid artery; with the pterygoid venous plexus by veins which pass through the emissary sphenoidal foramen (Vesalii), foramen ovale, and foramen lacerum; and with the anterior facial vein through the superior ophthalmic vein. The two sinuses also communicate with each other by means of the anterior and posterior intercavernous sinuses and the network of basilar sinuses.

Fig. 779.—An oblique section through the left cavernous sinus.



The **sphenoparietal sinuses** (fig. 778) run on the under surfaces of the lesser wings of the sphenoid bone, near their posterior edges. Each sinus receives some small veins from the adjacent part of the dura mater and may receive one of the middle meningeal sinuses; it opens into the anterior part of the cavernous sinus.

Applied Anatomy.—An arteriovenous communication may be established between the cavernous sinus and the internal carotid artery, giving rise to a pulsating tumour in the orbit. Such communication may be the result of a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation. Ligature of the internal or common carotid artery has been performed in these cases with considerable success.

It is now well known that caries in the upper parts of the nasal cavities and suppuration in certain of the accessory sinuses of the nose are frequently responsible for septic thrombosis of the cavernous sinuses, in exactly the same way as thrombosis of the sigmoid sinus is due to septic disease in the mastoid process. Many deaths from meningitis, hitherto unaccounted for, are in reality due to the spread of an infection from the ethmoidal or sphenoidal sinuses to the cavernous sinuses, and thence to the meninges.

The **ophthalmic veins** (fig. 780), two in number, superior and inferior, are devoid of valves.

The *superior ophthalmic vein* begins behind the medial angle of the upper eyelid by the union of two branches which communicate anteriorly with the anterior facial and supra-orbital veins (p. 806). It runs with the ophthalmic artery, receives tributaries corresponding to the branches of that vessel, passes through the medial part of the superior orbital fissure, and ends in the cavernous sinus.

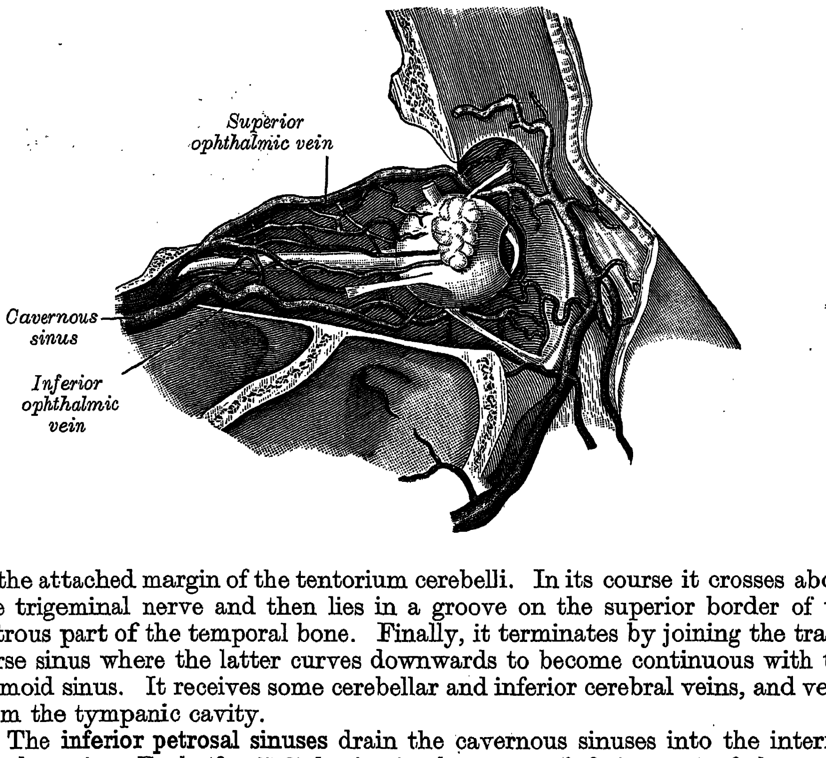
The *inferior ophthalmic vein* begins in a venous network at the fore part of the floor and medial wall of the orbit; it receives some veins from the Rectus

inferior, Obliquus inferior, lacrimal sac and eyelids, and runs backwards above the Rectus inferior. It frequently joins the superior ophthalmic vein, but may open into the cavernous sinus. It communicates with the pterygoid venous plexus by means of small veins which pass through the inferior orbital fissure.

The **intercavernous sinuses**, an anterior and a posterior, connect the cavernous sinuses across the median plane, and are situated in the anterior and posterior attached borders of the diaphragma sellæ; they form with the cavernous sinuses a venous circle (*circular sinus*) (fig. 778). The small, irregular venous sinuses which lie below the hypophysis cerebri drain into the intercavernous sinuses.

The **superior petrosal sinuses** (fig. 778), small and narrow, drain the cavernous sinuses into the transverse sinuses. After leaving the posterosuperior part of the cavernous sinus, each superior petrosal sinus runs backwards and laterally

FIG. 780.—The veins of the orbit. (Poirier and Charpy.)



in the attached margin of the tentorium cerebelli. In its course it crosses above the trigeminal nerve and then lies in a groove on the superior border of the petrous part of the temporal bone. Finally, it terminates by joining the transverse sinus where the latter curves downwards to become continuous with the sigmoid sinus. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **inferior petrosal sinuses** drain the cavernous sinuses into the internal jugular vein. Each (fig. 778) begins in the postero-inferior part of the corresponding cavernous sinus, runs backwards in the groove between the petrous part of the temporal bone and the basilar part of the occipital bone, and, passing through the anterior part of the jugular foramen, ends in the superior bulb of the internal jugular vein. It receives the internal auditory vein and also veins from the medulla oblongata, pons, and under surface of the cerebellum.

The relations of the structures transmitted through the jugular foramen are as follows: the inferior petrosal sinus lies medially and anteriorly with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downwards and backwards; the sigmoid sinus is situated at the lateral and posterior part of the foramen with a meningeal branch of the occipital artery; between the two sinuses are the glossopharyngeal, vagus, and accessory nerves. The junction of the inferior petrosal sinus with the internal jugular vein usually takes place on the lateral aspect of the nerves.

The **network of basilar sinuses** (fig. 778) consists of several interconnecting venous channels situated between the layers of the dura mater over the dorsum sellæ of the sphenoid bone and the basilar part of the occipital bone; it connects

the two inferior petrosal sinuses, and communicates with the internal vertebral venous plexus.

The **middle meningeal sinuses** (fig. 778) communicate above with the superior sagittal sinus through the adjoining venous lacunæ, and unite to form two principal trunks, an anterior and a posterior, which accompany the branches of the middle meningeal arteries more or less closely in the grooves on the inner surface of the parietal bone; sometimes they occupy grooves apart from the arteries. Their mode of ending is subject to some variation. The posterior trunk may leave the cranial cavity through the foramen spinosum and open into the pterygoid plexus. The anterior trunk may reach the pterygoid plexus by emerging through the foramen ovale, or it may end in the sphenoparietal sinus or in the cavernous sinus. Besides their meningeal tributaries they receive some small inferior cerebral veins, and communicate with the diploic veins and with the superficial middle cerebral vein.

Wood Jones * has pointed out that the grooves on the inner surfaces of the parietal bones are in reality impressed by the middle meningeal sinuses and not by the middle meningeal arteries, and says, " contrary to the general belief of surgeons, the vascular tunnel at the pterion, although it lodges arterial branches, is typically formed by, and typically lodges a venous sinus."

The Emissary Veins

The **emissary veins** pass through apertures in the cranial wall and establish communications between the venous sinuses inside the skull and the veins external to it. Some are constant, but others are not always present. 1. A mastoid emissary vein runs through the mastoid foramen and unites the sigmoid sinus with the posterior auricular or occipital vein. 2. A parietal emissary vein passes through the parietal foramen and connects the superior sagittal sinus with the veins of the scalp. 3. An anterior condylar emissary vein traverses the anterior condylar (hypoglossal) canal and joins the sigmoid sinus with the internal jugular vein. 4. A posterior condylar emissary vein passes through the posterior condylar canal and connects the sigmoid sinus with the veins in the suboccipital triangle. 5. A network of emissary veins unites the cavernous sinus with the pterygoid plexus through the foramen ovale. 6. Two or three small emissary veins run through the foramen lacerum and connect the cavernous sinus with the pterygoid plexus. 7. A vein traverses the emissary sphenoidal foramen (of Vesalius) and connects the same vessels. 8. A plexus of veins accompanies the internal carotid artery through the carotid canal of the temporal bone and unites the cavernous sinus with the internal jugular vein. 9. The petrosquamous sinus (p. 817) connects the transverse sinus with the external jugular vein. 10. An emissary vein may pass through the foramen cæcum, which, however, is only patent in a little over 1 per cent. of adult skulls,† and connect the veins of the nose with the superior sagittal sinus.

Applied Anatomy.—These emissary veins are of importance in surgery. Inflammatory processes commencing on the outside of the skull may travel inwards through them, and lead to thrombosis of the sinuses.

By means of these emissary veins blood may be abstracted from the intracranial circulation—e.g. leeches applied behind the ear drain blood from the transverse sinus through the mastoid vein.

THE VEINS OF THE UPPER LIMB AND THORAX

The veins of the upper limb are divided into two sets, *superficial* and *deep*, which anastomose freely with each other. The superficial veins are placed immediately under the skin, in the superficial fascia; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins.

* *Journal of Anatomy and Physiology*, vol. xlvi.

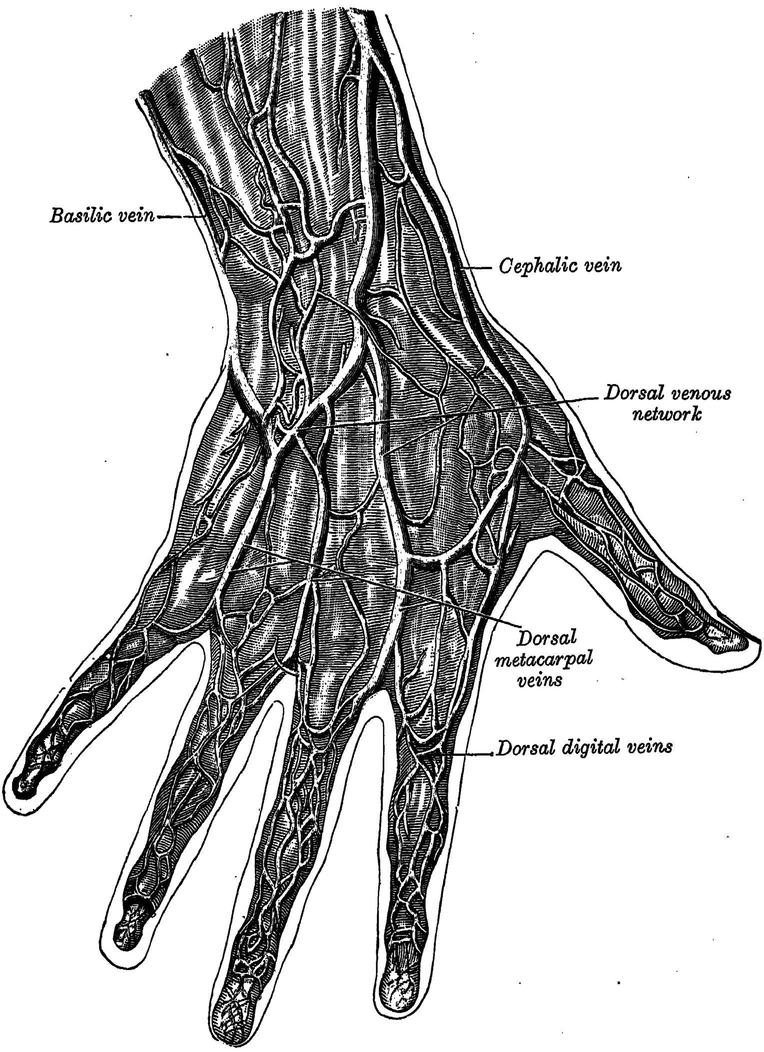
† G. I. Boyd, *Journal of Anatomy*, vol. lxv. 1930.

THE SUPERFICIAL VEINS OF THE UPPER EXTREMITY (figs. 781, 782)

The **superficial veins** of the upper limb are the cephalic, basilic, and median antebrachial veins, and their tributaries.

The *dorsal digital veins* pass along the sides of the fingers and are joined to one another by oblique communicating branches. Those from the adjacent sides of the fingers unite to form three *dorsal metacarpal veins* (fig. 781), which end in a *dorsal venous network* opposite the middle of the metacarpus. The

FIG. 781.—The veins of the dorsum of the hand. (Bourgery.)



radial part of the network is joined by the dorsal digital vein from the radial side of the index finger and by the dorsal digital veins of the thumb, and is prolonged upwards as the cephalic vein. The ulnar part of the network receives the dorsal digital vein of the ulnar side of the little finger and is continued upwards as the basilic vein. A communicating branch frequently connects the dorsal venous network with the cephalic vein about the middle of the forearm.

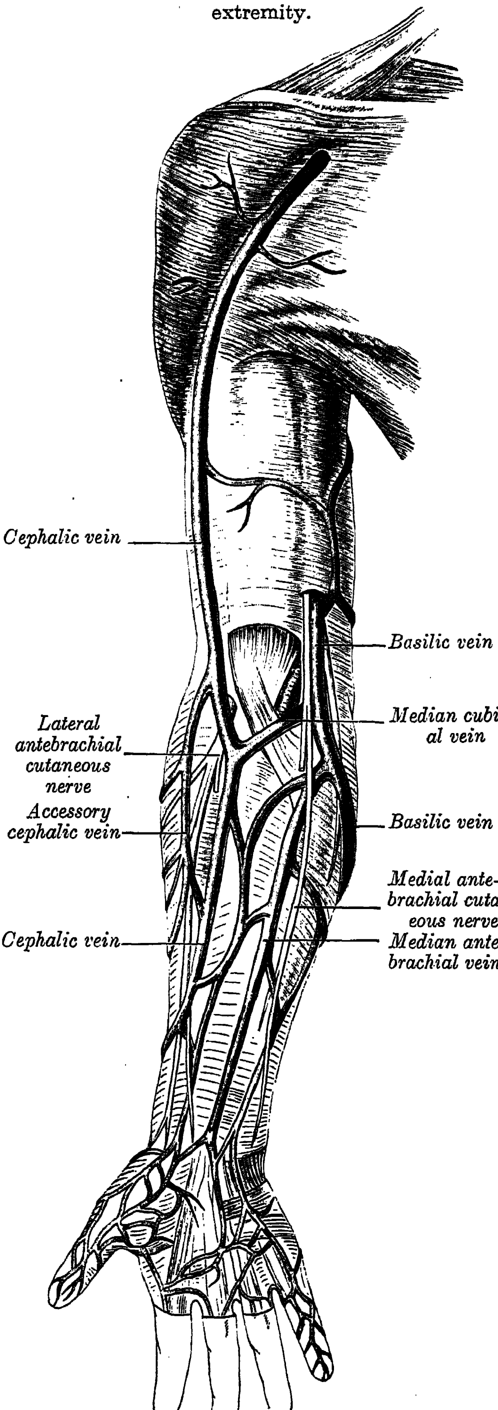
The *palmar digital veins* are connected to the dorsal digital veins by oblique *intercapitular veins*, which pass backwards between the heads of the metacarpal bones. They also drain into a venous plexus which lies superficial to the palmar aponeurosis, and extends over the thenar and hypothenar eminences.

The **cephalic vein** (fig. 782) begins in the radial part of the dorsal venous network of the hand and winds upwards round the radial border of the forearm to its anterior surface, receiving tributaries from both surfaces. Below the front of the elbow it gives off the *median cubital vein*, which receives a communicating branch from the deep veins of the forearm and passes medially to join the basilic vein. The cephalic vein then ascends in front of the elbow in the groove between the Brachioradialis and the Biceps. It crosses superficial to the lateral antebrachial cutaneous nerve and runs upwards along the lateral border of the Biceps. In the upper one-third of the arm it lies in the interval between the Pectoralis major and Deltoid, where it is accompanied by the deltoid branch of the acromio-thoracic artery. Entering the infraclavicular fossa (deltoideo-pectoral triangle), it passes under cover of the clavicular head of the Pectoralis major. It then pierces the clavipectoral fascia, crosses the axillary artery, and ends in the axillary vein just below the clavicle. Sometimes it communicates with the external jugular vein by a branch which ascends in front of the clavicle.

In some cases the median cubital vein is large and carries all or most of the blood from the cephalic into the basilic vein, the result being that the proximal half of the cephalic vein is either absent or of small size.

The *accessory cephalic vein* arises from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous network; it joins the cephalic below the elbow. In some cases it springs from the cephalic vein above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.

Fig. 782.—The superficial veins of the right upper extremity.



The **basilic vein** (fig. 782) begins in the ulnar part of the dorsal venous network of the hand. It runs up for some distance on the posterior surface of the ulnar side of the forearm but inclines forward to the anterior surface below the elbow. It is joined by the median cubital vein and ascends obliquely in the groove between the Biceps and Pronator teres; filaments of the medial ante-

brachial cutaneous nerve pass both in front of and behind this portion of the vein. It then runs upwards along the medial border of the Biceps, perforates the deep fascia a little below the middle of the upper arm, and, ascending on the medial side of the brachial artery to the lower border of the Teres major, is continued onwards as the axillary vein.

The **median vein of the forearm** (fig. 782) drains the venous plexus on the palmar surface of the hand. It ascends on the front of the forearm and ends in the basilic vein or the median cubital vein ; in a small proportion of cases it divides below the elbow into two branches, one of which joins the basilic vein, the other the cephalic vein.

Applied Anatomy.—Venesection is generally performed at the bend of the elbow, and as a matter of practice the largest vein in this situation, the median cubital, is commonly selected.

Intravenous infusion of normal saline solution is frequently required in modern surgery for conditions of severe shock and after profuse hæmorrhages, when suitable donors are not available for transfusion of blood. The patient's arm is surrounded by a tight bandage so as to impede the venous return, and the largest vein visible in front of the elbow is selected.

The Deep Veins of the Upper Limb

The **deep veins** follow the course of the arteries, and form their venæ comitantes. They are generally arranged in pairs, and are situated one on each side of the corresponding artery, and connected at intervals by short transverse branches. As most of the blood which supplies the upper limb is returned by the superficial veins, the deep veins are small and inconspicuous.

The deep veins of the hand.—The superficial and deep palmar arterial arches are each accompanied by a pair of venæ comitantes, which constitute respectively the *superficial* and *deep palmar venous arches*, and receive the veins corresponding to the branches of the arterial arches ; thus the *palmar digital veins* open into the superficial, and the *palmar metacarpal veins* into the deep, palmar venous arches. The deep veins accompanying the dorsal metacarpal arteries receive perforating branches from the palmar metacarpal veins, and end in the radial veins and in the dorsal venous network.

The **deep veins of the forearm** are the venæ comitantes of the radial and ulnar arteries and constitute respectively the upward continuations of the deep and superficial palmar venous arches ; they unite in front of the elbow to form the brachial veins. The radial veins are smaller than the ulnar, and receive the deep veins of the dorsum of the hand. The ulnar veins receive tributaries from the deep palmar venous arch and communicate with the superficial veins at the wrist ; near the elbow they receive the anterior and posterior interosseous veins and send a large communicating branch (profunda vein) to the median cubital vein.

The **brachial veins** are placed one on each side of the brachial artery, and receive tributaries corresponding with the branches of that artery ; near the lower margin of the Subscapularis, they join the axillary vein ; the medial one frequently joins the basilic vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **axillary vein** begins at the lower border of the Teres major, as the continuation of the basilic vein, increases in size as it ascends, and ends at the outer border of the first rib, where it becomes continuous with the subclavian vein. Near the lower border of the Subscapularis it receives the brachial veins and, close to its termination, the cephalic vein ; its other tributaries correspond with the branches of the axillary artery. It lies on the medial side of the axillary artery, which it partly overlaps ; between the two vessels are the medial pectoral (medial anterior thoracic) nerve, the medial cord of the brachial plexus, the ulnar nerve and the medial antebrachial cutaneous nerve. On its medial side it is accompanied by the medial cutaneous nerve of the arm, and both on its medial and posterior aspects it is intimately related to the lateral group of the axillary lymph glands. It is provided with a pair of valves opposite the

lower border of the Subscapularis ; valves are also found in the ends of the cephalic and subscapular veins.

Applied Anatomy.—Since the axillary vein is superficial to and larger than the axillary artery, which it overlaps, it is more liable to be wounded than the artery in the operation of excision of the axillary lymph glands, especially as these glands, when diseased, are apt to become adherent to it.

The **subclavian vein** (fig. 784), which is the continuation of the axillary vein, extends from the outer border of the first rib to the medial border of the Scalenus anterior, where it unites with the internal jugular vein to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius ; behind and above, with the subclavian artery, from which it is separated by the Scalenus anterior and, on the right side, by the phrenic nerve. Below, it rests in a shallow groove on the first rib and upon the pleura. It is usually provided with a pair of valves, which are situated about 2 cm. from its termination.

Its tributaries are the external jugular vein, sometimes the anterior jugular vein, and occasionally a small branch, which ascends in front of the clavicle, from the cephalic vein.

At its angle of junction with the internal jugular vein, the left subclavian vein receives the thoracic duct, and the right subclavian vein the right lymphatic duct.

The Veins of the Thorax (figs. 783, 784)

The **innominate veins** are two large trunks, placed in the root of the neck and in the uppermost part of the thorax ; each is formed by the union of the internal jugular and subclavian veins of the corresponding side and both are devoid of valves.

The **right innominate vein** (fig. 783), about 2·5 cm. long, begins behind the sternal end of the right clavicle, and, passing almost vertically downwards, joins the left innominate vein to form the superior vena cava behind the cartilage of the first rib, close to the right border of the sternum. It lies in front and to the right of the innominate artery and the right vagus nerve. The right pleura, phrenic nerve, and internal mammary artery are posterior to the upper part, and lateral to the lower part of the vein.

Its tributaries are the right vertebral, the right internal mammary and the right inferior thyroid veins, and sometimes the first right posterior intercostal vein.

The **left innominate vein** (fig. 783), about 6 cm. long, begins behind the sternal end of the left clavicle, where it lies in front of the left cervical pleura. It runs obliquely downwards and to the right behind the upper half of the manubrium sterni to the sternal end of the first right costal cartilage, where it unites with the right innominate vein to form the superior vena cava. It is separated from the left sternoclavicular joint and the manubrium sterni by the Sternohyoid and Sternothyroid, the thymus or its remains, and some loose areolar tissue, and, at its termination, is overlapped by the right pleura. In its course it crosses superficial to the left internal mammary, subclavian and common carotid arteries, the left phrenic and vagus nerves, the trachea and the innominate artery. The arch of the aorta lies below the vessel.

Its tributaries are the left vertebral, left internal mammary, left inferior thyroid, and left superior intercostal veins, sometimes the first left posterior intercostal vein and occasionally some thymic and pericardial veins.

Peculiarities.—Sometimes the innominate veins open separately into the right atrium ; in such cases the right vein takes the ordinary course of the superior vena cava ; the left vein—*left superior vena cava,* as it is then termed—which may communicate by a small branch with the right one, crosses the left side of the arch of the aorta, passes in front of the root of the left lung, and, turning to the back of the heart, ends in the right atrium. It replaces the oblique vein of the left atrium and the coronary sinus and receives all the tributaries of the latter vessel. This occasional condition in the adult is due to the persistence of the early fœtal condition (p. 158), and is the normal condition in birds and some mammals.

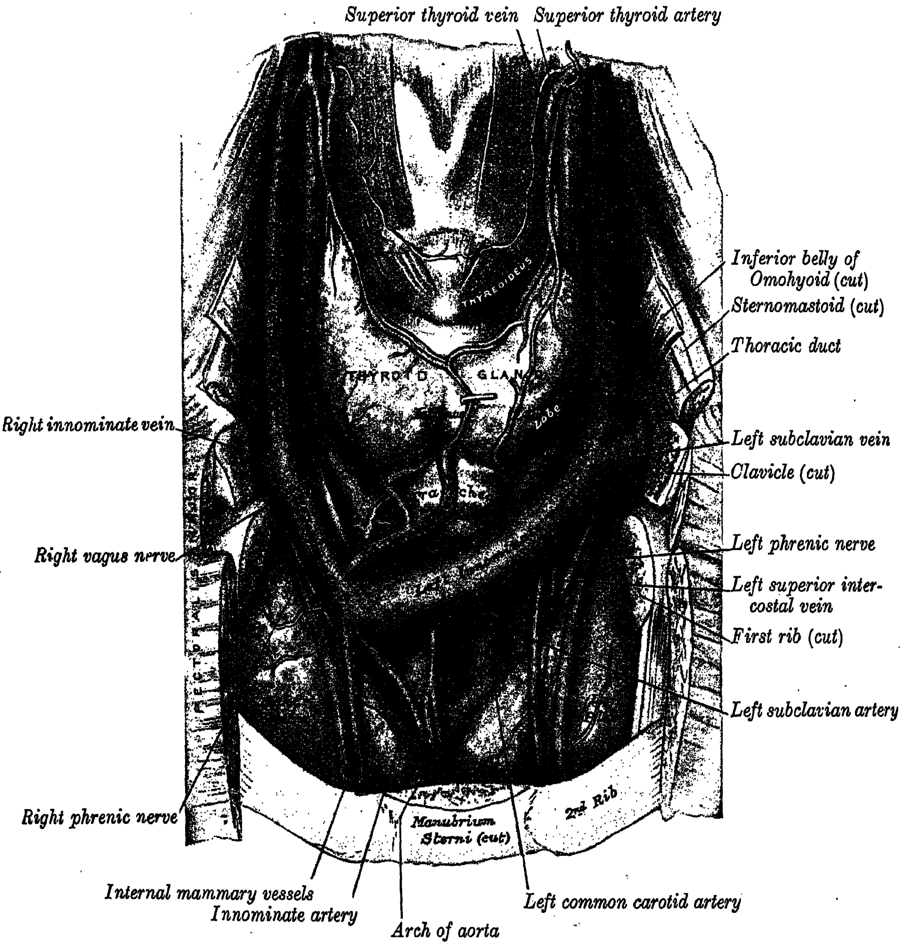
The left innominate vein sometimes projects above the level of the manubrium sterni, crossing the suprasternal fossa, and lying in front of the trachea.

The **internal mammary veins** (figs. 719, 783) are venæ comitantes to the lower half of the internal mammary artery, and are provided with a number of

valves. About the level of the third costal cartilage the venæ comitantes unite to form a single trunk, which runs up medial to the artery and ends in the corresponding innominate vein. They receive as tributaries the veins which accompany the branches of the internal mammary artery (p. 737), and usually the pericardiacophrenic vein.

The **inferior thyroid veins** (figs. 773, 783), two in number, arise in the thyroid gland in a venous network which communicates with the middle and

FIG. 783.—Dissection of the lower part of the neck, and the upper part of the thorax. Anterior aspect.



superior thyroid veins. They form a plexus in front of the trachea. From this plexus the left vein descends and joins the left innominate trunk, and the right vein passes obliquely downwards and to the right across the innominate artery to open into the right innominate vein, at its junction with the superior vena cava; frequently the two veins open by a common trunk in the latter situation. Not infrequently this common trunk terminates in the left innominate vein. These veins receive œsophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their terminations.

The **left superior intercostal vein** (fig. 784) receives the second and third (and sometimes the fourth) left posterior intercostal veins; it runs obliquely upwards and forwards on the left side of the aortic arch, passing lateral to the left vagus and medial to the left phrenic nerve, and opens into the left innominate vein. It usually receives the left bronchial veins, and sometimes the left pericardiacophrenic vein; it communicates below with the superior hemiazygos (accessory hemiazygos) vein. Occasionally it gives off, near its termination, a small

vessel which runs downwards across the aortic arch and behind the left pulmonary artery to enter the ligament of the left vena cava (p. 669). Gaining the dorsal aspect of the left atrium this small vessel becomes continuous with the oblique vein.

The **superior vena cava** (figs. 695, 696, 697, 699) drains the blood from the upper half of the body. It measures about 7 cm. in length, is formed by the junction of the two innominate veins, and is devoid of valves. It begins behind the cartilage of the right first rib close to the sternum, and, descending vertically behind the first and second intercostal spaces, ends in the upper part of the right atrium opposite the third right costal cartilage; the lower half of the vessel is within the fibrous pericardium, which it pierces at the level of the second costal cartilage, and is covered in front and on its sides with the serous pericardium. In its course it describes a slight curve, the convexity of which is to the right side.

Relations.—*In front,* the superior vena cava is related to the anterior margins of the right lung and pleura with the pericardium intervening below; these separate it from the internal mammary artery, and the first and second intercostal spaces, and from the second and third costal cartilages; the trachea and the right vagus nerve are *posteromedial* and the right lung and pleura *posterolateral* to its upper part, while the root of the right lung is a direct posterior relation below. On its *right side,* it is related to the right phrenic nerve and right pleura; on its *left side,* to the commencement of the innominate artery and the ascending aorta, the latter overlapping it.

Tributaries.—The superior vena cava receives the azygos vein and several small veins from the pericardium and other structures in the mediastinum.

The **azygos vein** * (fig. 785) is inconstant in its mode of origin. On morphological grounds it may be expected to arise from the posterior aspect of the inferior vena cava, at or below the level of the renal veins. Such a vein (*lumbar azygos*) is very frequently present and ascends in front of the upper lumbar vertebræ. It may pass deep to the lateral border of the right crus of the diaphragm, or it may pierce the crus, or it may occasionally pass through the aortic opening of the diaphragm, on the right side of the cisterna chyli. In front of the body of the twelfth thoracic vertebra, it is joined by a large vessel which, formed by the union of the right ascending lumbar with the right subcostal vein, passes forwards on the right side of the body of the twelfth thoracic vertebra under cover of the right crus of the diaphragm. This common trunk may, in the absence of a lumbar azygos vein, form the azygos vein. Whatever its mode of origin, the azygos vein ascends in the posterior mediastinum to the level of the fourth thoracic vertebra where it arches forward over the root of the right lung, and ends in the superior vena cava, just before that vessel pierces the pericardium. In its course it lies in front of the bodies of the lower eight thoracic vertebræ, the anterior longitudinal ligament, and the right posterior (aortic) intercostal arteries. On its right side are the greater splanchnic nerve, the right lung and pleura; on its left side, throughout the greater part of its course, are the thoracic duct and aorta, and higher up, where it arches forward above the root of the right lung, the œsophagus, trachea and right vagus. In the lower part of the thorax it is covered anteriorly by a recess of the right pleural sac and by the œsophagus, but it emerges from behind the right edge of the latter and ascends behind the hilum of the right lung.

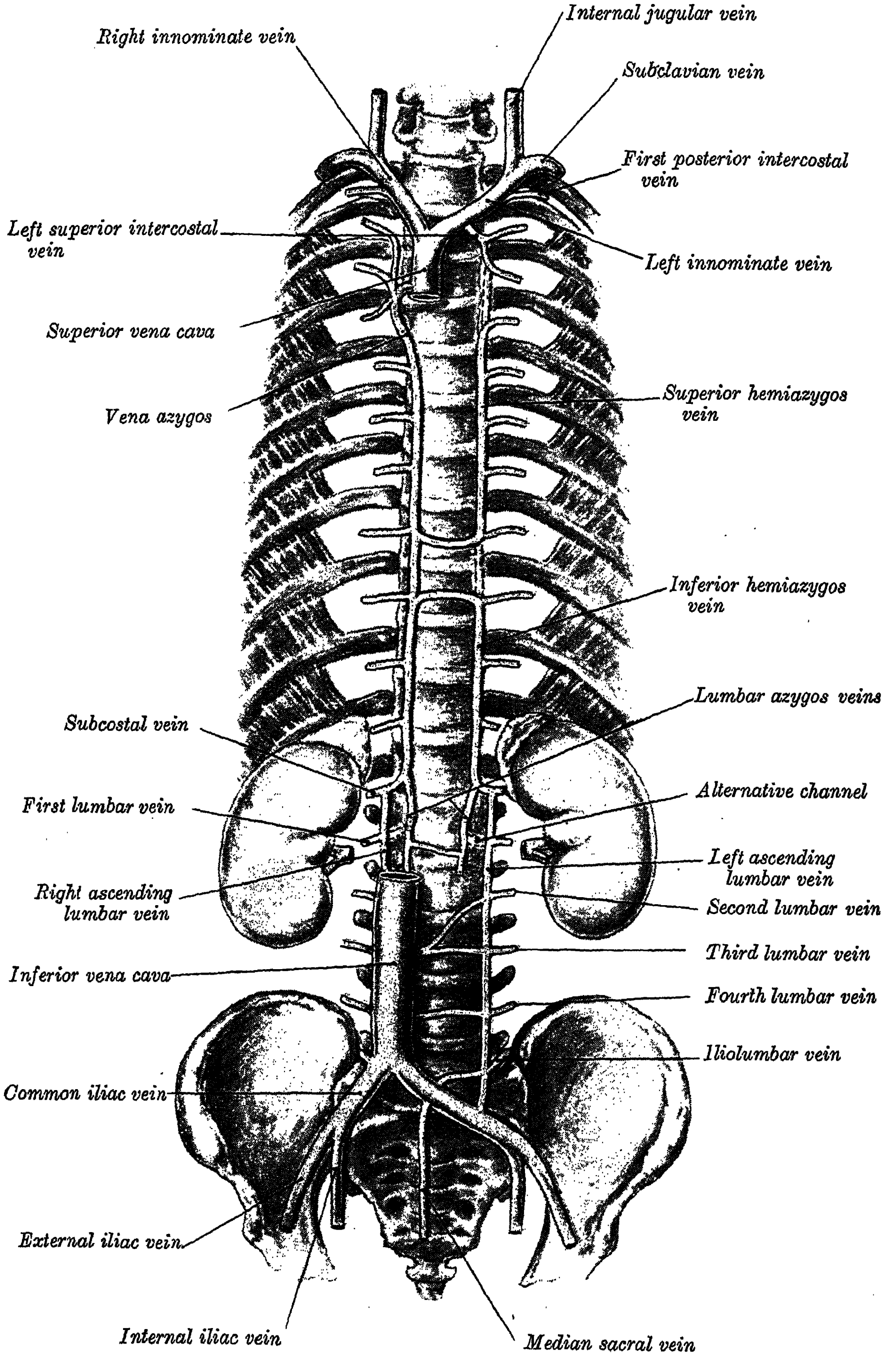
Tributaries.—It receives the posterior intercostal veins of the right side, with the exception of the vein from the first intercostal space; the veins from the second, third and fourth intercostal spaces open by a common stem called the right superior intercostal vein. It receives also the superior and inferior hemiazygos veins, several œsophageal, mediastinal, and pericardial veins, and, near its termination, the right bronchial veins. When it begins as a lumbar azygos vein, the common trunk formed by the union of the right ascending lumbar and subcostal veins is its largest tributary. A few imperfect valves are found in the azygos vein; but its tributaries are provided with complete valves.

The **inferior hemiazygos vein** * (hemiazygos vein) (fig. 784) arises on the left side in a manner corresponding to the origin of the azygos vein on the right

* The arrangement of the rootlets of the azygos and hemiazygos veins is subject to a wide range of variation. See R. J. Gladstone, *Journal of Anatomy,* vol. lxiv. 1929.

side and, ascending on the front of the vertebral column as high as the eighth thoracic vertebra, passes across the column, behind the aorta, œsophagus, and

Fig. 784.—The azygos, hemiazygos and ascending lumbar veins, their tributaries and connexions.

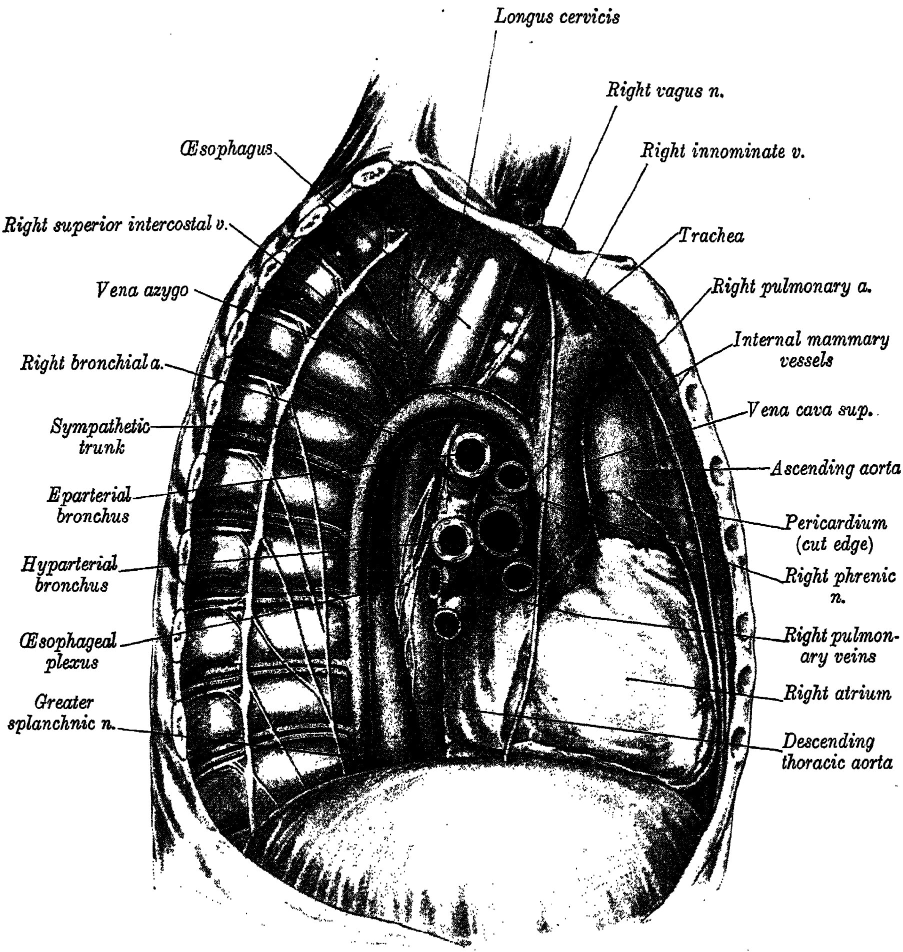


N.B.—On both sides the first lumbar vein is shown terminating in the ascending lumbar vein, but its occasional termination in the lumbar azygos vein is indicated as well.

thoracic duct, to end in the azygos vein. It receives the lower three posterior intercostal veins and the common trunk formed by the union of the ascending lumbar and the subcostal veins of the left side, and some œsophageal and mediastinal veins.

The **superior hemiazygos vein** (accessory hemiazygos vein) (fig. 784) descends on the left side of the vertebral column. It receives the veins from the fourth (or fifth) to the eighth intercostal spaces inclusive, and sometimes the left bronchial veins. It crosses the body of the seventh thoracic vertebra and joins the azygos vein. The superior hemiazygos vein sometimes joins the inferior hemiazygos vein, and the common trunk thus formed opens into the azygos vein.

FIG. 785.—The mediastinum, dissected from the right side.



A portion of the pericardial sac has been removed in order to expose the lateral aspect of the right atrium.
In this specimen the fourth right posterior intercostal vein did not join the superior intercostal vein, the œsophagus was somewhat dilated and an unusually large extent of the descending thoracic aorta was visible from the right side.

The **posterior intercostal veins** (figs. 737, 784, 785) run with the posterior (aortic) intercostal arteries and are eleven in number on each side. As they approach the vertebral column each vein receives a tributary which accompanies the posterior branch of the corresponding artery and returns blood from the muscles and skin of the back and from the vertebral venous plexuses.

On both sides of the thorax the first posterior intercostal vein ascends in front of the neck of the first rib and, arching forwards above the pleura, ends in the corresponding innominate or vertebral vein.

On the right side the second, third and, often, the fourth posterior intercostal veins unite to form the *right superior intercostal vein*, which joins the terminal part of the azygos vein. The veins from the intercostal spaces below the fourth open separately into the vena azygos.

On the left side the second and third (and sometimes the fourth) posterior intercostal veins unite to form the left superior intercostal vein (p. 826). The veins from the fourth (or fifth) to the eighth intercostal spaces inclusive end in the superior hemiazygos vein, and the veins from the lower three spaces in the inferior hemiazygos vein.

The posterior intercostal veins are called 'posterior' to distinguish them from the small *anterior intercostal veins*, which are tributaries of the internal mammary and musculophrenic veins.

Applied Anatomy.—In obstruction of the superior vena cava, the azygos and hemiazygos veins are one of the principal means by which the venous circulation is carried on, connecting, as they do, the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The **bronchial veins**, usually two on each side, return the blood from the larger bronchi, and from the structures at the roots of the lungs. The bronchial veins of the right side open into the terminal part of the vena azygos; those of the left side, into the left superior intercostal vein or the superior hemiazygos vein. Some of the blood carried to the lungs through the bronchial arteries is returned to the heart through the pulmonary veins.

The Veins of the Vertebral Column (figs. 786, 787)

The veins of the vertebral column form intricate plexuses extending along the entire length of the column; these plexuses are divisible into two groups, termed external and internal, according to their positions outside or inside the vertebral canal. The plexuses of the two groups anastomose freely with each other, and end in the intervertebral veins.

The **external vertebral venous plexuses**, best marked in the cervical region, consist of anterior and posterior plexuses, which anastomose freely with each other. The *anterior external plexuses* lie in front of the bodies of the vertebræ, communicate with the basivertebral and intervertebral veins, and receive tributaries from the vertebral bodies. The *posterior external plexuses* are placed on the posterior surfaces of the laminæ and around the spines and the transverse and articular processes. They anastomose with the internal vertebral venous plexuses, and end in the vertebral, posterior intercostal and lumbar veins.

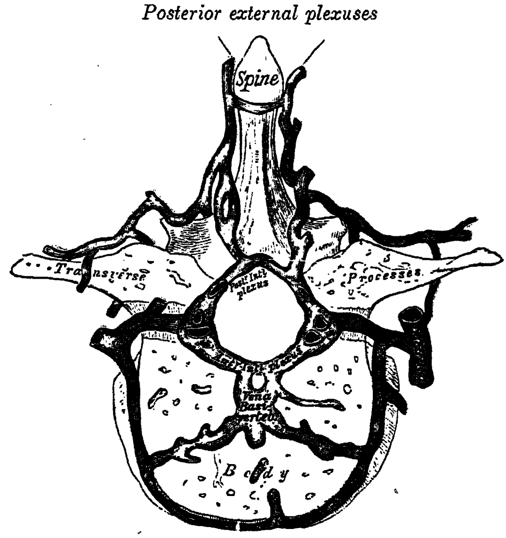
The **internal vertebral venous plexuses** lie within the vertebral canal between the dura mater and the vertebræ, and receive tributaries from the bones and from the spinal cord. They form a closer network than the external plexuses, and, running mainly in a vertical direction, form four longitudinal veins, two in front and two behind; they therefore may be divided into anterior and posterior groups. The *anterior internal plexuses* consist of large veins which lie on the posterior surfaces of the vertebral bodies and intervertebral discs, on each side of the posterior longitudinal ligament; under cover of this ligament they are connected by transverse branches into which the basivertebral veins open. The *posterior internal plexuses* are placed one on each side of the median plane in front of the vertebral arches and ligamenta flava, and anastomose, by veins passing through those ligaments, with the posterior external plexuses.

The anterior and posterior internal plexuses communicate freely with one another by a series of venous rings, one opposite each vertebra. Around the foramen magnum they form an intricate network, which opens into the vertebral veins and is connected above with the occipital and sigmoid sinuses, the network of basilar sinuses, and with the anterior and posterior condylar emissary veins.

The **basivertebral veins** emerge from the foramina on the posterior surfaces of the vertebral bodies. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. They communicate with the anterior external vertebral plexuses through small openings on the front and sides of the bodies of the

vertebræ, and converge behind to form single (sometimes double) veins, which open by valved orifices into the transverse branches uniting the anterior internal vertebral plexuses. The basivertebral veins become enlarged in advanced age.

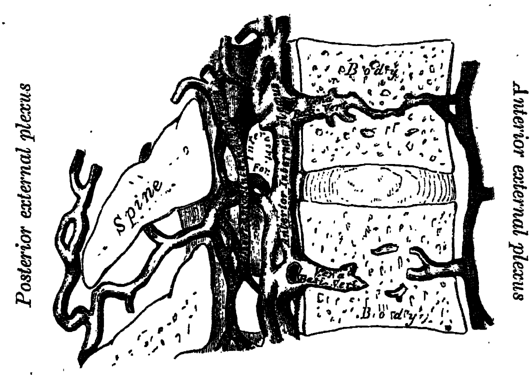
FIG. 786.—A transverse section through a thoracic vertebra, showing the vertebral venous plexuses.



The **intervertebral veins** accompany the spinal nerves through the intervertebral foramina; they receive veins from the spinal cord, drain the internal and external vertebral plexuses and end in the vertebral, posterior intercostal, lumbar and lateral sacral veins, their orifices being provided with valves.

The **veins of the spinal cord** are situated in the pia mater and form a tortuous venous plexus in this membrane. In this plexus there are: (*a*) two median

FIG. 787.—A median sagittal section through two thoracic vertebræ, showing the vertebral venous plexuses.



longitudinal veins, one in front of the anterior median fissure, and the other behind the posterior septum of the spinal cord; and (*b*) two anterolateral and two posterolateral longitudinal veins, which run behind the anterior and the posterior nerve-roots respectively. They communicate with the internal vertebral venous plexuses, and with the intervertebral veins. Near the base of the skull they unite to form two or three small trunks, which communicate with the vertebral veins, and end in the inferior cerebellar veins, or in the inferior petrosal sinuses.

THE VEINS OF THE LOWER LIMB, ABDOMEN AND PELVIS

The veins of the lower limb are subdivided, like those of the upper limb, into two sets, *superficial* and *deep* : the superficial veins are placed immediately under the skin in the superficial fascia ; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins. Valves are more plentiful in the veins of the lower than in those of the upper limb.

The Superficial Veins of the Lower Limb

The **superficial veins** of the lower limb are the long and short saphenous veins and their tributaries.

The *dorsal digital veins* receive, in the clefts between the toes, communications from the plantar digital veins, and then join to form *dorsal metatarsal veins*, which unite across the distal ends of the metatarsal bones in a *dorsal venous arch*. Proximal to this arch there is an irregular dorsal venous network, which receives tributaries from the deep veins and is continuous with the venous network on the front of the leg. At the sides of the foot this network communicates with a *medial* and a *lateral marginal vein*, both of which are formed mainly by the union of veins from the superficial parts of the sole of the foot.

On the sole of the foot the superficial veins form a *plantar cutaneous venous arch*, which extends across the roots of the toes and opens at the sides of the foot into the medial and lateral marginal veins. Proximal to this arch there is a *plantar cutaneous venous network*, which is especially dense in the fat beneath the heel ; this network communicates with the plantar cutaneous venous arch and with the deep veins, but is chiefly drained into the medial and lateral marginal veins.

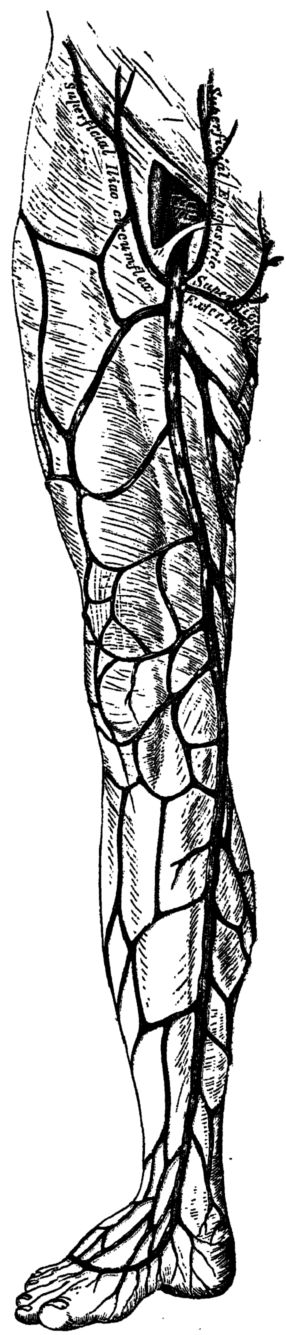
The **long saphenous vein** (great saphenous vein) (fig. 788), the longest vein in the body, begins in the medial marginal vein of the foot, and ends in the femoral vein about 3 cm. below the inguinal ligament. It ascends in front of the tibial malleolus and runs upwards, crossing the medial surface of the tibia obliquely to gain its medial border, along which it ascends to the knee. It runs upwards on the posterior parts of the medial condyles of the tibia and femur and along the medial side of the thigh and, passing through the saphenous opening (fossa ovalis) (p. 624), ends in the femoral vein. In the thigh it is accompanied by some branches of the medial femoral cutaneous nerve, at the knee by the saphenous branch of the descending genicular artery, and in the leg and foot by the saphenous nerve, which is placed in front of the vein. The long saphenous vein is often duplicated, especially below the knee. The valves in it number from ten to twenty and are more numerous in the leg than in the thigh.

Tributaries.—At the ankle it receives veins from the sole of the foot through the medial marginal vein ; in the leg it communicates freely with the short saphenous vein and with the anterior and posterior tibial veins, and receives many cutaneous veins ; in the thigh it receives numerous tributaries ; those from the medial and posterior parts of the thigh frequently unite to form a large *accessory saphenous vein*, which joins the main vein at a variable level. Near the saphenous opening (fig. 788) it is joined by the superficial epigastric, superficial circumflex iliac and external pudendal veins. The superficial epigastric and superficial circumflex iliac veins drain the lower part of the abdominal wall, the latter vein also receiving tributaries from the upper and lateral parts of the thigh ; the external pudendal veins drain part of the scrotum and one is joined by the superficial dorsal vein of the penis.

A vein, named the *thoraco-epigastric*, runs along the anterolateral wall of the trunk, connecting the superficial epigastric vein, or the femoral vein, with the lateral thoracic veins and establishing a communication between the femoral and axillary veins. The importance of this communication lies in the fact that it serves as a connecting channel between the superior and the inferior vena caval fields of drainage.

The **short saphenous vein** (small saphenous vein) (fig. 789) begins behind the lateral malleolus as a continuation of the lateral marginal vein of the foot; it first ascends on the lateral border of the tendo calcaneus, and then along the middle of the back of the leg. It perforates the deep fascia in the lower part of the popliteal fossa, and ends in the popliteal vein from 3 to 7·5 cm. above the level of the knee-joint. It communicates with the deep veins on the dorsum of the foot, receives numerous tributaries from the back of the leg, and sends several branches upwards and medially to join the long saphenous vein. In the leg the vein is in close relation with the sural nerve.

Fig. 788.—The long saphenous vein and its tributaries.



The short saphenous vein possesses from seven to thirteen valves, one of which is found near its termination in the popliteal vein.

The mode of ending of the short saphenous vein is subject to considerable variations. It may join the long saphenous vein in the upper one-third of the thigh, or may divide into two branches, one of which joins the long saphenous vein, the other the popliteal vein or the deep posterior veins of the thigh; occasionally it ends, below the level of the knee-joint, in the long saphenous vein or in the deep muscular veins of the calf.*

Applied Anatomy.—A varicose condition is more frequently met with in the saphenous veins than in the other veins of the body, except perhaps the testicular and rectal veins. The main cause of this is the high blood-pressure, determined chiefly by the erect position, and the length of the column of blood, which has to be propelled in an uphill direction. In normal vessels there is only just sufficient force to perform this task; and in those cases where there is diminished resistance of the walls of the veins, these vessels are liable to dilate and a varicose condition is set up. Increased blood-pressure in the veins, caused by any obstacle to the return of the venous blood, such as the pressure of a tumour, or the gravid uterus, or tight gartering, may also produce varix. In the normal condition of the veins, the valves in their interior break up the column of blood into a number of smaller columns, and so to a considerable extent mitigate the ill effects of the erect position; but when the dilatation of the veins has reached a certain limit, the valves become incapable of supporting the overlying column of blood, and the pressure is increased, tending to emphasise also the varicose condition.

Excision of portions of the dilated veins, with or without ligature of the long saphenous vein at a higher level, used to be practised for this condition. The modern method of treatment† aims at obliteration of the vessels concerned by the injection into them of chemical irritants, such as quinine hydrochloride or salicylic acid. A short length of vein is temporarily occluded and a few c.cs. of the material injected. A non-suppurative phlebitis ensues, which is followed by permanent fibrosis of the vessel. Since the flow of blood in these veins tends to be reversed, there is no fear of embolism.

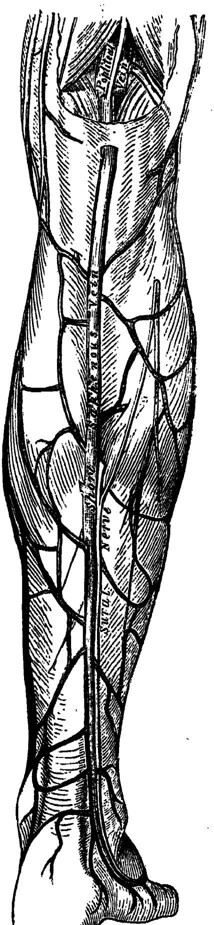
The Deep Veins of the Lower Extremity

The **deep veins** of the lower extremity accompany the arteries and their branches; they possess numerous valves.

The *plantar digital veins* arise from plexuses on the plantar surfaces of the digits, and, after sending communications to join the dorsal digital veins, unite to form four *plantar metatarsal veins*; these run backwards in the metatarsal spaces, communicate, by means of perforating veins, with the veins on the dorsum of the foot, and unite to form the *deep plantar venous arch*, which lies alongside the plantar arterial arch. From the deep plantar venous arch the *medial* and *lateral plantar veins* run backwards close to the corresponding arteries and, after communicating with the long and short saphenous veins, unite behind the medial malleolus to form the posterior tibial veins.

Fig. 789.—The short saphenous vein.



The **posterior tibial veins** accompany the posterior tibial artery, and are joined by the *peroneal veins*.

The **anterior tibial veins** are the upward continuations of the venæ comitantes of the dorsalis pedis artery. They leave the front of the leg by passing between the tibia and fibula, through the upper part of the interosseous membrane of the leg, and unite with the posterior tibial veins to form the *popliteal vein*.

The **popliteal vein**, formed by the junction of the anterior and posterior tibial veins at the lower border of the Popliteus, ascends through the popoliteal fossa to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is medial to the popliteal artery; between the heads of the Gastrocnemius it is superficial to it; above the knee-joint it is posterolateral to it. Its tributaries are the short saphenous vein and the veins corresponding to the branches of the popliteal artery. There are usually four valves in the popliteal vein.

The **femoral vein** accompanies the femoral artery, beginning at the opening in the Adductor magnus, as the continuation of the popliteal vein, and ending at the level of the inguinal ligament, by becoming the external iliac vein. In the lower part of the subsartorial (adductor) canal it is posterolateral to the femoral artery; in the upper part of the canal, and in the lower part of the femoral triangle, it is behind the artery. At the base of the femoral triangle it is medial to the artery (figs. 755, 758); here it occupies the middle compartment of the femoral sheath, and is placed between the femoral artery and the femoral canal. It receives numerous muscular tributaries, and about 4 cm. below the inguinal ligament is joined on its posterior aspect by the vena profunda femoris, and a little higher by the long saphenous vein, which enters its anterior aspect. In addition, it usually receives the lateral and medial circumflex femoral veins. A valve, which may be single or double, is placed at the upper end of the femoral vein, and another is usually present above the opening of its profunda femoris tributary.

The *vena profunda femoris* usually lies superficial to the profunda femoris artery; it receives tributaries corresponding to the muscular and perforating branches of that artery, and through these establishes communications with the popliteal vein below and the inferior gluteal vein above. It sometimes receives the medial and lateral circumflex femoral veins.

The Veins of the Abdomen and Pelvis (figs. 738, 790)

The **external iliac vein**, the upward continuation of the femoral vein, begins behind the inguinal ligament, and ascends along the brim of the true pelvis,

to a point opposite the sacro-iliac joint, where it unites with the internal iliac (hypogastric) vein to form the common iliac vein. On the right side, it lies at first medial to the artery; but, as it passes upwards, gradually inclines behind it. On the left side, it lies altogether on the medial side of the artery. On its medial aspect, it is crossed by the vas deferens (ductus deferens), in the male, the ureter and the internal iliac artery; elsewhere it is covered with peritoneum. In the female it is crossed by the round ligament of the uterus and the ovarian vessels. Posteriorly it is related to the obturator nerve and, laterally to the Psoas major muscle, except where the external iliac artery intervenes. It frequently contains one, sometimes two, valves.

Tributaries.—It receives the inferior epigastric, deep circumflex iliac and pubic veins.

The **inferior epigastric vein** is formed by the union of the venæ comitantes of the inferior epigastric artery, which communicate above with the superior epigastric vein; it joins the external iliac vein about 1 cm. above the inguinal ligament.

The **deep circumflex iliac vein** is formed by the union of the venæ comitantes of the deep circumflex iliac artery, and joins the external iliac vein about 2 cm. above the inguinal ligament after crossing in front of the external iliac artery.

The **pubic vein,** which connects the external iliac with the obturator vein in the obturator foramen, ascends on the pelvic surface of the pubis alongside the pubic branch of the inferior epigastric artery. It is frequently enlarged and replaces the normal obturator vein.

The **internal iliac vein** (hypogastric vein) begins near the upper part of the greater sciatic foramen, ascends behind and slightly medial to the internal iliac artery, and, at the brim of the pelvis, joins with the external iliac vein to form the common iliac vein. It lies in front of the lower part of the sacro-iliac joint and is covered with peritoneum on its anteromedial aspect.

Tributaries.—With the exception of the iliolumbar vein, which usually joins the common iliac vein, the tributaries of the internal iliac vein correspond with the branches of the internal iliac artery. It receives (*a*) the gluteal, internal pudendal, and obturator veins, which have their origins outside the pelvis; (*b*) the lateral sacral veins, which lie in front of the sacrum; and (*c*) the middle rectal, the vesical, uterine, and vaginal veins, which originate in venous plexuses connected with the pelvis viscera.

1. The **superior gluteal veins** are the venæ comitantes of the superior gluteal artery; they receive tributaries from the buttock corresponding with the branches of the artery, enter the pelvis through the greater sciatic foramen, above the Piriformis, and end in the internal iliac vein; they frequently unite to form a single trunk before ending in this vein.

2. The **inferior gluteal veins** are the venæ comitantes of the inferior gluteal artery; they begin on the upper part of the back of the thigh, where they anastomose with the medial circumflex femoral and first perforating veins; they enter the pelvis through the lower part of the greater sciatic foramen and join to form a stem which opens into the lower part of the internal iliac vein.

3. The **internal pudendal veins** are the venæ comitantes of the internal pudendal artery. They begin in the prostatic venous plexus (p. 836), accompany the internal pudendal artery, and unite to form a single vessel, which ends in the internal iliac vein. They receive the veins from the bulb of the penis, and the scrotal or labial and inferior rectal veins. The deep dorsal vein of the penis and the dorsal vein of the clitoris communicate with the internal pudendal veins, but end mainly in the prostatic plexus.

4. The **obturator vein** begins in the upper portion of the adductor region of the thigh, and enters the pelvis through the upper part of the obturator foramen. It runs backwards and upwards on the lateral wall of the pelvis below the obturator artery and lateral to the peritoneum; it passes between the ureter and the internal iliac artery, and ends in the internal iliac vein. Sometimes it is replaced by an enlarged pubic vein, which joins the external iliac vein.

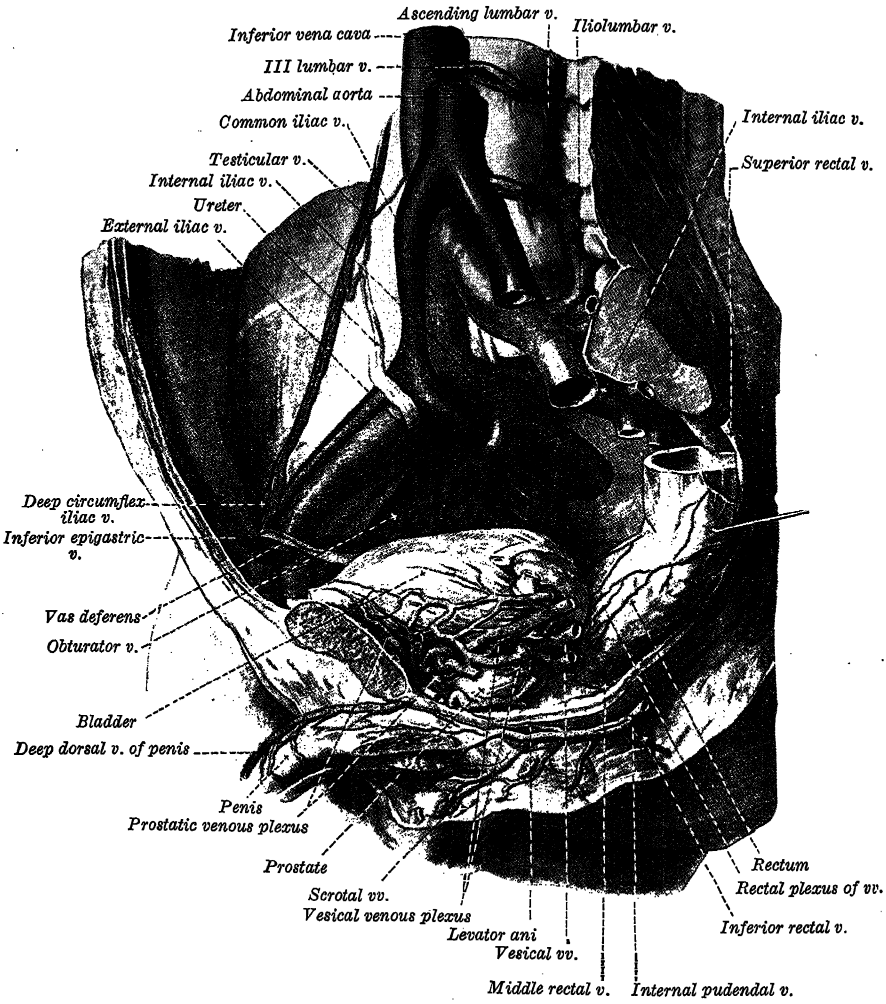
5. The **lateral sacral veins** accompany the lateral sacral arteries and end in the internal iliac vein.

6. The **middle rectal vein** (middle hæmorrhoidal vein) varies in size; it begins in the rectal venous plexus, and receives tributaries from the bladder,

prostate and seminal vesicle; it runs laterally on the pelvic surface of the Levator ani and ends in the internal iliac vein.

The **rectal venous plexus** (hæmorrhoidal plexus) surrounds the rectum, and communicates in front with the vesical plexus in the male, and the uterovaginal plexus in the female. It consists of two parts, an *internal* in the submucosa, and an *external* outside the muscular coat of the rectum and anal canal. The internal

FIG. 790.—The veins of the right half of the male pelvis. (Spalteholz.)



plexus presents a series of dilated pouches, connected by transverse branches, which are arranged in a circle around the tube, immediately above the anal orifice. It drains mainly into the superior rectal vein but communicates freely with the external plexus. The lower part of the external plexus is drained by the inferior rectal veins into the internal pudendal vein; the middle part by the middle rectal vein into the internal iliac vein; and the upper part by the superior rectal vein, which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the rectal plexus.

The **prostatic venous plexus** (pudendal plexus) lies behind the inferior pubic ligament and the lower part of the symphysis pubis, and in front of the bladder and prostate. Its chief tributary is the deep dorsal vein of the penis, but it

also receives tributaries from the front of the bladder and prostate. It communicates with the vesical plexus and with the internal pudendal vein, and drains into the vesical and internal iliac veins. The *prostatic veins* form a well-marked plexus, which lies partly in the fascial sheath of the prostate and partly between the sheath and the prostatic capsule; they communicate with the prostatic and vesical plexuses.

The **vesical plexus** envelops the lower part of the bladder and, in the male, the base of the prostate. It communicates with the prostatic plexus in the male, and with the vaginal plexus in the female. It is drained, by means of several vesical veins, into the internal iliac veins.

Applied Anatomy.—The veins of the rectal plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood-pressure; the condition is favoured by the fact that the superior rectal and portal veins have no valves; the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defæcation; they are affected by every form of portal obstruction.

The **dorsal veins of the penis** are two in number, a superficial and a deep: The *superficial dorsal vein* drains the prepuce and skin of the penis, and, running backwards in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding external pudendal vein, a tributary of the long saphenous vein. The *deep dorsal vein* lies within the fibrous envelope of the penis; it receives blood from the glans penis and corpora cavernosa penis, and courses backwards in the median plane between the dorsal arteries; near the root of the penis it passes between the two parts of the suspensory ligament and then through an aperture between the inferior pubic ligament and the anterior margin of the perineal membrane, and divides into two branches, which enter the prostatic plexus. It also communicates below the symphysis pubis with the internal pudendal vein. The *dorsal vein of the clitoris*, after a similar course to that of the deep dorsal vein of the penis, ends in the vesical plexus.

The **uterine plexuses** lie along the sides and superior angles of the uterus between the two layers of the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by a pair of uterine veins on each side; these arise from the lower parts of the plexuses, opposite the external os of the uterus, and open into the corresponding internal iliac vein.

The **vaginal plexuses** are placed at the sides of the vagina; they communicate with the uterine, vesical and rectal plexuses, and are drained by the vaginal veins, one on each side, into the internal iliac veins.

The **common iliac veins** (fig. 790) are formed by the union of the external and internal iliac veins, in front of the sacro-iliac joint; passing obliquely upwards they end on the right side of the fifth lumbar vertebra by uniting with each other at an acute angle to form the inferior vena cava. The *right common iliac vein,* shorter than the left, is nearly vertical in its direction, and ascends behind, and then lateral to its artery. The right obturator nerve passes behind it obliquely, as it runs downwards and forwards to the obturator foramen. The *left common iliac vein,* longer and more oblique than the right, is at first situated on the medial side of its artery, and then behind the right common iliac artery. It is crossed anteriorly by the root of the pelvic mesocolon and the superior rectal vessels. In the rest of its course it is covered with peritoneum. Each common iliac vein receives the iliolumbar, and sometimes the lateral sacral veins; the left vein receives the median sacral vein. There are no valves in these veins.

The **median sacral veins** (middle sacral veins) accompany the corresponding artery along the front of the sacrum, and join to form a single vein, which usually ends in the left common iliac vein, but sometimes in the angle of junction of the two common iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses the aorta, and joins the right vein to form the vena cava. In such cases the anomalous vessel represents the persistent caudal half of the posterior cardinal or of the supracardinal vein of the left side.

The **inferior vena cava** (figs. 738, 790) conveys the blood from the parts below the Diaphragm to the right atrium of the heart. It is formed by the junction of the two common iliac veins, in front of the body of the fifth lumbar vertebra, a little to the right of the median plane. It ascends in front of the vertebral column, on the right side of the aorta, and, having reached the liver, is contained in a deep groove on its posterior surface—a groove which is occasionally converted into a tunnel by a band of liver substance. It then perforates the Diaphragm between the median and right portions of its central tendon, inclining slightly forwards and medially. After piercing the fibrous pericardium, it passes behind the serous pericardium to open into the lower and posterior part of the right atrium. In front and to the left of its atrial orifice there is a semilunar valve, termed the *valve of the inferior vena cava* ; this valve is rudimentary in the adult, but is of large size and exercises an important function in the fœtus (p. 674). The trunk of the inferior vena cava is devoid of valves.

Relations of the abdominal portion.—*Anteriorly* the inferior vena cava is overlapped at its commencement by the right common iliac artery and is covered, below the third part of the duodenum, with the posterior parietal peritoneum. It is crossed obliquely by the root of the mesentery and its contained vessels, and by the right testicular artery and, sometimes, transversely by the right colic artery. Passing behind the third part of the duodenum, it loses its peritoneal covering and ascends behind the head of the pancreas and then behind the first part of the duodenum, from which it is separated by the bile duct and the portal vein. Above the duodenum it is again covered for a short distance with peritoneum and lies in the posterior wall of the aditus to the lesser sac (epiploic foramen) (figs. 1162 and 1164), by which it is separated from the right free border of the lesser omentum and its contents. Above this level it is covered by the liver.

Posteriorly, in its lower part, the inferior vena cava lies on the bodies of the lower three lumbar vertebræ and the anterior longitudinal ligament, the right Psoas major and the right sympathetic trunk, while the third and fourth right lumbar arteries pass deep to its medial border. In its upper part, it lies on the right crus of the Diaphragm, from which it is partially separated by the medial part of the right suprarenal gland and the right cœliac ganglion, and the right renal, suprarenal and phrenic arteries, which cross behind it.

On its *right side* the inferior vena cava is related to the right ureter—with which, however, it is not in immediate contact—the second part of the duodenum, the medial border of the right kidney and the right lobe of the liver.

On its *left side* it is related to the aorta, below, and to the right crus of the Diaphragm and the caudate lobe of the liver above.

Relations of the thoracic portion.—This part of the inferior vena cava is very short, and is situated partly inside and partly outside the pericardial sac. The *extrapericardial part* is separated from the right pleura and lung by the right phrenic nerve. The *intrapericardial part* is covered on the front and sides by the serous layer of the pericardium.

Peculiarities.—Numerous anomalies of the inferior vena cava have been recorded and are attributable to arrests or errors in the complicated series of developmental changes which result in its formation. The vessel is sometimes represented, below the level of the renal veins, by two, more or less symmetrical veins. The condition is often associated with failure of the cross anastomosis connecting the two common iliac veins and is due to persistence on the left side of the body of one of the longitudinal channels (usually supra- or subcardinal) which normally disappear in early fœtal life (p. 157). In complete transposition of the viscera, the inferior vena cava lies to the left side of the aorta.

Applied Anatomy.—Thrombosis of the inferior vena cava is due to much the same causes as thrombosis of the superior vena cava. It usually causes œdema of the legs and back, without ascites ; if the renal veins are involved, blood and albumin will often appear in the urine. An extensive collateral venous circulation is soon established by enlargement either of the superficial or of the deep veins, or of both. In the first case the epigastric, the circumflex iliac, the lateral thoracic, thoraco-epigastric (p. 832), the internal mammary, the posterior intercostals, the external pudendal and the lumbovertebral anastomotic veins effect the communication with the superior vena cava ; in the second, the deep anastomosis is made by the azygos and hemiazygos and the lumbar veins.*

* G. Blumer, in Osler and McCrae's *System of Medicine*, London, 1908, vol. iv.

Tributaries.—In addition to the two common iliac veins the inferior vena cava receives the following veins :

Lumbar.	Renal.	Inferior phrenic.
Right testicular or ovarian.	Right suprarenal.	Hepatic.

The **lumbar veins**, four in number on each side, collect the blood by dorsal tributaries from the muscles and skin of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the vertebral column they receive veins from the vertebral plexuses, and they are connected with one another in this situation by the *ascending lumbar vein*—a longitudinal vessel placed in front of the roots of the transverse processes of the lumbar vertebræ. The *third* and *fourth lumbar veins* pass forwards on the sides of the bodies of the corresponding vertebræ and enter the posterior aspect of the inferior vena cava. Those of the left side pass behind the abdominal aorta and are longer than those of the right side. The *first* and *second lumbar veins* may end in the inferior vena cava or they may end in the ascending lumbar or lumbar azygos veins. As a rule, the first lumbar vein does not pass directly into the inferior vena cava. It may turn downwards to join the second and so open into it indirectly, but more frequently it ends in the ascending lumbar vein or passes forwards over the side of the body of the first lumbar vertebra and terminates in the lumbar azygos vein (p. 827). The second lumbar vein may join the inferior vena cava at or below the level of the renal veins. Sometimes it joins the third lumbar vein or it may terminate in the ascending lumbar vein. The first and second lumbar veins are frequently connected to each other, to the vessels of the opposite side, and to the right and left lumbar azygos veins by a plexiform network which lies on the bodies of the upper lumbar vertebræ.

The *ascending lumbar vein* is a longitudinal vessel which connects the common iliac, iliolumbar and lumbar veins. It is placed deeply under cover of the Psoas major and in front of the roots of the transverse processes of the lumbar vertebræ. At its upper end it joins the subcostal vein, and the trunk so formed turns forwards over the side of the body of the twelfth thoracic vertebra and, passing deep to the crus of the Diaphragm, ascends in the thorax as the azygos vein, on the right side, and as the inferior hemiazygos vein, on the left side. There is an angled bend on the vessel as it turns upwards, and it is usually joined at this point by a small vessel which springs from the back of the inferior vena cava (or from the left renal vein, on the left side). This little vessel represents the azygos line (p. 156), and has already been described as the *lumbar azygos vein*. Not infrequently the ascending lumbar vein ends in the first lumbar vein, which then turns forwards over the side of the first lumbar vertebra in company with the first lumbar artery and joins the lumbar azygos vein. In this case the subcostal vein joins the azygos vein (inferior hemiazygos vein, on the left side).

The **testicular veins** (spermatic veins) (fig. 738) emerge from the back of the testis, and receive tributaries from the epididymis ; they unite and form a convoluted plexus, called the *pampiniform plexus*, which constitutes the chief mass of the spermatic cord and ascends along the cord, in front of the vas deferens. Below the superficial inguinal ring (subcutaneous inguinal ring) the veins of the plexus unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the deep inguinal ring (abdominal inguinal ring), coalesce to form two veins, which run upwards in front of the Psoas major and the ureter, behind the peritoneum, lying one on each side of the testicular artery. These two veins join to form a single vessel, which on the right side opens into the inferior vena cava at an acute angle a little below the level of the renal veins ; on the left side it opens into the left renal vein at a right angle. The testicular veins are provided with valves.* The left vein passes behind the lower part of the descending colon and the lower margin

* Rivington has pointed out that valves are usually found at the orifices of both the right and left testicular veins. When, however, valves are not found at the opening of the left testicular vein into the left renal vein, they are generally present in the left renal vein within 6 mm. from the orifice of the testicular vein.—*Journal of Anatomy and Physiology*, vol. vii. p. 163.

of the pancreas and is crossed by the left colic vessels ; the right passes behind the terminal part of the ileum and the third part of the duodenum and is crossed by the root of the mesentery, the ileocolic and the right colic vessels.

Applied Anatomy. The testicular veins are very frequently varicose, constituting the condition known as *varicocele*. Varicocele almost invariably occurs on the left side, and this has been accounted for by the facts that the left testicular vein joins the left renal at a right angle ; that it is overlaid by the lower part of the descending colon, and that when this portion of the gut is full of fæcal matter, in cases of constipation, its weight impedes the return of the venous blood.

After the removal of a varicocele the venous return is subsequently carried out by the small veins of the vas deferens, of the Cremaster and those connecting with the scrotal tissues.

The **ovarian veins** in the female correspond with the testicular veins in the male ; each forms a plexus between the layers of the broad ligament near the ovary and uterine tube, and communicates with the uterine plexus. Two veins issue from this plexus and ascend across the external iliac artery, one lying on each side of the ovarian artery. Their further course and their mode of termination are the same as those of the testicular veins. Valves are occasionally found in the ovarian veins. Like the uterine veins, they become much enlarged during pregnancy.

The **renal veins**, which are of large size, are placed in front of the renal arteries, and they open into the inferior vena cava almost at right angles. The *left* is thrice the length of the right (7·5 cm. to 2·5 cm.), and crosses the posterior abdominal wall, lying behind the splenic vein and the body of the pancreas. Near its termination it passes in front of the aorta, just below the origin of the superior mesenteric artery. The left testicular (or ovarian) vein enters it from below, and the left suprarenal vein, which generally receives one of the left phrenic veins, enters its upper border a little nearer the median plane. The left renal vein opens into the inferior vena cava at a slightly higher level than the right. The *right renal vein* lies behind the second part of the duodenum and, sometimes, the lateral part of the posterior aspect of the head of the pancreas.

Occasionally the left renal vein may be duplicated, and in these cases one vein passes behind the aorta to join the inferior vena cava—persistence of the renal collar (p. 157)—or the anterior vessel may be entirely absent. The latter condition represents persistence of the posterior limb of the renal collar combined with absence of the intersubcardinal anastomosis.

The **suprarenal veins** are two in number, one issuing from the hilum of each suprarenal gland. The right vein is very short and passes directly into the posterior aspect of the inferior vena cava ; the left runs downwards and medially, in front of or just lateral to the left cœliac ganglion, and passes behind the body of the pancreas to end in the left renal vein.

The **phrenic veins** (inferior phrenic veins) follow the course of the corresponding arteries on the Diaphragm ; the right ends in the inferior vena cava ; the left is often represented by two branches, one of which ends in the left renal or suprarenal vein, while the other passes in front of the œsophageal opening in the Diaphragm and joins the inferior vena cava.

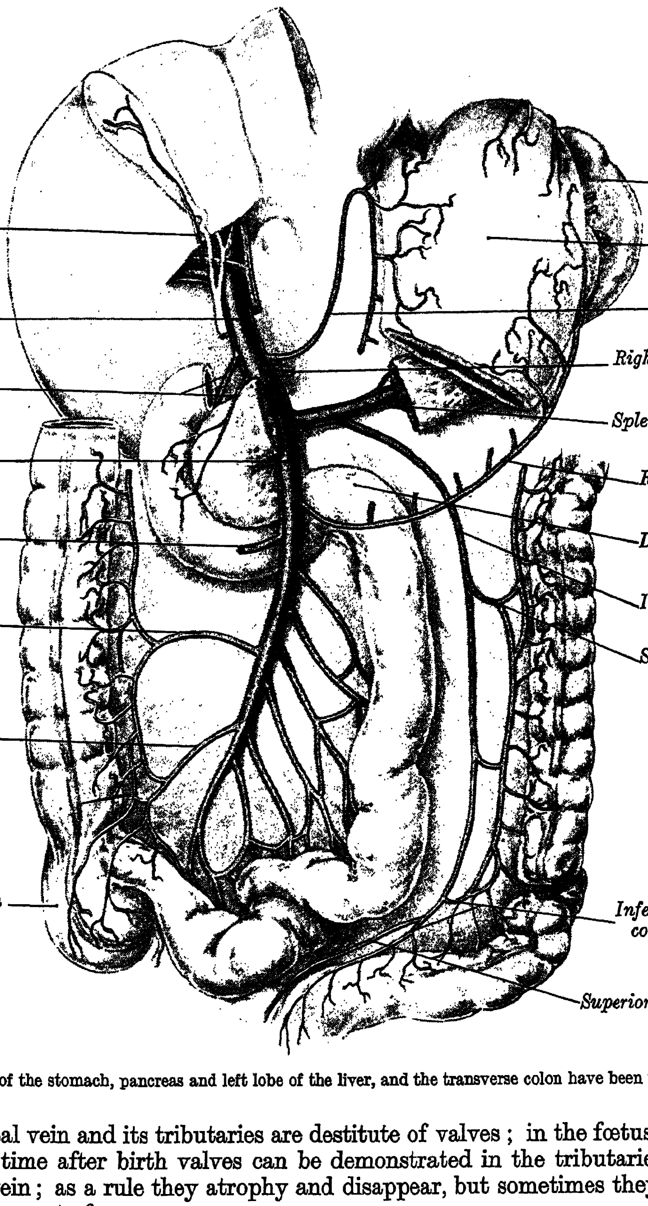
The **hepatic veins** drain the liver, and commence in the *intralobular veins*, which receive the blood from the sinusoids of the liver lobules. The intralobular veins open into the *sublobular veins*, and these in turn unite to form the hepatic veins, which open into the inferior vena cava as it lies in the groove on the posterior surface of the liver. The hepatic veins are arranged in two groups, upper and lower. The *upper group* usually consists of three large veins, right, left and middle, the last emerging from the caudate lobe ; those of the *lower group* vary in number ; they are of small size and come from the right and caudate lobes. The hepatic veins are in direct contact with the hepatic tissue and are destitute of valves.

The Portal System of Veins (fig. 791)

The portal system includes all the veins which drain the blood from the abdominal part of the digestive tube (with the exception of the lower part of the

rectum and anal canal) and from the spleen, pancreas, and gall-bladder. From these viscera the blood is conveyed to the liver by the *portal vein*. In the liver this vein ramifies like an artery and ends in capillary-like vessels termed sinusoids; from which the blood is conveyed to the inferior vena cava by the hepatic veins. The blood of the portal system therefore passes through two sets of minute vessels, viz. (*a*) the capillaries of the digestive tube, spleen, pancreas, and gall-bladder ; and (*b*) the sinusoids of the liver. In the adult

FIG. 791.—The portal vein and its tributaries. Semidiagrammatic.



Portions of the stomach, pancreas and left lobe of the liver, and the transverse colon have been removed.

the portal vein and its tributaries are destitute of valves ; in the fœtus and for a short time after birth valves can be demonstrated in the tributaries of the portal vein ; as a rule they atrophy and disappear, but sometimes they persist in a degenerate form.

The **portal vein** (figs. 791, 792) is about 8 cm. long, and is formed at the level of the second lumbar vertebra by the junction of the superior mesenteric and splenic veins, the union of these veins taking place in front of the inferior vena cava and behind the neck of the pancreas. It may be separated from the inferior vena cava by the upper part of the head of the pancreas, when that structure projects to the left. The vein inclines to the right as it passes upwards

behind the first part of the duodenum, the bile-duct and the gastroduodenal artery, and in front of the inferior vena cava; it then ascends in the right border of the lesser omentum in front of the aditus to the lesser sac (epiploic foramen) to reach the right extremity of the porta hepatis, where it divides into a right and a left branch, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the lesser omentum it is placed behind the bile duct and the hepatic artery, the former lying to the right of the latter; it is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymph glands. The *right branch* of the portal vein enters the right lobe of the liver, but before doing so generally receives the cystic vein. The *left branch*, longer but of smaller calibre than the right, gives branches to the caudate and quadrate lobes, and then enters the left lobe of the liver. As it does so, it is joined in front by the para-umbilical veins (p. 844) and by a fibrous cord, named the *ligamentum teres*, which represents the obliterated umbilical vein. It is connected to the inferior vena cava by a second fibrous cord, termed the *ligamentum venosum*, which ascends in a fissure on the posterior aspect of the liver.

The tributaries of the portal vein are:

1. Splenic.
2. Superior mesenteric.
3. Left gastric.
4. Right gastric.
5. Cystic.
6. Para-umbilical.

1. The **splenic vein** (fig. 791) is of large size, but is not tortuous like the artery; it commences by five or six branches which return the blood from the spleen. These unite to form a single vessel, which traverses the lienorenal ligament in company with the splenic artery and the tail of the pancreas. It then passes to the right with a downward inclination across the posterior abdominal wall, lying at a lower level than the splenic artery and grooving the upper part of the posterior surface of the pancreas, to which it is closely connected by numerous short tributaries from the gland. In its course it crosses the anterior surface of the left kidney and its hilum (or the lower pole of the left suprarenal gland), and it is separated from the left sympathetic trunk and crus of the Diaphragm by the left renal vessels, and from the abdominal aorta by the superior mesenteric artery and the left renal vein. It ends behind the neck of the pancreas where it unites at a right angle with the superior mesenteric vein, to form the portal vein.

Tributaries.—It receives the short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein.

(*a*) The **short gastric veins,** four or five in number, drain the fundus and left part of the greater curvature of the stomach, and pass between the two layers of the gastrosplenic ligament to end in the splenic vein or in one of its large tributaries.

(*b*) The **left gastro-epiploic vein** receives branches from both surfaces of the stomach and from the greater omentum; it runs from right to left along the greater curvature of the stomach and ends in the commencement of the splenic vein.

(*c*) The **pancreatic veins** are several small vessels which drain the body and tail of the pancreas.

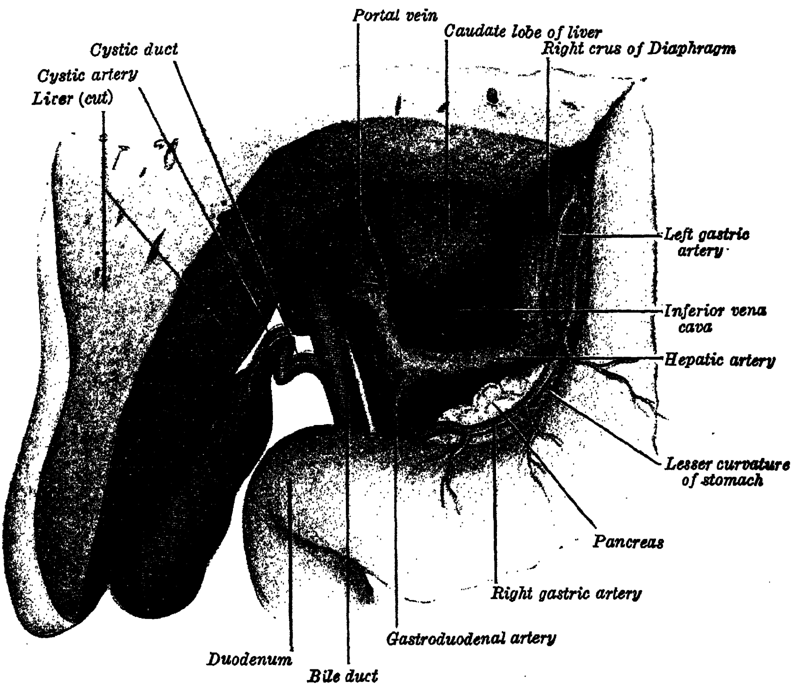
(*d*) The **inferior mesenteric vein** (fig. 791) returns blood from the rectum, and from the pelvic and descending parts of the colon. It begins in the rectum as the *superior rectal* (superior hæmorrhoidal) *vein*, which has its origin in the rectal plexus (p. 836), and through this plexus communicates with the middle and inferior rectal veins. The superior rectal vein leaves the true pelvis, crosses the left common iliac vessels with the superior rectal artery, and is continued upwards as the inferior mesenteric vein. This vein lies to the left of its artery and ascends behind the peritoneum and in front of the left Psoas major; its course is usually curved, convex to the left, and it may cross the testicular (or ovarian) vessels or lie to their medial side; it then passes above, or behind, the duodenojejunal flexure and opens into the splenic vein behind the body of the pancreas; sometimes it ends in the angle of union of the splenic and superior mesenteric veins.

If a superior duodenal or a paraduodenal fossa be present, the inferior mesenteric vein usually lies between the layers of the fold of peritoneum which forms the anterior wall of the fossa (fig. 1165).

Tributaries.—The inferior mesenteric vein receives the inferior left colic veins from the pelvic colon, and the superior left colic vein from the descending colon and left colic flexure.

2. The **superior mesenteric vein** (fig. 791) returns the blood from the small intestine, from the cæcum, and from the ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of the veins which drain the terminal part of the ileum, the cæcum and vermiform appendix. It ascends between the two layers of the mesentery on the right side of the superior mesenteric artery, and in its upward course passes in front of the right ureter, the inferior vena cava, the third part of the duodenum, and the uncinate

FIG. 792.—Drawing of a dissection to show the relations of the hepatic artery, bile duct and portal vein in the lesser omentum.



process of the head of the pancreas. Behind the neck of the pancreas it unites with the splenic vein to form the portal vein.

Tributaries.—The superior mesenteric vein receives the veins which correspond to the branches of the superior mesenteric artery, viz. the jejunal, ileal, ileocolic, right colic, and middle colic veins; it is also joined by the right gastro-epiploic and the pancreaticoduodenal veins.

The **right gastro-epiploic vein** receives branches from the greater omentum and from the lower part of the stomach; it runs from left to right along the greater curvature of the stomach, between the anterior two layers of the greater omentum and joins the superior mesenteric vein below the neck of the pancreas.

The **pancreaticoduodenal veins** accompany their corresponding arteries; the lower one frequently joins the right gastro-epiploic vein; the upper one usually passes upwards and to the left behind the bile duct and terminates in the portal vein.

3. The **left gastric vein** derives tributaries from both surfaces of the stomach; it runs upwards along the lesser curvature of the stomach between the two layers of the lesser omentum, to the œsophageal opening of the stomach, where it receives some œsophageal veins. It then turns backwards and passes downwards and to the right behind the lesser sac of the peritoneum (omental

bursa), and ends in the portal vein at the upper border of the first part of the duodenum.

4. The **right gastric vein**, of small size, runs from left to right along the pyloric portion of the lesser curvature of the stomach between the two layers of the lesser omentum, and ends in the portal vein.

5. The **cystic vein** drains the blood from the gall-bladder; it accompanies the cystic duct, and usually ends in the right branch of the portal vein.

6. The **para-umbilical veins**, which establish an anastomosis between the veins of the anterior abdominal wall and the portal vein, are found in the course of the ligamentum teres of the liver and of the middle umbilical ligament. The best marked of these small veins is one which begins at the umbilicus and runs backwards and upwards in, or on the surface of, the ligamentum teres between the layers of the falciform ligament, to end in the left branch of the portal vein.

Applied Anatomy.—Obstruction to the portal vein may produce ascites, and this may arise from many causes, e.g. (1) the pressure of a tumour on the portal vein, such as cancer or hydatid cyst in the liver, enlarged lymph glands in the lesser omentum, or cancer of the head of the pancreas; (2) from cirrhosis of the liver, when the radicles of the portal vein are pressed upon by the contracting fibrous tissue in the portal canals; (3) from valvular disease of the heart, and back pressure on the hepatic veins, and so on the whole of the circulation through the liver. In this condition the prognosis as regards life and freedom from ascites may be much improved by the establishment of a good collateral circulation between the portal and systemic veins. This is effected by communications between (*a*) the gastric veins, and the œsophageal veins which often project as a varicose bunch into the stomach, emptying themselves into the inferior hemiazygos vein; (*b*) the veins of the colon and duodenum, and the left renal vein; (*c*) the accessory portal system of Sappey, branches of which pass in the round and falciform ligaments (particularly the latter) to unite with the epigastric and internal mammary veins, and through the diaphragmatic veins with the azygos; a single large vein, shown to be a para-umbilical vein, may pass from the hilum of the liver by the round ligament to the umbilicus, producing there a bunch of prominent varicose veins known as the *caput Medusæ*; (*d*) the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; (*e*) the superior, middle and inferior rectal; (*f*) very rarely the ductus venosus remains patent, affording a direct connexion between the portal vein and the inferior vena cava.

Thrombosis of the portal vein is a very serious event, and is most often due to pathological processes causing compression of the vessel or injury to its wall, such as tumours or inflammation about the pylorus or head of the pancreas, or to gall-stones, or cirrhosis of the liver.

THE LYMPHATIC SYSTEM

In most of the tissues of the body there exists a wide-meshed plexus of vessels which contain a clear, colourless fluid. This fluid is termed *lymph* and it is composed, for the most part, of blood plasma which has transuded through the walls of the blood capillaries into the minute tissue spaces and has there become mixed with the tissue juices. As the pressure in these tissue spaces rises, the fluid which they contain passes into a closed system of vessels, termed *lymph vessels*. These eventually discharge the lymph into the great veins at the root of the neck, but all, save the terminal vessels, are interrupted in some part of their course by small, solid masses of lymphoid tissue, termed *lymph glands*. The lymphatic system comprises not only all the lymph vessels and lymph glands which will be described in this section, but also certain masses of lymphoid tissue found mainly in the walls of the alimentary canal which will be described with the digestive system.

The **lymph vessels** are exceedingly delicate and their coats so transparent that the fluid they contain is readily seen through them. In contrast with the blood-capillaries, which can absorb only those substances which are soluble in water, the lymph vessels are able to take up substances which are insoluble in water.* They are constricted at intervals and so present a knotted or beaded appearance; these constrictions correspond to the attachments of valves in the interior of the vessels. The smallest lymph vessels form a meshwork which is found interspersed amongst the elements and blood-vessels of the

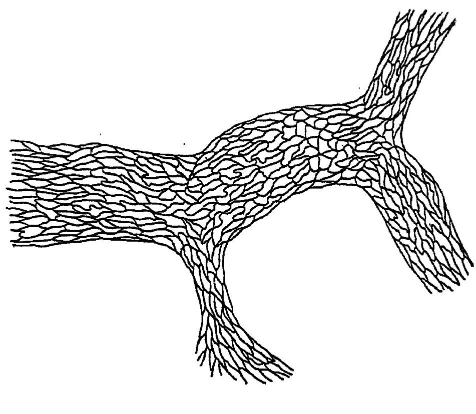
* P. T. Herring and F. G. Macnaughton, *The Lancet*, June 3rd, 1922.

tissues that they drain. The meshes of the network and the vessels themselves are much larger than those of the capillary plexuses. The walls of the vessels are complete and, in all probability, there are no direct communications between the lumen of a lymph vessel and the tissue spaces.

Lymph vessels have been found in nearly every tissue of the body which contains blood-vessels, but it would appear that they are more numerous in epithelial tissues. The lymph vessels of the small intestine are called *lacteals*; they differ from other lymph vessels only in regard to their function of fat absorption. After a meal containing this foodstuff, the lymph which they contain is milk-white in appearance and is termed *chyle*.

Lymph vessels are absent from the central nervous system, striped muscle and from non-vascular structures such as cartilage, nails, cuticle and hair. Their occurrence in bone is doubtful. Although no lymph vessels are found in the central nervous system, the blood-vessels entering the brain and spinal cord appear to be surrounded by perivascular spaces which are lined with the mesothelial cells of the pia mater. The cerebrospinal fluid circulates through these spaces and may therefore play the part of lymph. Woollard,* who used the vital method of injecting the subarachnoid space in cats, found that subsequently the dye was confined to the pia and arachnoid mater, and that these structures, together with the pial septa, were everywhere coloured. Further, the mesothelial cells of the pia mater contained granules of the dye and could be traced for considerable distances along the spaces in the sheaths of the blood-vessels entering the brain and spinal cord. These perivascular spaces may therefore be regarded as playing the part of lymph vessels.

FIG. 793.—A small lymph vessel, from the diaphragm of a rabbit. Silvered. ×65.



From the networks in the tissues small lymph vessels emerge and either pass to a neighbouring lymph gland or join some larger lymph trunk. The vessels are arranged in superficial and deep sets. The *superficial lymph vessels* lie immediately under the skin and may run independently or may accompany the superficial veins; in certain situations they join the deep vessels, but these connexions are by no means frequent. The superficial lymph vessels are especially numerous around the orifices where skin and mucous membrane become continuous, e.g., the mouth, the anus, the vagina, etc. Lymph vessels of a similar type are found in the submucous areolar tissue of the digestive, respiratory and urogenital systems and in the subserous tissue of the thoracic and abdominal walls. The *deep lymph vessels* always accompany vascular or neurovascular bundles; they are fewer in number but larger in calibre than the superficial vessels, although their mode of origin is probably similar.

The lymph vessels of any part exceed the veins in number, but they are much smaller in size. Their anastomoses—especially those of the larger trunks—are more numerous and are effected by vessels equal in diameter to those which they connect.

The lymph vessels unite with one another and ultimately form two main channels, named the *thoracic duct* and the *right lymphatic duct*, which open into the venous system at the root of the neck.

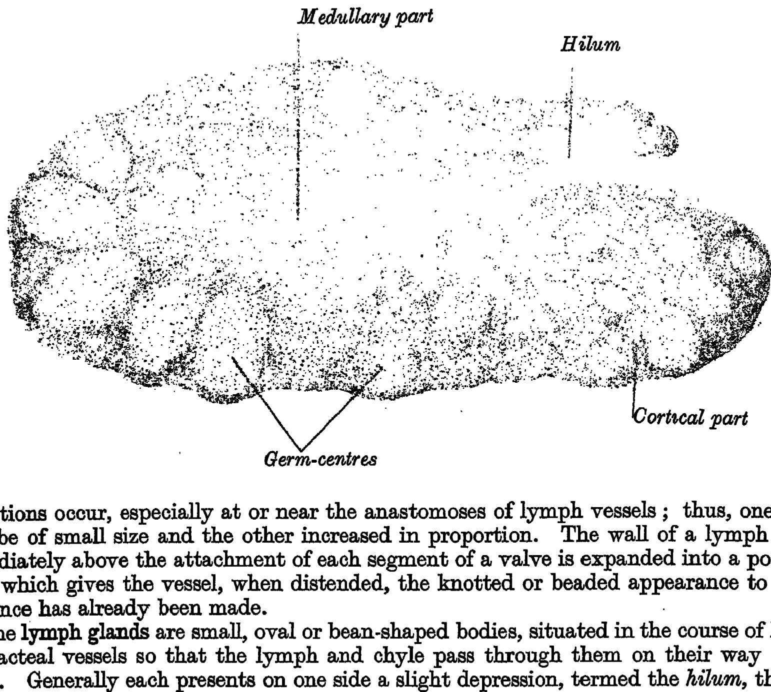
The structure of the lymph vessels.—The walls of the larger lymph vessels are composed of three coats. The *internal* coat is thin, transparent, and slightly elastic, and consists of a layer of elongated endothelial cells supported on an elastic membrane; the cells have wavy margins, by which contiguous cells are dovetailed into one another. The *middle* coat is composed of smooth muscular, and fine elastic fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscular

* H. H. Woollard, *Journal of Anatomy*, vol. lviii.

fibres longitudinally or obliquely disposed; it forms a protective covering to the other coats and serves to connect the vessel with the neighbouring structures. In the smaller vessels there are no muscular or elastic fibres, and the wall consists only of a connective tissue coat lined by endothelium (fig. 793). The thoracic duct has a more complex structure than the other lymph vessels; it presents a distinct subendothelial layer, similar to that found in the arteries; in the middle coat there is, in addition to the muscular and elastic fibres, a layer of connective tissue with its fibres arranged longitudinally. Nutrient blood-vessels and many non-medullated nerves in the form of fine plexuses are distributed to the outer and middle coats of the larger lymph vessels.

In the lymph vessels the valves are placed at much shorter intervals than in the veins. They are most numerous near the lymph glands, and are found more frequently in the lymph vessels of the neck and upper limb than in those of the lower limb; they are wanting in the vessels composing the plexiform network in which the lymph vessels usually originate on the surface of the body. The valves are formed of thin layers of fibrous tissue covered on both surfaces by endothelium which presents the same arrangement as on the valves of veins (p. 666). They are semilunar in form, and are attached by their convex edges to the wall of the vessel, the concave edges being free and directed along the course of the lymph-current. Usually two valves, of equal size, are found opposite each other; but occasionally

FIG. 794.—A section through a lymph gland of a dog. Stained with hæmatoxylin and eosin. ×34.



exceptions occur, especially at or near the anastomoses of lymph vessels; thus, one valve may be of small size and the other increased in proportion. The wall of a lymph vessel immediately above the attachment of each segment of a valve is expanded into a pouch or sinus which gives the vessel, when distended, the knotted or beaded appearance to which reference has already been made.

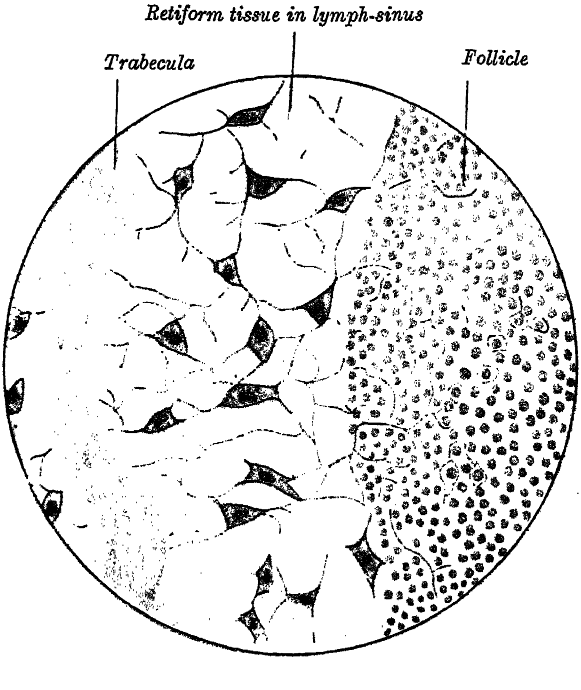
The **lymph glands** are small, oval or bean-shaped bodies, situated in the course of lymph and lacteal vessels so that the lymph and chyle pass through them on their way to the blood. Generally each presents on one side a slight depression, termed the *hilum*, through which the blood-vessels enter and leave the gland. The efferent lymph vessel also emerges from the gland at this spot, while the afferent vessels enter it at different parts of the periphery. On section (fig. 794), a lymph gland displays two different structures: an external, of lighter colour—the *cortical*; and an internal, darker—the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent lymph vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

The **structure of the lymph glands** (figs. 794, 795). A lymph gland consists of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculæ*) proceeds inwards, imperfectly dividing the gland into a number of freely communicating spaces; (2) a quantity of lymphoid tissue occupying these spaces without filling them completely; (3) a *lymph-path* or *lymph-sinus*, consisting of a large number of irregular, interconnecting spaces, which communicate with both the afferent and the efferent lymph vessels; and (4) a free supply of blood-vessels, which are supported in the trabeculæ. The nerves passing into the hilum are few in number and are chiefly distributed to the blood-vessels supplying the gland.

In man the *capsule* and *trabeculæ* are composed of fibro-areolar tissue with some plain muscular fibres, but in many of the lower animals they consist almost entirely of the latter.

The trabeculæ pass inwards towards the centre of the gland for about one-third or one-fourth of the distance between the circumference and the centre of the gland. In some animals they are sufficiently well marked to divide the peripheral or cortical portion of the gland into a number of compartments, but in man this arrangement is not obvious. The larger trabeculæ springing from the capsule break up into finer bands, and these interlace to form a meshwork in the central or medullary portion of the gland. In the *cortex* the gland-pulp or lymphoid tissue is arranged in imperfectly separated follicles or nodules, surrounded peripherally by the lymph-sinus, which separates them from the capsule and trabeculæ (fig. 795). In stained sections the central portions of the follicles appear clearer than the surrounding gland-pulp. Their cells are larger, frequently show karyokinetic figures and are not so densely packed together. In these areas, which are termed *germ-centres*, the cells are actively dividing. In the *medulla* the lymphoid tissue is arranged in irregular cords, separated from one another by the lymph-sinus and trabeculæ. These cords do not contain germ centres, but otherwise they show the same structure as the follicles, with which they are continuous at their peripheral ends.

FIG. 795.—Retiform and adenoid tissue, from a lymph gland. ×255.



The gland-pulp consists of ordinary lymphoid tissue (fig. 795), being made up of a delicate network of retiform tissue packed with lymphocytes. The network of the gland-pulp is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; moreover, the fibres of the retiform tissue of the lymph-paths are continuous with those of the trabeculæ. The gland-pulp is traversed by a dense plexus of capillary blood-vessels.

The *afferent vessels*, as stated above, enter at different parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule, open into the part of the lymph sinus immediately beneath the capsule. This *subcapsular lymph space* is everywhere in continuity with the lymph-sinuses of the cortical part. As the afferent vessels enter they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. The *efferent vessel* commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessels thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; after flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph sinuses is much retarded by the presence of the reticulum, hence morphological elements carried

in the lymph stream, either normal or morbid, are easily arrested and deposited in the sinuses. Many lymph corpuscles pass with the efferent lymph-stream to join the general blood-stream. The arteries of the gland enter at the hilum and go to the gland-pulp, there to break up into a capillary plexus, either directly or after running in the trabeculæ for a certain distance. The veins emerge from the gland at the hilum.

Applied Anatomy.—The lymph vessels and lymph glands draining any infected area of the body are very liable to become inflamed, resulting in acute or chronic lymphangitis and lymphadenitis. In acute cases the paths of the superficial lymph vessels are often marked out on the skin by painful, red lines leading to tender, swollen lymph glands, which may suppurate. Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm *Microfilaris nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterised by enormous enlargement and thickening of the skin of some part of the body, most frequently of the leg and scrotum. Tuberculous, syphilitic and cancerous enlargements of the lymph vessels and lymph glands are very commonly met with.

The present view is that cancer spreads more frequently by permeating the lymph vessels as a solid cell-growth, than by minute emboli. Operations for the removal of cancer are therefore planned to take away in one mass the cancer, the intervening lymph vessels, and the lymph glands.

The appearance of secondary malignant deposits or of secondary infection in parts of the body that seem not to be directly associated by any lymphatic connexion with the seat of the primary growth or infection has often been observed, and explained as due to 'retrograde transport' of cancer-cells or bacteria by a reversed flow of lymph. Weleminsky* however, believes that the explanation is to be found in the fact that when the infected lymph glands have grown to a certain size they no longer permit the normal flow of lymph through them, and that in these circumstances very delicate lymphatic connexions, whose existence normally remains unsuspected, develop to a surprising extent between groups of lymph glands that at first sight appear to be unconnected with one another. In this connexion the possibility of spread by the blood-stream should not be disregarded entirely. Recent work † has shown that lymph vessels in a pedicle skin graft survive in the graft and can replace vessels which have been destroyed.

The Thoracic Duct

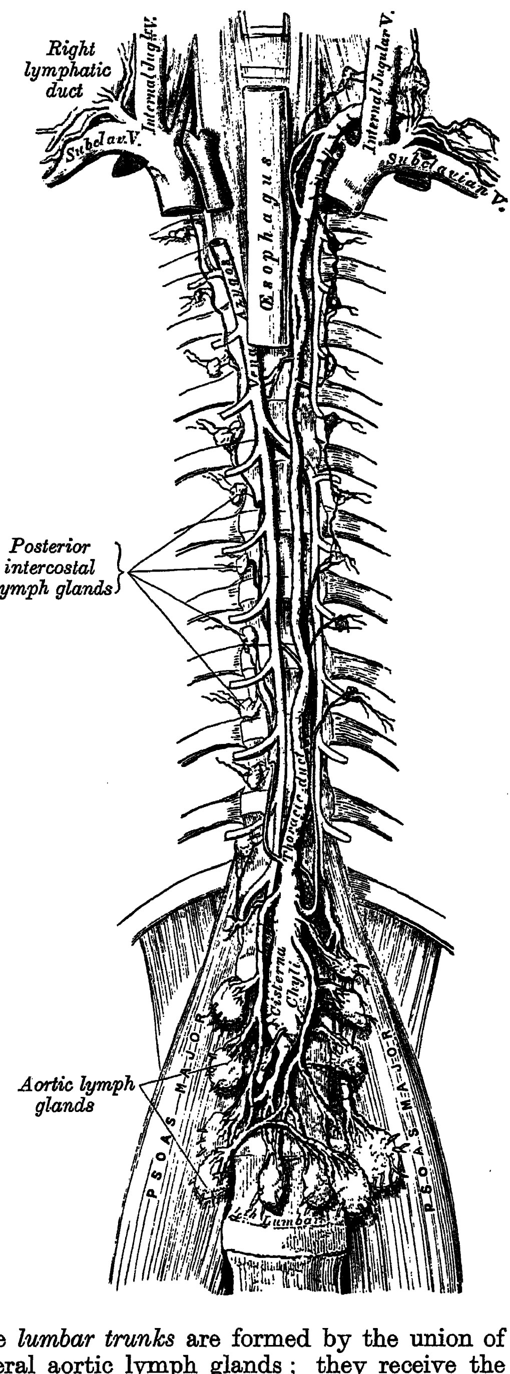
The **thoracic duct** (fig. 796) conveys the chyle and the greater part of the lymph into the blood. It is the common trunk of all the lymph vessels of the body, excepting those of the right side of the head, neck, and thoracic wall, the right upper limb, right lung, right side of the heart, and part of the convex surface of the liver. In the adult it varies in length from 38 cm. to 45 cm. and, including the cisterna chyli, extends from the second lumbar vertebra to the root of the neck. It begins at the upper end of the cisterna chyli (p. 849) near the lower border of the twelfth thoracic vertebra and enters the thorax through the aortic opening of the Diaphragm. It then ascends through the posterior mediastinum with the aorta on its left, and the azygos vein on its right side. In this part of its course the vertebral column and anterior longitudinal ligament, the right aortic intercostal arteries, and the terminal parts of the hemiazygos veins lie behind it. The Diaphragm and the œsophagus lie in front of it, but a recess of the right pleural cavity may intervene between the duct and the œsophagus. Opposite the fifth thoracic vertebra the thoracic duct inclines towards the left side, enters the superior mediastinum, and ascends to the thoracic inlet along the left edge of the œsophagus. After being crossed by the aortic arch, it lies behind the commencement of the left subclavian artery and in close contact with the mediastinal pleura of the left side. Passing into the neck it arches laterally at the level of the transverse process of the seventh cervical vertebra, the arch rising about 3 cm. or 4 cm. above the clavicle. In this part of its course the duct runs anterior to the vertebral artery and vein, the sympathetic trunk and the thyrocervical trunk or its branches. It also passes in front of the phrenic nerve and the medial border of the Scalenus anterior, but is separated from these two structures by the prevertebral fascia. In this part of its course it is placed behind the left common carotid artery, vagus nerve, and internal jugular vein. Finally, it

* *Berliner klin. Woch.*, 1905, No. 24, p. 743.

† J. H. Gray, *Journal of Anatomy*, vol. lxxii. part i.

descends in front of the first part of the left subclavian artery. It ends by opening into the angle of junction of the left subclavian vein with the left internal jugular vein, but it sometimes breaks up into a variable number of smaller vessels just prior to its termination. At its commencement the thoracic duct is about ·5 cm. in diameter, but it diminishes considerably in calibre in the middle of the thorax, and is again slightly dilated just before its termination. It is generally flexuous, and constricted at intervals so as to present a varicose appearance. Not infrequently it divides in the middle of its course into two vessels of unequal size which soon reunite, or into several branches which form a plexiform interlacement. It occasionally divides at its upper part into two branches, right and left; the left ending in the usual manner, while the right opens into the right subclavian vein, in connexion with the right lymphatic duct. The thoracic duct has several valves, and these tend to be placed in situations where the duct is exposed to pressure; at its termination it is provided with a pair, the free borders of which are turned towards the vein so as to prevent the passage of venous blood into the duct.

FIG. 796.—The thoracic and right lymphatic ducts.



The **cisterna chyli** (fig. 797) is a sac-like dilatation on the lymphatic pathway from the abdomen and lower limbs. It is 5 cm. to 7 cm. long and is situated in front of the bodies of the first and second lumbar vertebræ, immediately to the right of the abdominal aorta. The upper two lumbar arteries of the right side and the right lumbar azygos vein, when it is present, intervene between the cisterna chyli and the vertebral column. Anteriorly the cisterna chyli is covered by the medial edge of the right crus of the Diaphragm. It receives the right and left lumbar and the intestinal lymphatic trunks. The *lumbar trunks* are formed by the union of the efferent vessels from the lateral aortic lymph glands; they receive the lymph from the lower limbs, from the walls and viscera of the pelvis, from the kidneys and suprarenal glands, the testes (or ovaries), and the deep lymph vessels of the greater part of the abdominal wall. The *intestinal trunk* receives the lymph from the stomach, intestine, pancreas and spleen, and from the lower and anterior part of the liver.

Tributaries.—At its commencement the thoracic duct receives a descending trunk from the posterior intercostal lymph glands of the lower six or seven intercostal spaces, on each side. In the thorax the thoracic duct is joined on each side by a trunk which drains the upper lumbar lymph glands and pierces the crus of the Diaphragm. It also receives the efferents from the posterior mediastinal lymph glands and from the posterior intercostal lymph glands of

FIG. 797.—Modes of origin of the thoracic duct. (Poirier and Charpy.)

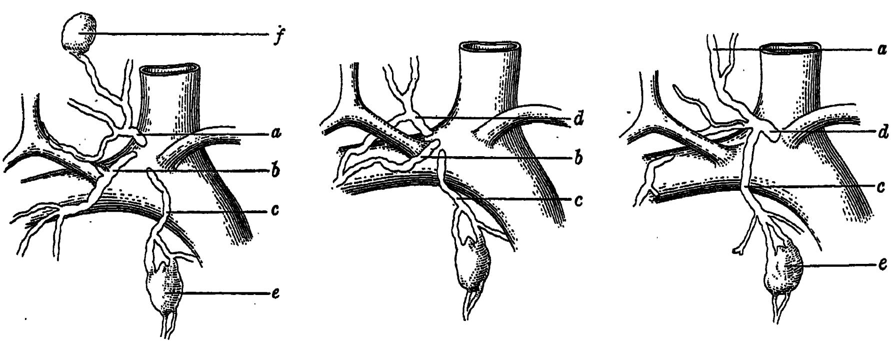
the upper six spaces of the left side. In the neck it is joined usually by the *left jugular trunk* from the left side of the head and neck, and the *left subclavian trunk* from the left upper limb, but these vessels may open independently into the internal jugular vein and the subclavian vein, respectively; sometimes it is joined by the *left bronchomediastinal trunk*, but this trunk usually opens independently into the junction of the left subclavian and internal jugular veins.

FIG. 798.—The terminal lymph trunks of the right side. (Poirier and Charpy.)



a. Jugular trunk. *b*. Subclavian trunk. *c*. Bronchomediastinal trunk. *d*. Right lymphatic duct. *e*. Lymph gland of internal mammary chain. *f*. Lymph gland of deep cervical chain.

The **right lymphatic duct** (figs. 796, 798), about 1 cm. in length, courses along the medial border of the Scalenus anterior at the root of the neck, and ends by opening into the angle of junction of the right subclavian and right internal jugular veins. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—The right lymphatic duct receives the lymph from the right side of the head and neck through the *right jugular trunk*; from the right upper limb through the *right subclavian trunk*; from the right side of the thorax, right lung, right side of the heart, and part of the convex surface of the liver,

through the *right bronchomediastinal trunk*. These three trunks frequently open separately in the angle of union of the two veins (fig. 798).

Applied Anatomy.—Blockage of the thoracic duct by mature specimens of the minute parasitic worm *Microfilaria nocturna* gives rise to stasis of the chyle, and to its passage in various abnormal directions on its course past the obstruction. The neighbouring abdominal, renal, and pelvic lymph vessels become enlarged, varicose, and tortuous, and chyle may make its way into the urine (chyluria), the tunica vaginalis (chylocele), the abdominal cavity (chylous ascites) or the pleural cavity (chylous pleural effusion), in consequence of rupture of some of these distended lymph vessels.

The thoracic duct has been wounded in removing tuberculous glands from the neck. When this happens the duct should be ligatured in the same way as a vein. The chyle then appears to find its way into the veins by anastomosing channels.

THE LYMPHATIC DRAINAGE OF THE HEAD AND NECK *

The lymph glands of the head and neck comprise a terminal group and a number of intermediary, outlying groups. The terminal group is closely associated with the carotid sheath and is named the *deep cervical group*. All the lymph vessels of the head and neck drain into this group, either directly from the tissues themselves, or indirectly after passing through one of the outlying groups. The efferents of the deep cervical lymph glands form the *jugular trunk*, which, on the right side, may end in the junction of the internal jugular and subclavian veins or may join the right lymphatic duct; on the left side, it usually enters the thoracic duct, although it may join either the internal jugular or the subclavian vein.

THE DEEP CERVICAL LYMPH GLANDS

The deep cervical lymph glands are found lying along the carotid sheath from the base of the skull to the root of the neck. They may be subdivided into (1) a superior and (2) an inferior group, both of which receive *afferents* direct from the tissues themselves as well as from the outlying, intermediary groups.

(1) The **superior deep cervical lymph glands** lie in close relationship with the upper part of the internal jugular vein. Most of them are hidden by the sternomastoid, but a few are found extending beyond the borders of the muscle. One group, which comprises one large and several small glands, is placed in the triangular area bounded by the posterior belly of the digastric, the common facial vein, and the internal jugular vein, and is termed the *jugulodigastric group*; it is associated particularly with the lymph drainage of the tongue.

Efferents from the upper deep cervical lymph glands pass to the lower deep cervical group as well as to the jugular trunk.

(2) The **inferior deep cervical lymph glands** are situated under cover of the lower part of the sternomastoid, and extend also into the subclavian triangle, where they are closely related to the brachial plexus and the subclavian vessels. One gland of this group lies on, or just above the intermediate tendon of the omohyoid muscle; it is called the jugulo-omohyoid gland (Jamieson and Dobson) † and is concerned especially with the drainage of the tongue (p. 856). The efferents from the lower deep cervical lymph glands join the jugular trunk.

From the point of view of their lymphatic drainage the tissues of the head and neck can conveniently be considered in two groups, viz.: (*a*) The superficial tissues and (*b*) the deeper structures, including the viscera.

* In this and the following sections only the larger and more constant groups of lymph glands are included. For a detailed description and references to the literature, the reader is referred to *Anatomie des Lymphatiques de l'homme*, by H. Rouvière. Masson et Cie. Paris, 1932.

† J. K. Jamieson and J. F. Dobson, "The lymphatics of the tongue," *British Journal of Surgery*, vol. viii. No. 29, 1920.

A. Lymphatic Drainage of the Superficial Tissues of the Head and Neck (fig. 800).

Most of the superficial tissues are drained by vessels which go first to outlying groups of glands, and the efferents from these glands pass to the deep cervical lymph glands. Some of the lymph, however, may pass directly to the deep cervical glands.

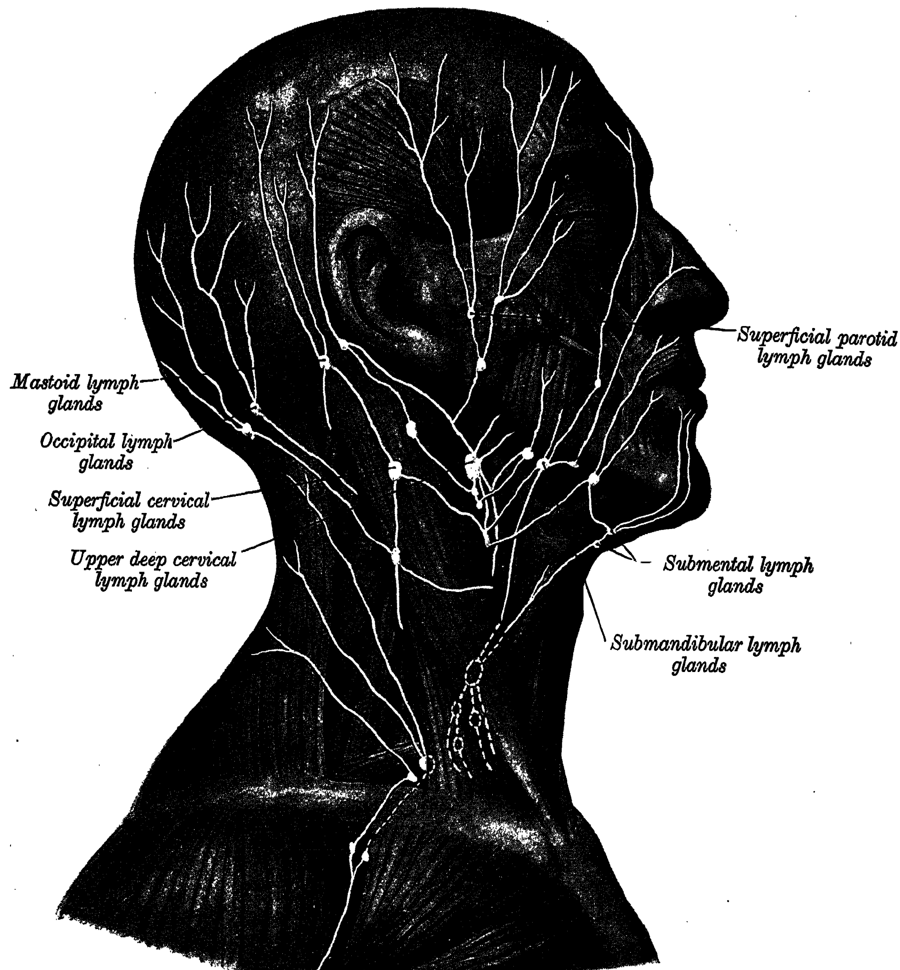


Fig. 799.—The superficial lymph glands and lymph vessels of the head and neck.

The outlying groups concerned in the drainage of the superficial tissues are:

In the head.	*In the neck.*
Occipital.	Submandibular.
Mastoid.	Submental.
Parotid.	Anterior cervical.
Facial.	Superficial cervical.

1. **Lymphatic drainage of the scalp and ear.**—(i) The lymph vessels from the frontal region just above the root of the nose drain into the submandibular group of glands (fig. 799) and will be considered with the lymphatics of the face.

(ii) The vessels from the rest of the forehead, from the temporal region of the scalp, and from the upper half of the lateral surface of the auricle and the anterior wall of the external auditory meatus drain into the *superficial parotid*

lymph glands, which lie immediately in front of the tragus, on, or deep to, the fascial investment of the parotid gland. These glands receive also the lateral lymph vessels from the eyelids and those from the skin over the zygomatic bone. Their efferent vessels pass to the upper deep cervical lymph glands.

(iii) A strip of the scalp above the auricle, the upper half of the cranial surface and margin of the auricle, and the posterior wall of the external auditory meatus are drained by vessels which pass, some to the upper deep cervical glands and others to the mastoid group.

The *mastoid lymph glands* (fig. 799) are placed superficial to the mastoid insertion of the Sternomastoid muscle, and deep to the Auricularis posterior. Their efferents pass to the upper deep cervical glands.

(iv) The lobule of the auricle, the floor of the external auditory meatus, and the skin over the angle of the jaw and the lower part of the parotid region are drained by vessels which may pass to the superficial cervical group of glands or to the upper deep cervical group. The *superficial cervical glands* are placed along the external jugular vein superficial to the Sternomastoid. Some of the efferents from this group pass round the anterior border of the Sternomastoid to reach the upper deep cervical glands; others follow the external jugular vein and join the lower deep cervical glands in the subclavian triangle.

(v) The occipital region of the scalp is drained partly by vessels which pass to the occipital group of glands, and partly by a trunk which descends along the posterior border of the Sternomastoid to end in the lower deep cervical glands. The *occipital lymph glands* are placed in the upper angle of the posterior triangle, superficial to the attachment of the Trapezius to the occipital bone.

2. **Lymphatic drainage of the face.**—(i) The lymph vessels draining the eyelids and conjunctiva commence in a superficial plexus beneath the skin and in a deep plexus in front of and behind the tarsi; these plexuses communicate with one another and medial and lateral sets of vessels arise from them. The lymph vessels of the lateral set drain the whole thickness of the upper lid with the exception of the skin over its medial part; they also drain the whole thickness of the lateral half of the lower lid and all the ocular conjunctiva. They pass laterally from the lateral commissure to end in the superficial parotid glands (p. 852) and also in the *deep parotid lymph glands*, which are imbedded in the substance of the parotid salivary gland. The deep parotid glands receive vessels also from the middle ear (p. 855). The lymph vessels of the medial set drain the skin over the medial part of the upper eyelid, the whole thickness of the medial half of the lower lid, and the caruncula lacrimalis. Following the course of the anterior facial vein they end in the submandibular group of glands.

The *submandibular lymph glands* (submaxillary glands) (figs. 799, 801) are placed beneath the deep cervical fascia in the submandibular triangle. They are usually three in number, one at the anterior end of the submandibular salivary gland, and one in front of, and another behind the facial artery where it reaches the mandible. Additional glands of this group are often found imbedded in the submandibular salivary gland or on its deep surface. The submandibular lymph glands receive afferents from a wide area, including vessels from the submental, facial, and lingual groups of glands; their efferents pass to both the upper and lower deep cervical glands.

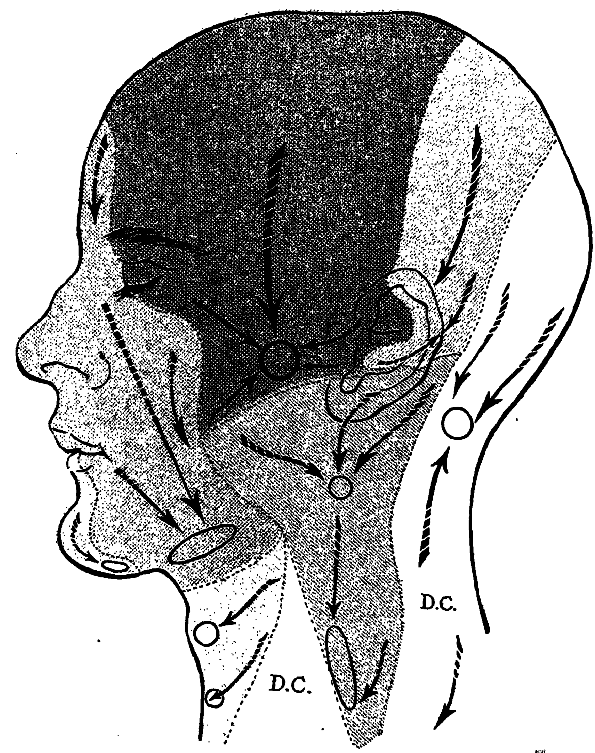
(ii) The external nose, cheek and upper lip, and the lateral part of the lower lip send their lymph to the submandibular glands. These vessels may have along their course a few *facial lymph glands* lying in relation to the anterior facial vein. The mucous membrane covering the oral surfaces of the lips and cheeks is drained by vessels which end also in the submandibular glands. The lymph from the lateral part of the cheek drains into the parotid group of lymph glands, whilst that from the skin over the root of the nose and the central part of the forehead just above this drains partly into the parotid glands, and partly, along the facial lymphatics, into the submandibular glands.

(iii) The central part of the lower lip, together with the floor of the mouth and the tip of the tongue, is drained by vessels which pass to the submental group of glands. The *submental lymph glands* are placed on the Mylohyoid muscle between the anterior bellies of the two Digastric muscles (fig. 801). They receive afferents from both sides of the median plane, some of the vessels

decussating over the symphysis of the mandible; their efferents pass to the submandibular and jugulo-omohyoid lymph glands.

3. **Lymphatic drainage of the neck.**—Many of the vessels draining the superficial tissues of the neck pass round the borders of the Sternomastoid to either the upper or the lower deep cervical glands. Some, however, pass from the region over the upper part of the Sternomastoid muscle and the posterior triangle of the neck to the superficial cervical and occipital lymph glands. The lymph from the upper part of the anterior triangle of the neck is drained into the submandibular and submental lymph glands, whilst the vessels from the skin of the anterior part of the neck below the hyoid bone pass to the *anterior*

Fig. 800.—The areas of lymphatic drainage of the superficial tissues of the head and neck.



cervical lymph glands, which are associated with the anterior jugular veins. The efferents from this group pass to the deep cervical glands of both sides of the neck; they also pass to the infrahyoid, prelaryngeal, and pretracheal glands (p. 855). One of the anterior cervical lymph glands often occupies the suprasternal space (p. 537).

B. Lymphatic Drainage of the Deeper Tissues of the Head and Neck.

The deeper tissues of the head and neck are drained by vessels which pass to the deep cervical glands either directly, or indirectly after passing through one of the outlying groups. In addition to the outlying groups which have been considered already, the following groups also are concerned with the drainage of the deeper tissues, viz.:

The retropharyngeal lymph glands.
The paratracheal lymph glands.
The lingual lymph glands.
The infrahyoid, prelaryngeal and pretracheal lymph glands.

The retropharyngeal lymph glands comprise a median and two lateral groups, the former near the median plane, and the latter in front of the lateral mass of the atlas along the lateral border of the Longus capitis muscle. The glands all lie in the interval between the fascia covering the pharynx and the prevertebral fascia. Their efferents pass to the upper deep cervical lymph glands.

The paratracheal lymph glands on each side are situated lateral to the trachea and œsophagus, along the course of the recurrent laryngeal nerve. Efferents from this group pass to the deep cervical lymph glands.

The infrahyoid, prelaryngeal and pretracheal lymph glands lie deep to the investing layer of the deep cervical fascia. They receive some of their afferents from the anterior cerv cal glands (p. 854) and their efferents join the deep cervical groups. The glands of the infrahyoid group are placed on the front of the thyrohyoid membrane; those of the prelaryngeal group lie on the cricovocal membrane; the pretracheal glands lie in front of the trachea in close relation with the inferior thyroid veins.

The lingual lymph glands are small and inconstant. They are found on the Hyoglossus muscle and between the two Genioglossi.

1. **The lymphatic drainage of the nasal cavity, nasopharynx and middle ear.**—The lymphatics of the nasal cavity can be injected from the subarachnoid space, through communications which exist along the course of the olfactory nerves. The lymph vessels from the anterior part of the nose pass superficially to join those draining the skin covering the nose and end in the submandibular lymph glands. The remainder of the nasal cavity, the paranasal sinuses, the nasopharynx, and the pharyngeal end of the pharyngotympanic tube are drained by vessels which pass to the upper deep cervical lymph glands, either directly or after traversing the retropharyngeal glands. It is probable that the posterior part of the floor of the nose is drained by vessels which enter the parotid group of lymph glands.

The lymph vessels of the mucous lining of the tympanum and mastoid antrum pass to the parotid or upper deep cervical lymph glands; those from the tympanic end of the pharyngotympanic tube probably end in the deep cervical glands.

2. **The lymphatic drainage of the larynx, trachea, and thyroid gland.**—The lymph vessels of the larynx comprise upper and lower groups; on the lateral wall the two systems are distinct one from another, the line of division being the vocal fold; the two systems anastomose on the posterior wall of the larynx. The vessels of the upper set pierce the thyrohyoid membrane, and, accompanying the superior laryngeal vessels, end in the upper deep cervical glands. The vessels of the lower set either pass between the cricoid cartilage and the first tracheal ring to go directly to the lower deep cervical glands, or, piercing the cricovocal membrane, pass to the pretracheal and prelaryngeal groups before reaching the deep cervical glands.

The cervical part of the trachea is drained by vessels which pass to the pretracheal and paratracheal lymph glands, or directly to the glands of the lower deep cervical group.

The lymph vessels of the thyroid gland accompany the veins. Vessels of the upper set pass to the deep cervical glands; those of the lower set to the pretracheal and paratracheal glands. Some of the vessels may run down into the superior mediastinum.

3. **The lymphatic drainage of the mouth, teeth, tonsil and tongue.**—(i) The *mouth.*—The vessels of the gums end in the submandibular lymph glands; those of the hard palate are continuous in front with those of the upper gum, but run backwards to pierce the superior constrictor muscle, and end in the upper deep cervical and retropharyngeal lymph glands; those of the soft palate pass backwards and laterally and end partly in the retropharyngeal, and partly in the upper deep cervical lymph glands. The vessels of the anterior part of the floor of the mouth go to the inferior lymph glands of the upper deep cervical group, either directly or indirectly through the submental lymph glands; the vessels from the rest of the floor of the mouth pass to the submandibular and upper deep cervical lymph glands.

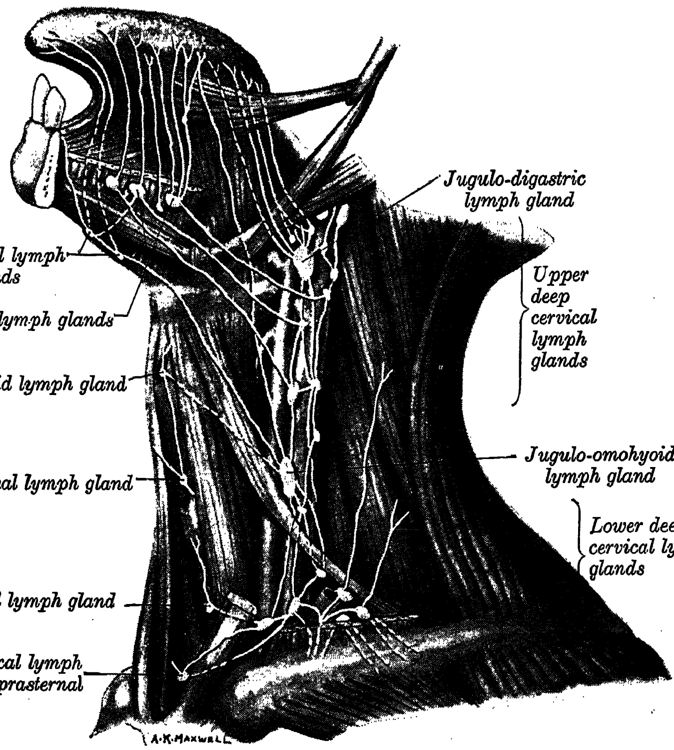
(ii) The *teeth.*—Lymph vessels were demonstrated in the pulp of the teeth

by Schweitzer * in 1907, and his observations have been confirmed by Dewey and Noyes.† They pass to the submandibular and deep cervical lymph glands.

(iii) The *tonsil*.—The lymph vessels of the tonsil, usually three to five in number, pierce the buccopharyngeal fascia and the superior constrictor muscle and pass between the stylohyoid and the internal jugular vein to reach the upper deep cervical lymph glands. Most of them end in the jugulodigastric lymph gland ; occasionally one or two additional vessels run to small lymph glands on the lateral side of the internal jugular vein, under cover of the sternomastoid.

(iv) The *tongue* (figs. 801, 802).‡—The lymphatic plexus in the mucous membrane of the tongue is continuous with the intramuscular plexus. The part of the tongue in front of the papillæ vallatæ is drained into marginal and

FIG. 801.—The lymphatic drainage of the tongue. (After Jamieson and Dobson.)



Note.—The removal of the Sternomastoid muscle has exposed the whole chain of deep cervical lymph glands.

central lymph vessels. The part of the tongue behind the papillæ vallatæ drains into a set of dorsal lymph vessels.

1. *Marginal vessels*.—The lymph vessels from the tip of the tongue, and region of the frenulum, descend under the mucous membrane and end in widely distributed lymph glands.

(*a*) Vessels pierce the origin of the mylohyoid in contact with the periosteum of the mandible ; one or two of these vessels enter the submental lymph glands, and one descends over the hyoid bone to the jugulo-omohyoid lymph gland. (It should be noted (1) that vessels arising in the plexus on one side of the tongue may cross under the frenulum and end in the lymph glands of the opposite side, and (2) that the efferent vessels of the submental lymph glands, which are placed in or near the median plane, pass impartially to either side.)

* *Archiv für Mikrosk. Anat. u. Entwickl.*, 1907 and 1909.

† *Dental Cosmos*, vol. lix. No. 4.

‡ This description of the lymphatic vessels of the tongue is based on the researches of Jamieson and Dobson (*loc. cit.* p. 851).

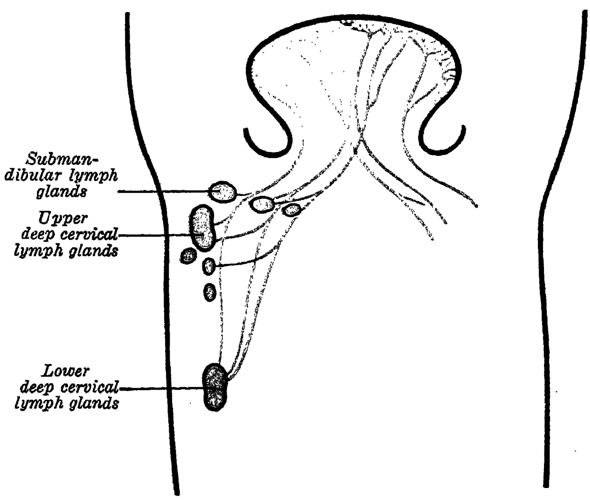
(*b*) Some vessels pierce the origin of the mylohyoid, and enter the anterior or the middle submandibular lymph gland.

(*c*) Some vessels pass deeply under the sublingual salivary gland and, accompanying the ranine vein, end in the jugulo-digastric lymph glands. One vessel often descends over or deep to the central tendon of the Digastric to reach the jugulo-omohyoid lymph gland.

Some of the lymph vessels from the lateral margin of the tongue pass over the sublingual salivary gland, pierce the Mylohyoid, and end in the submandibular lymph glands ; others pass under the salivary gland and end in the jugulo-digastric or jugulo-omohyoid glands.

The vessels from the posterior part of the margin of the tongue make their way through the pharyngeal wall to the jugulo-digastric lymph glands.

FIG. 802.—A diagram to show the course of the central lymph vessels of the tongue to the lymph glands on both sides of the neck. (Jamieson and Dobson.) *British Journal of Surgery*, vol. viii. 1920.



2. *Central vessels.*—There is no clear line of demarcation between areas on the surface of the tongue draining into the marginal or into the central vessels. The central lymph vessels descend in the median plane between the Genioglossi. Some turn laterally through the muscles, but the majority appear between their free borders and diverge to the right or left, i.e. the vessels from one side of the tongue may run to the lymph glands of the opposite side (fig. 802). They follow the lingual blood-vessels, and end in the deep cervical lymph glands, especially in the jugulo-digastric and jugulo-omohyoid glands. Some pierce the Mylohyoid and enter the submandibular lymph glands.

3. *Dorsal vessels.*—The vessels draining the area of the papillæ vallatæ, and the part of the tongue behind these papillæ, run downwards and backwards—those near the median plane may divide and run to both sides. They turn laterally to join the marginal vessels, and all pierce the pharyngeal wall, passing in front of or behind the external carotid artery, to reach the jugulo-digastric and jugulo-omohyoid lymph glands, or the glands between them. One vessel may descend behind the hyoid bone, perforate the thyrohyoid membrane, and end in the jugulo-omohyoid lymph gland.

4. **The lymphatic drainage of the pharynx and œsophagus.**—The collecting vessels from the pharynx and œsophagus pass to the deep cervical lymph glands either directly, or indirectly through the retropharyngeal or paratracheal glands. From the region of the epiglottis the lymph vessels run to the infrahyoid lymph glands.

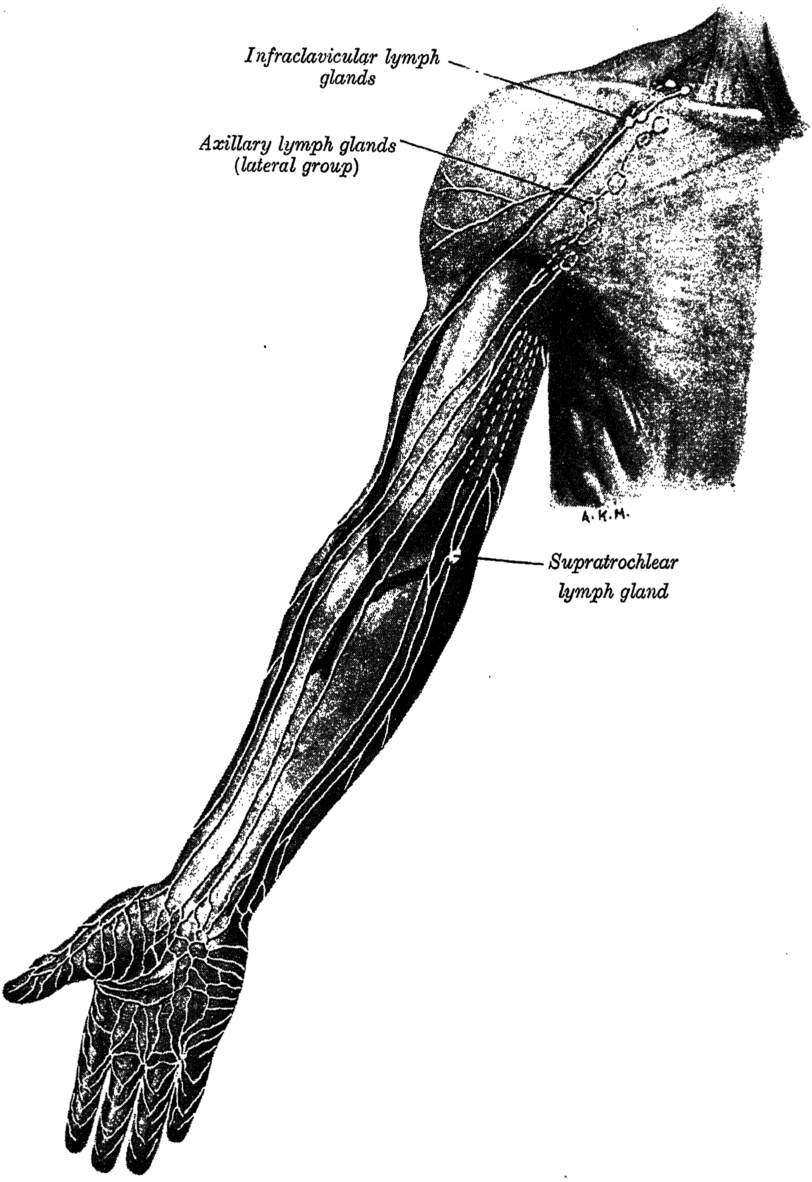
THE LYMPHATIC DRAINAGE OF THE UPPER LIMB

All the lymph vessels of the upper limb drain into a terminal group of lymph glands situated in the axilla, either directly from the tissues, or indirectly after passing through an outlying group of glands. The lymph vessels comprise deep and superficial sets. The deep vessels follow the principal vascular and neurovascular bundles, while the superficial vessels, except in the hand and on the back of the forearm, accompany the superficial veins more or less closely.

The axillary lymph glands (fig. 804), which are the terminal group for the whole of the upper limb, are of large size ; they vary from twenty to thirty in number, and may be divided into five groups, which are not sharply demarcated from one another :

1. A *lateral group* (fig. 803) of from four to six lymph glands lies medial to, and behind, the axillary vein ; the afferents of this group drain the whole

FIG. 803.—The lymphatic drainage of the superficial tissues of the upper limb. Anterior aspect. Semi-diagrammatic.



limb with the exception of that portion whose lymph vessels accompany the cephalic vein. The efferent vessels pass partly to the central and apical groups of axillary lymph glands, and partly to the lower deep cervical lymph glands.

2. An *anterior* or *pectoral group* of four or five lymph glands lies along the lower border of the Pectoralis minor, in relation with the lateral thoracic vessels.

Its afferents drain the skin and muscles of the anterior and lateral walls of the body, above the level of the umbilicus, and the central and lateral parts of the mammary gland (p. 861); its efferents pass partly to the central, and partly to the apical groups of axillary lymph glands.

3. A *posterior* or *subscapular group* of six or seven lymph glands is placed along the lower margin of the posterior wall of the axilla in the course of the subscapular vessels. The afferents of this group drain the skin and muscles of the lower part of the back of the neck and of the dorsal aspect of the trunk, as low down as the iliac crest; their efferents pass to the apical and to the central group of axillary lymph glands.

4. A *central group* of three or four large lymph glands is imbedded in the fat near the base of the axilla. It has no special area of drainage, but it receives afferents from all the preceding groups of axillary lymph glands: its efferents pass to the apical group.

5. An *apical group* of six to twelve lymph glands is situated partly posterior to the upper portion of the Pectoralis minor and partly above the upper border of this muscle, and extends upwards into the apex of the axilla along the medial side of the axillary vein. The only direct territorial afferents of this group are those which accompany the cephalic vein and one or two which drain the upper and peripheral part of the mammary gland, but it receives the efferents of all the other axillary lymph glands. The efferent vessels of this group unite to form the *subclavian trunk*, which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk; on the left side it may end in the thoracic duct. A few efferents from the apical group usually pass to the lower deep cervical lymph glands.

The outlying groups of lymph glands in the upper limb are few in number. They comprise (1) the supratrochlear group, (2) the infraclavicular group (which are both interposed on the path of the superficial vessels), and (3) a few isolated lymph glands which are occasionally present along the course of the principal blood-vessels of the arm and forearm.

1. The *supratrochlear lymph glands*, one or two in number, lie on the deep fascia above the medial epicondyle of the humerus on the medial side of the basilic vein. Their efferents accompany the basilic vein and join the deep lymph vessels.

2. The *infraclavicular lymph glands*, one or two in number, are found beside the cephalic vein, between the Pectoralis major and the Deltoid, immediately below the clavicle. Their efferents pass through the clavipectoral fascia to reach the apical group of the axillary glands, or, more rarely, they may pass across the clavicle to reach the lower deep cervical group.

3. Isolated lymph glands, small in size, are sometimes found in the forearm along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, and in the arm along the medial side of the brachial vessels.

The lymphatic drainage of the superficial tissues of the upper limb.—The superficial lymph vessels begin in the lymphatic plexuses in the skin.

In the hand, the meshes of the plexus are much finer on the palmar than on the dorsal surface. The digital plexuses are drained by vessels which run along the borders of the digits to reach the web, where they receive vessels from the distal part of the palm and then pass backwards to reach the dorsal surface of the hand (figs. 803, 805). The rest of the palm is drained by vessels which pass proximally towards the wrist, medially to join vessels along the ulnar border of the hand, and laterally to join those on the thumb. Several collecting vessels from the central part of the palmar plexus unite to form a trunk which winds round the metacarpal bone of the index finger to join the dorsal vessels from the same finger and from the thumb.

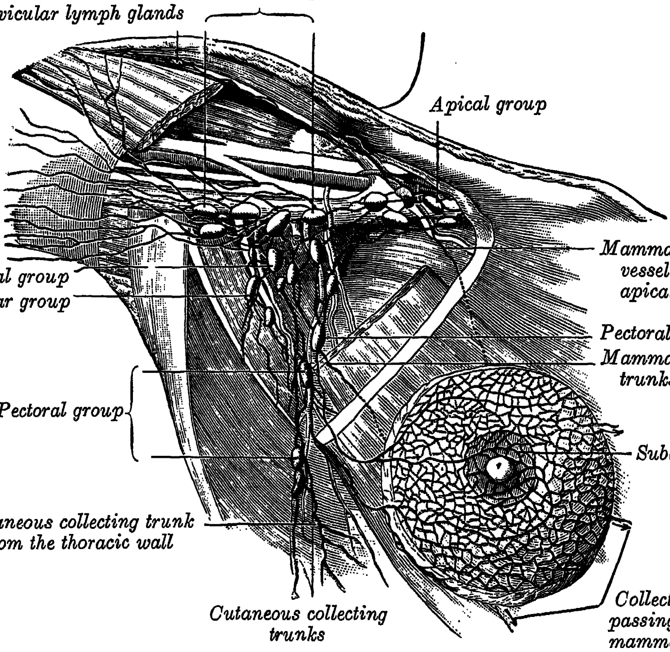
In the forearm and arm, the superficial lymph vessels run, for the most part, in company with the superficial veins. Collecting vessels from the hand pass into the forearm on all aspects of the wrist.

The vessels on the dorsum, after running vertically upwards parallel with one another, finally pass successively round the borders of the limb to join vessels on the front (fig. 805). The vessels on the front of the wrist pass up the forearm parallel with the median antebrachial vein to the cubital region.

Beyond this point they follow the medial border of the biceps muscle and, piercing the deep fascia at the anterior axillary fold, they end in the lateral group of axillary lymph glands.

The vessels on the lateral side of the wrist become associated in the forearm with the cephalic vein. They follow it to the level of the insertion of the Deltoid, where most of them incline medially to enter the lateral group of axillary lymph glands; a few continue with the cephalic vein and end in the infraclavicular glands. These lateral lymph vessels receive the vessels which wind round the lateral border of the limb from the posterior surface.

FIG. 804.—The lymph vessels of the mammary gland, and the axillary lymph glands. Semi-diagrammatic. (Poirier and Charpy.)



The vessels on the medial side of the wrist follow the basilic vein in the forearm. Just above the elbow some of them end in the supratrochlear lymph glands. The efferents from these, together with the medial vessels which have not ended in the supratrochlear glands, pierce the deep fascia with the basilic vein, and end in the lateral group of axillary glands or join the deep vessels. The vessels which wind round the medial border of the limb from the back join those of this medial set.

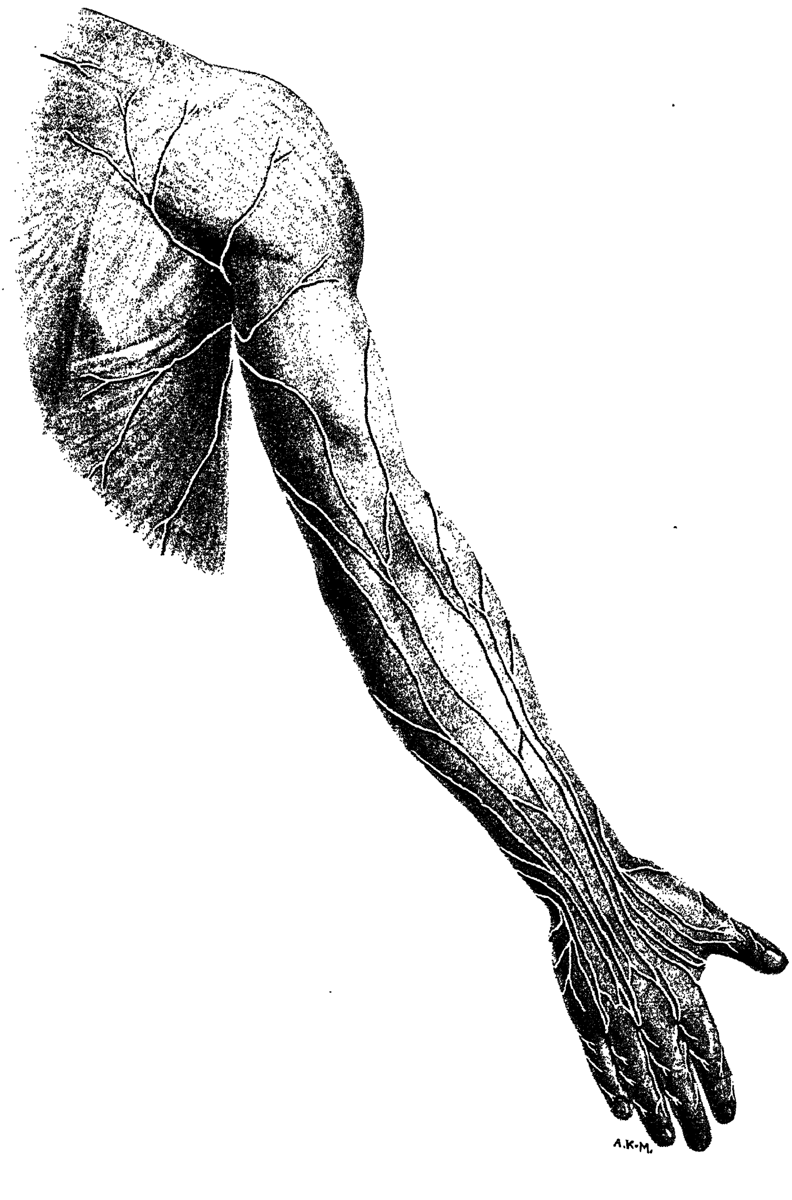
The collecting vessels from the front and back of the deltoid region pass respectively round the anterior and posterior axillary folds to end in the axillary lymph glands. The skin over the scapular region is drained by vessels which either end in the subscapular group of axillary glands, or follow the transverse cervical vessels and end in the lower deep cervical lymph glands.

The **lymphatic drainage of the deep tissues of the upper limb.**—The deep lymph vessels follow the main bundles of vessels and nerves (radial, ulnar, interosseous and brachial) and end in the lateral axillary lymph glands. They are less numerous than the superficial vessels, with which they communicate at intervals. Along their course there are a few deep lymph glands.

The muscles of the scapular region are drained by vessels which pass mainly to the subscapular group of axillary lymph glands. The lymph from the pectoral muscles is drained into the pectoral, central and apical groups.

The **lymphatic drainage of the breast.**—The *lymph vessels of the mammary gland* originate in a plexus in the interlobular spaces and in the walls of the lactiferous ducts. Those from the central part of the gland enter an intricate plexus which is situated beneath the areola. This plexus also receives the lymph vessels from the skin over the central part of the gland, and from the areola and nipple.

FIG. 805.—The lymphatic drainage of the superficial tissues of the upper limb. Posterior aspect. Semi-diagrammatic.



The efferent lymph vessels from the greater part of the mammary gland anastomose with the lymphatic plexus in the fascia on the Pectoralis major muscle, and subsequently end in the pectoral group of axillary glands; one vessel from the upper part of the gland pierces the Pectoralis major, and ends in the apical group of axillary glands. Through this fascial plexus also the lymph vessels from the medial part of the gland communicate with

(*a*) the internal mammary lymph glands (p. 876), and (*b*) with the lymph vessels of the opposite breast. The lymph vessels from the lower and medial parts of the mammary gland anastomose with a lymphatic plexus on the sheath of the upper part of the rectus abdominis, and on the front of the linea alba between the xiphoid process of the sternum and the seventh costal cartilage; although no direct communications between this plexus and the lymph vessels in the subperitoneal areolar tissue have been demonstrated by injection, the clinical and pathological investigations of W. Sampson Handley* leave no doubt that such exist.

Applied Anatomy.—Enlargement of the axillary lymph glands is very often found in malignant disease and also in infective processes implicating the upper part of the back and shoulder, the front of the chest and mammary gland, the upper part of the front and side of the abdomen, or the hand, forearm, and arm.

In operations for cancer of the breast the fascia covering the Pectoralis major and the adjoining muscles is removed over a wide area on account of the connexions and ramifications of the lymphatic plexus which it contains. In addition the axillary lymph glands, the sternocostal head of Pectoralis major and, frequently, the Pectoralis minor are taken away, in the endeavour to ensure, as far as possible, the complete removal of infected lymph vessels.

THE LYMPHATIC DRAINAGE OF THE LOWER LIMB

All the lymph from the lower limb, with the exception of that from the gluteal and ischial regions, traverses a terminal group of lymph glands in the groin. Before reaching these terminal glands the lymph may have passed through outlying, intermediary glands, which, however, are less numerous in the lower limb than they are in other parts of the body.

The terminal lymph glands are named the inguinal lymph glands, and they are in two sets: superficial and deep.

The **superficial inguinal lymph glands** (fig. 806) are themselves arranged in two groups, upper and lower. The *upper group*, usually 5 or 6 in number, forms a chain immediately below the inguinal ligament. The lateral members of the group receive afferent vessels from the gluteal region and from the adjoining part of the anterior abdominal wall below the umbilicus. The medial members of the group receive the superficial lymph vessels from the external genitalia (including in the female the vagina below the hymen), from the lower part of the anal canal and the circumanal region, from the adjoining part of the anterior abdominal wall below the umbilicus and uterine lymph vessels which run along the round ligament of the uterus.

The *lower group*, usually four or five in number, is disposed vertically along the terminal part of the long saphenous vein. They receive all the superficial lymph vessels of the lower limb, with the exception of those from the back and lateral side of the calf of the leg.

All the superficial inguinal lymph glands send their *efferents* to the external iliac lymph glands, some traversing the femoral canal, others passing in front of or lateral to the femoral vessels. In addition numerous vessels connect the individual glands one with another.

The **deep inguinal lymph glands** vary from one to three in number, and are placed deep to the fascia lata, on the medial side of the femoral vein. When three are present, the lowest is situated just below the junction of the long saphenous and femoral veins, the middle in the femoral canal, and the highest in the lateral part of the femoral ring. The middle one is the most inconstant, but the highest is frequently absent. They receive as afferents the deep lymph vessels which accompany the femoral vessels, the lymph vessels from the glans penis (or glans clitoridis), and, possibly, a few of the efferents from the superficial inguinal lymph glands; their efferents pass through the femoral canal to the external iliac lymph glands.

* *Cancer of the Breast and its Treatment*, 2nd edition, 1922, and "The Breast," *Choyce's System of Surgery*, 2nd edition, vol. ii.

FIG. 806.—The lymphatic drainage of the superficial tissues of the lower limb. Antero-medial aspect. Semi-diagrammatic.

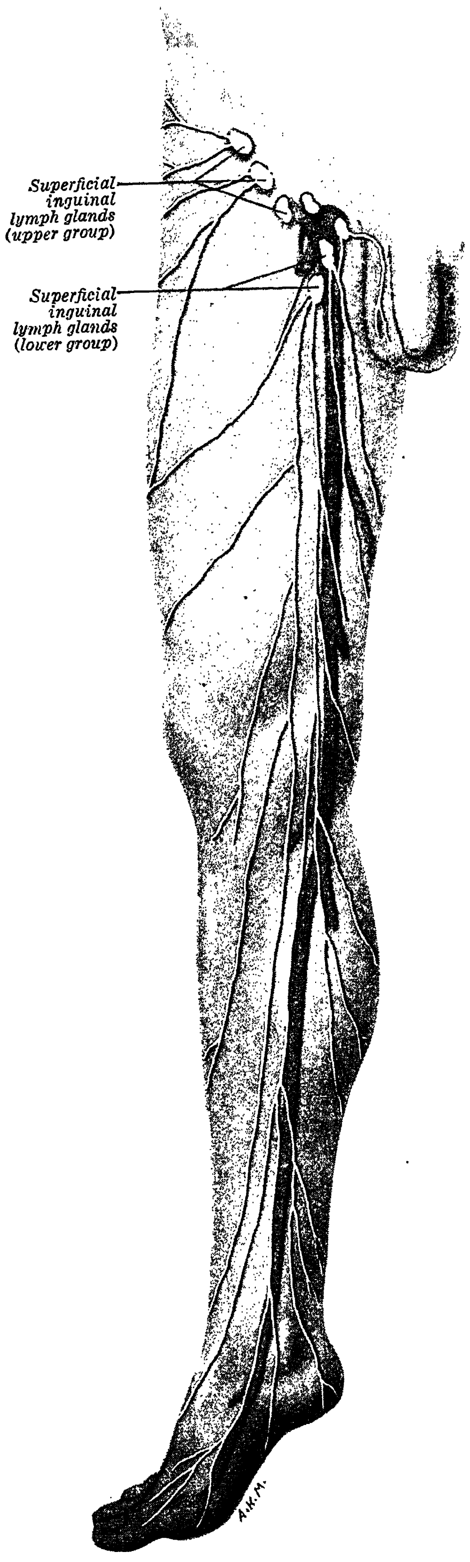


FIG. 807.—The lymphatic drainage of the superficial tissues of the lower limb. Posterior aspect. Semi-diagrammatic.

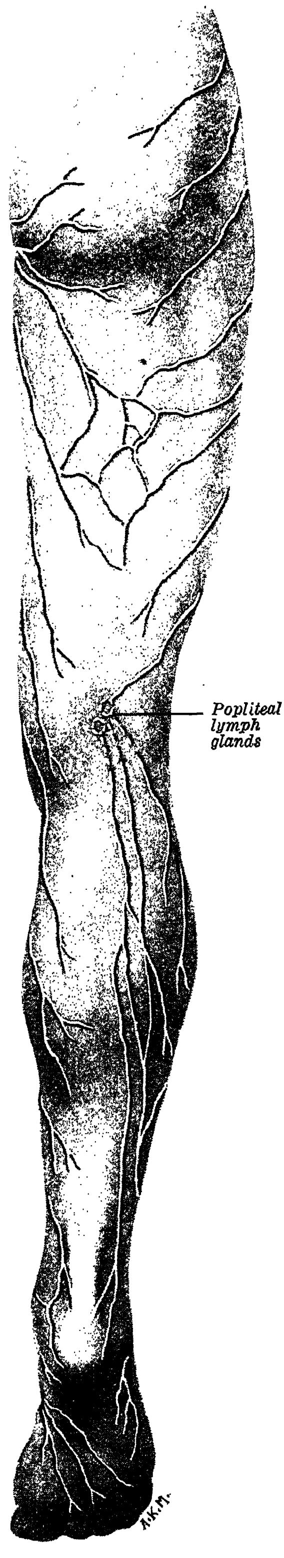


The outlying, intermediary lymph glands are few in number and are all deeply placed. Except for a gland which is sometimes present on the upper part of the interosseous membrane of the leg in relation with the anterior tibial vessels, they are restricted to a single group found in the popliteal fossa.

The **popliteal lymph glands** (fig. 807), small in size and six or seven in number, are imbedded in the fat contained in the popliteal fossa. One lies near the termination of the short saphenous vein, and drains the region from which this vein derives its tributaries. Another is placed between the popliteal artery and the posterior surface of the knee-joint; it receives the lymph vessels from the knee-joint together with those which accompany the genicular arteries. The remainder lie at the sides of the popliteal vessels, and receive as afferents the trunks which accompany the anterior and posterior tibial vessels. The efferents of the popliteal lymph glands pass almost entirely alongside of the femoral vessels to the deep inguinal lymph glands, but a few may accompany the long saphenous vein and end in the superficial inguinal lymph glands.

Applied Anatomy.—Inflammation and suppuration of the popliteal lymph glands are most commonly due to a sore on the lateral side of the heel.

The superficial inguinal lymph glands frequently become enlarged in diseases implicating the parts from which their lymph vessels originate. Thus in malignant or syphilitic affections of the prepuce and penis, or labia majora, in cancer of the scrotum, in abscess in the perineum, anus and lower part of the vagina, or in similar diseases affecting the skin and superficial structures in those parts, or the infra-umbilical part of the abdominal wall, or the gluteal region, the upper group of lymph glands is almost invariably enlarged, the lower group being implicated in diseases affecting the lower limb.

The lymphatic drainage of the superficial tissues of the lower limb.—The superficial lymph vessels begin in the lymphatic plexuses beneath the skin. Collecting vessels leave the foot in two sets—a medial set, whose vessels follow the general course of the long saphenous vein, and a lateral set, associated with the short saphenous vein.

The vessels of the *medial group* are larger and more numerous than those of the lateral group and begin on the tibial side of the dorsum of the foot. They ascend, some in front of the medial malleolus and others behind it, and accompany the long saphenous vein to the groin, where they end in the lower group of the superficial inguinal lymph glands. The vessels of the *lateral group* begin on the fibular side of the dorsum of the foot. Some of them cross the front of the leg to join the vessels of the medial group and so reach the lower group of the superficial inguinal lymph glands; others accompany the short saphenous vein and end in the popliteal lymph glands.

The superficial lymph vessels of the buttock pass round to the front of the limb and terminate in the upper group of the superficial inguinal lymph glands.

The lymphatic drainage of the deeper tissues of the lower limb.—The deep lymph vessels accompany the main blood-vessels of the limb and so comprise anterior tibial, posterior tibial, peroneal, popliteal and femoral sets. The deep lymph vessels of the foot and leg are interrupted by the popliteal lymph glands, but those from the thigh pass direct to the deep inguinal lymph glands.

The deep lymph vessels of the gluteal and ischial regions follow the course of the corresponding blood-vessels. Those accompanying the superior gluteal vessels end in a lymph gland which lies on the intrapelvic portion of the superior gluteal artery, near the upper border of the greater sciatic foramen. Those following the inferior gluteal vessels traverse one or two small lymph glands which lie below the piriformis muscle, and end in the internal iliac lymph glands.

THE LYMPHATIC DRAINAGE OF THE ABDOMEN AND PELVIS

The lymph from most of the abdominal wall and from all the abdominal viscera except a small part of the liver is returned to the blood-stream *viâ* the thoracic duct. The lymph vessels run with the corresponding arteries. The lymph glands comprise a large number of outlying, intermediary groups which

are placed along the arteries concerned, and a smaller number of terminal groups which are all in close relation with the abdominal aorta.

The **aortic lymph glands** comprise three principal groups of terminal lymph glands and one subsidiary group, each of which, though not sharply separated from the others topographically, nevertheless has its own particular area of drainage for the most part. These four groups are named according to their relation to the abdominal aorta, viz., pre-aortic, lateral aortic (right and left), and retro-aortic. The pre-aortic group drains the viscera supplied by the ventral branches of the aorta, i.e. the abdominal part of the alimentary canal and its derivatives. The lateral aortic groups drain the viscera and other structures supplied by the lateral and dorsal branches of the aorta and receive the efferents from the large, outlying groups associated with the iliac arteries. They therefore constitute the terminal groups for the suprarenal glands, kidneys, ureters, testes, ovaries, pelvic viscera (apart from the gut) and the posterior abdominal wall. The retro-aortic group has no particular area of drainage. Although it may have been primarily associated with the drainage of the posterior abdominal wall, it may be regarded as being formed by outlying members of both lateral aortic groups.

A. The Pre-aortic Lymph Glands and their Area of Drainage.

The **pre-aortic lymph glands** lie in close relationship with the anterior surface of the abdominal aorta. They receive lymph from the outlying, intermediary lymph glands associated with the subdiaphragmatic part of the alimentary canal, the pancreas, liver and spleen. Their efferents unite to form the *intestinal trunk*, which enters the cisterna chyli. They are divisible into cœliac, superior mesenteric and inferior mesenteric groups, which are in intimate relationship with the origins of the arteries of the same names.

In the alimentary canal the lymph vessels begin as minute subepithelial radicles, blind at one end but opening at the other into a fine *periglandular plexus*. In the small intestine a central lacteal occupies each villus. From the periglandular plexus vessels pierce the muscularis mucosæ and join the *submucous plexus*, efferents from which pass through the muscular coat, where they anastomose more or less freely, before entering the *subserous plexus*. The main collecting vessels arise from the subserous plexus and follow the course of the corresponding artery. Nodules of lymphoid tissue, either solitary or aggregated, are interposed along the course of the deeper vessels and function like lymph glands.

The collecting vessels from the alimentary canal pass through outlying groups of lymph glands before reaching the pre-aortic group.

1. **The cœliac lymph glands and their areas of drainage.**—The **cœliac lymph glands** lie on the front of the abdominal aorta close to the origin of the cœliac artery. They are the terminal group for the stomach, duodenum, liver, gall bladder, pancreas and spleen, and their afferents are derived from the outlying lymph glands which are placed along the branches of the cœliac artery. Of these there are, therefore, three main sets, viz.—gastric, hepatic and pancreaticosplenic.

(i) The **gastric lymph glands** (figs. 808, 809) consist of three sets, left gastric, right gastro-epiploic and pyloric.

The **left gastric lymph glands** (superior gastric lymph glands) accompany the left gastric artery and are divisible into three groups, viz. : (*a*) *upper*, on the stem of the artery ; (*b*) *lower*, accompanying the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the lesser omentum ; and (*c*) *paracardial*, disposed in a manner comparable to a chain of beads around the cardiac orifice of the stomach (Jamieson and Dobson).* They receive their afferents from the stomach, and also some vessels from the pylorus ; their efferents pass to the cœliac group of pre-aortic lymph glands.

The **right gastro-epiploic lymph glands** (inferior gastric lymph glands), four to seven in number, lie between the two layers of the greater omentum along the

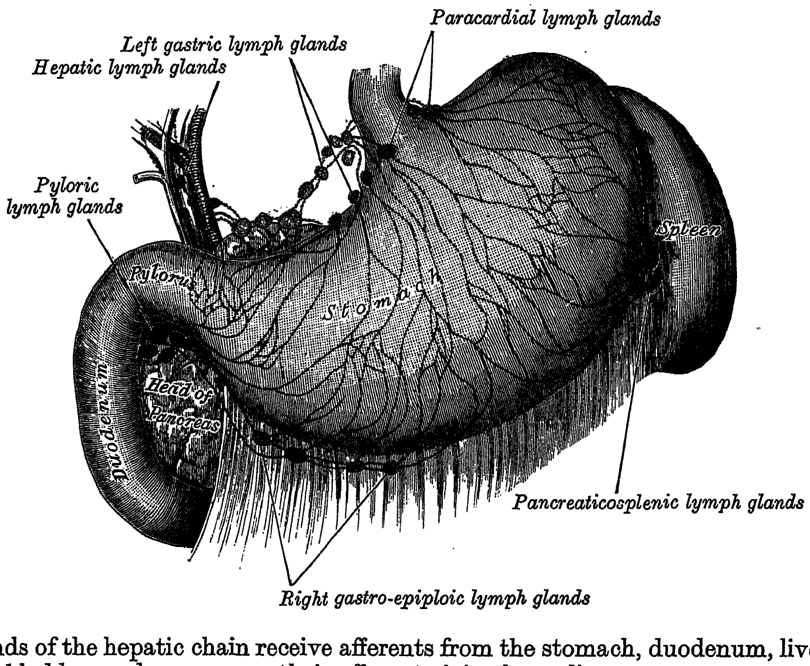
* J. K. Jamieson and J. F. Dobson, *Lancet*, April 20th and 27th, 1907.

pyloric half of the greater curvature of the stomach in relation with the vessels of the same name. They receive afferents from the stomach ; their efferents mostly pass to the pyloric lymph glands.

The **pyloric lymph glands** (subpyloric lymph glands of Jamieson and Dobson), four or five in number, lie in close relation to the bifurcation of the gastroduodenal artery, in the angle between the first and second parts of the duodenum ; an outlying member of this group is sometimes found above the duodenum on the right gastric artery. They receive afferents from the pyloric part of the stomach, the first part of the duodenum, and the right gastro-epiploic glands ; their efferents end in the cœliac group.

(ii) The **hepatic lymph glands** (fig. 808) are related to the stem of the hepatic artery, and extend upwards along the bile-duct, between the two layers of the lesser omentum, as far as the porta hepatis ; one member of this group, termed the *cystic lymph gland*, is placed near the neck of the gall-bladder. The lymph

FIG. 808.—The lymphatic drainage of the stomach, etc. (Jamieson and Dobson.)



glands of the hepatic chain receive afferents from the stomach, duodenum, liver, gall-bladder, and pancreas ; their efferents join the cœliac group.

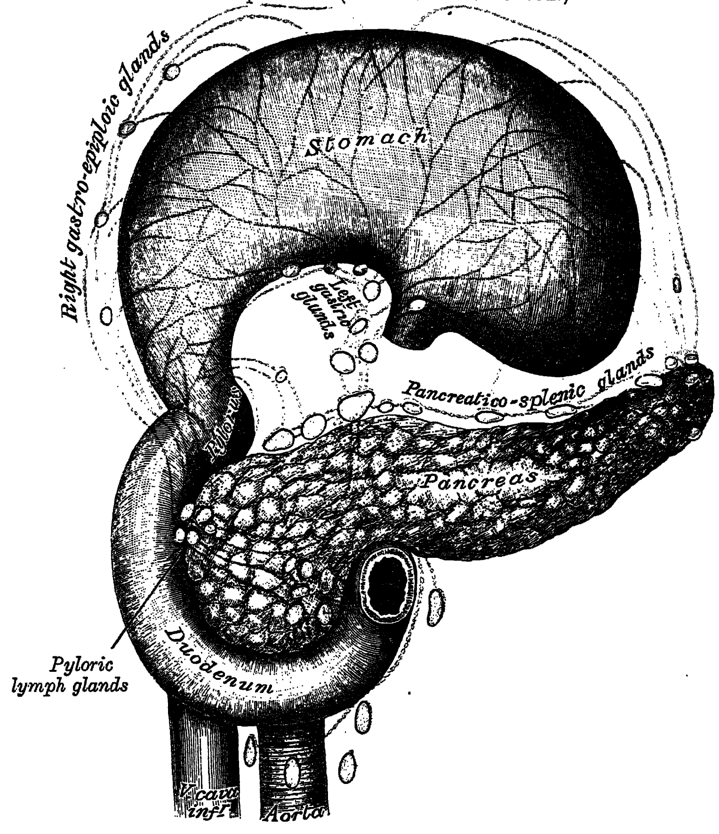
(iii) The **pancreaticosplenic lymph glands** (fig. 809) accompany the splenic (lienal) artery, and are situated in relation to the posterior surface and upper border of the pancreas ; one or two members of this group are found in the gastrosplenic ligament (Jamieson and Dobson, *loc. cit.*). Their afferents are derived from the stomach, spleen, and pancreas ; their efferents join the cœliac group.

(*a*) The *lymphatic drainage of the stomach and duodenum.*—The *lymph vessels of the stomach* (figs. 808, 809) are continuous at the cardiac orifice with those of the œsophagus, and at the pylorus with those of the duodenum. They follow the blood-vessels for the most part, and may be arranged in four sets. The first set accompanies the branches of the left gastric artery, receives tributaries from a large area on both surfaces of the stomach, and terminates in the left gastric lymph glands. Those of the second set drain the fundus and body of the stomach on the left of a line drawn vertically from the œsophagus ; they accompany, more or less closely, the short gastric and left gastro-epiploic vessels and end in the pancreaticosplenic lymph glands. The third set drains the right part of the greater curvature as far as the pyloric portion, and ends in the right gastro-epiploic lymph glands, the efferents of which pass to the pyloric group. Those of the fourth set drain the pyloric portion and pass to the hepatic, pyloric, and left gastric lymph glands. Although the vessels of

these sets communicate with one another, their valves are arranged so that the lymph flow is directed from the left part of the stomach towards the lesser curvature and from the right part towards the greater curvature.*

The *lymph vessels of the duodenum* comprise an anterior and a posterior set, which open into a series of small *pancreaticoduodenal lymph glands,* on the anterior and posterior parts of the groove between the head of the pancreas and the duodenum. The efferents of these glands run in two directions, upwards to the hepatic lymph glands, and downwards to the pre-aortic lymph glands around the origin of the superior mesenteric artery.

FIG. 809.—The lymph vessels and glands of the stomach, etc. The stomach has been turned upwards. (Jamieson and Dobson.)



(*b*) The *lymphatic drainage of the liver and gall-bladder.*—The collecting vessels from the liver are divisible into two main groups—superficial and deep.

The *superficial lymph vessels of the liver* run in the subserous areolar tissue over the whole surface of the organ. They drain in four directions. (1) From the middle part of the posterior surface, from the caudate lobe, from the posterior part of the convex surfaces of both lobes near the attachment of the falciform ligament, and from the posterior part of the inferior surface of the right lobe the vessels accompany the inferior vena cava and end in glands round the terminal part of that vessel. (2) The vessels from the remainder of the inferior surface, and from the anterior part of the convex surface of both lobes near the attachment of the falciform ligament converge on the porta hepatis and end in the hepatic group of glands. (3) From the posterior part of the left lobe a few vessels pass towards the œsophageal opening in the diaphragm and end in the paracardial glands. (4) From the remainder of the convex surface of the right lobe one or two trunks accompany the phrenic artery across the right crus of the Diaphragm and end in the cœliac glands.

* J. H. Gray, *Journal of Anatomy,* vol. lxxi. 1937.

The *deep lymph vessels* of the liver join one another to form ascending and descending trunks. The ascending trunks accompany the hepatic veins and, passing through the vena caval opening, end in the glands round the termination of the inferior vena cava. The descending trunks emerge from the porta hepatis and end in the hepatic lymph glands.

The collecting vessels from the gall-bladder pass to the cystic gland and the hepatic glands ; those from the bile-ducts end in the hepatic glands alongside the bile-duct and in the upper pancreaticosplenic glands.

(*c*) The *lymphatic drainage of the pancreas*.—The lymph vessels of the pancreas follow the course of its blood-vessels. Most of them end in the pancreaticosplenic glands, but some end in the glands along the pancreaticoduodenal vessels and others in the superior mesenteric group of the pre-aortic glands.

(*d*) The *lymphatic drainage of the spleen*.—The collecting vessels from the spleen comprise a superficial set and a deep set, both of which end in the pancreaticosplenic lymph glands.

2. The **superior and inferior mesenteric lymph glands and their area of drainage**.—The superior and inferior mesenteric lymph glands lie on the front of the abdominal aorta close to the points of origin of the arteries of the same names. They are the terminal groups for the alimentary canal from the duodenojejunal flexure to the upper part of the rectum, and receive afferents from the outlying groups which lie along the jejunal, ileal, colic and superior rectal arteries.

(*a*) The *lymphatic drainage of the jejunum and ileum*.—The lacteals pass between the layers of the mesentery, but, before reaching the superior mesenteric glands, the lymph passes through the **lymph glands of the mesentery**. These vary from one hundred to one hundred and fifty in number and comprise three sets, viz.—one lying close to the wall of the intestine amongst the terminal twigs of the jejunal and ileal arteries : a second, in relation to the loops and primary branches of the same vessels ; and a third, along the upper part of the trunk of the superior mesenteric artery. The lymph from the terminal few inches of the ileum follows the ileal branch of the ileocolic artery to end in the ileocolic lymph glands.

Applied Anatomy.—Enlargement of the mesenteric lymph glands is seen in most diseased conditions of the intestinal tract, and is well marked in enteric fever, tuberculous ulceration or malignant growths of the bowel. The enlarged lymph glands can often be palpated through the wall of the abdomen.

(*b*) The *lymphatic drainage of the colon*.—The lymph from the colon drains into both the superior and the inferior mesenteric lymph glands, in accordance with the arterial supply of this part of the gut. Outlying groups of lymph glands, which are placed along the course of the colic, ileocolic and superior rectal arteries, are interposed on the pathway of the colic lymph vessels.

The **lymph glands of the colon** are divided into four groups (Jamieson and Dobson, *loc. cit.*) : (*a*) epicolic, (*b*) paracolic, (*c*) intermediate colic and (*d*) terminal colic.

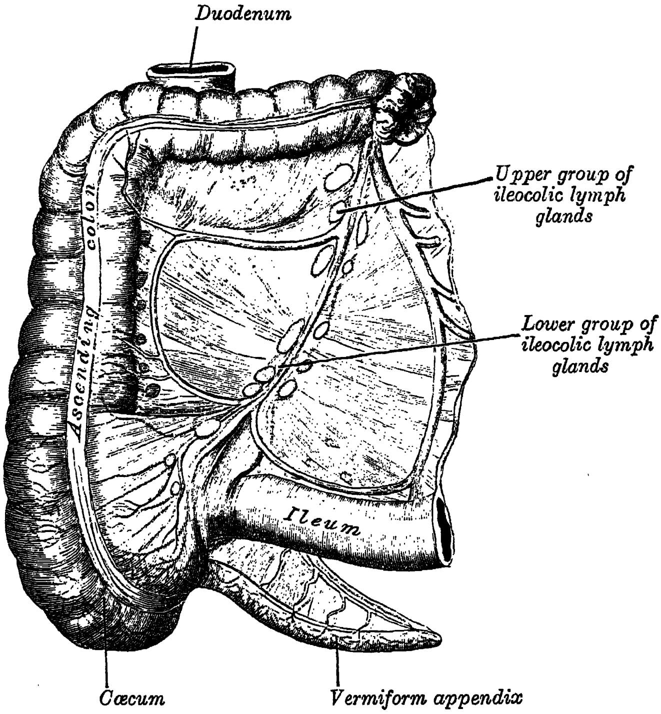
The *epicolic lymph glands* are merely minute nodules situated on the wall of the gut. The *paracolic lymph glands* lie along the medial borders of the ascending and descending colon, and along the mesenteric borders of the transverse and pelvic colon. The *intermediate colic lymph glands* lie along the right, middle and left colic arteries. The *terminal colic lymph glands* are placed on the main trunks of the superior and inferior mesenteric arteries, and are in direct continuity with the corresponding pre-aortic lymph glands.

The **pararectal lymph glands** lie in contact with the muscular coat of the rectum. Their efferents pass to an intermediate group around the superior rectal artery (superior hæmorrhoidal artery), and thence to the lymph glands at the origin of the inferior mesenteric artery. Others pass to the lymph glands at the bifurcation of the common iliac artery.

The **ileocolic lymph glands** (figs. 810, 811), from ten to twenty in number, form a chain around the ileocolic artery, but show a tendency to subdivision into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the vessel divides into its terminal branches the

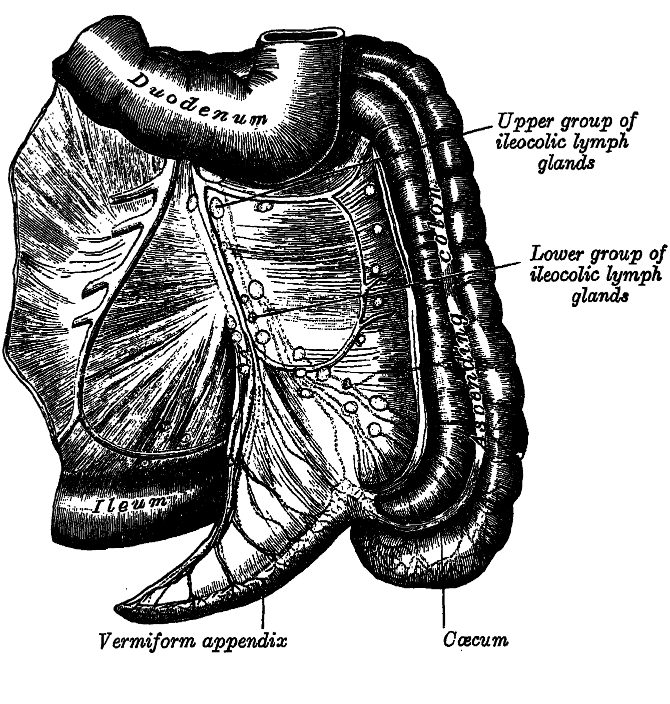
chain is broken up into several groups, viz.: (*a*) *ileal*, in relation to the ileal branch of the artery; (*b*) *anterior ileocolic*, usually three in number, in the

FIG. 810.—The lymph vessels and glands of the cæcum and vermiform appendix. Anterior aspect. (Jamieson and Dobson.)



ileocæcal fold, near the wall of the cæcum; (*c*) *posterior ileocolic*, mostly placed in the angle between the ileum and the colon, but partly lying behind the

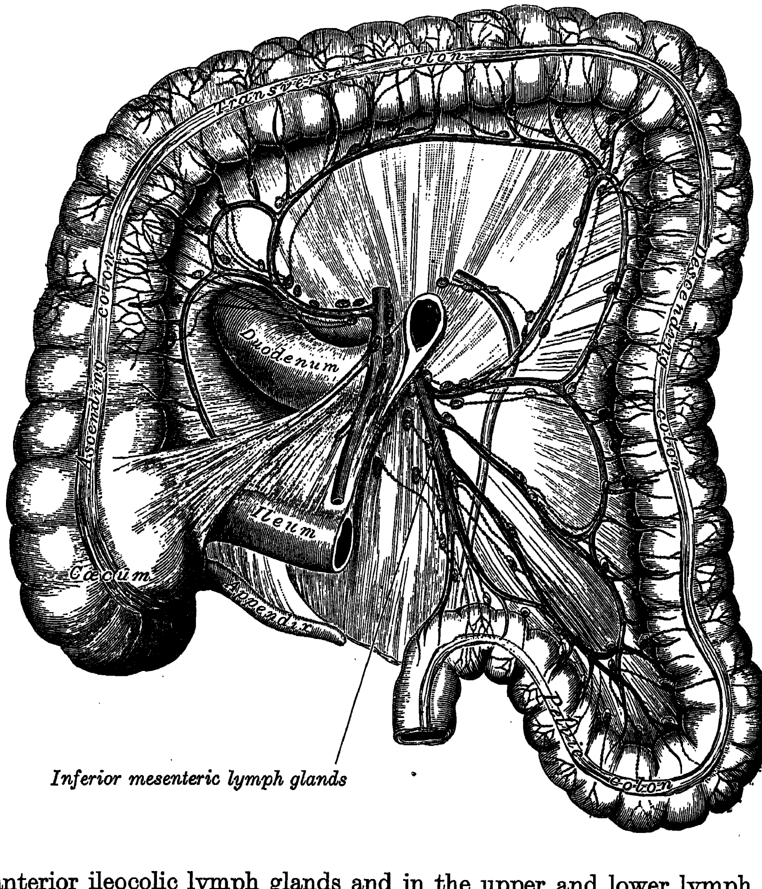
FIG. 811.—The lymph vessels and glands of the cæcum and vermiform appendix. Posterior aspect. (Jamieson and Dobson.)



cæcum at its junction with the ascending colon ; (*d*) a single gland in the mesentery of the vermiform appendix.

The *lymph vessels of the vermiform appendix and cæcum* (figs. 810, 811) are numerous, since there is a large amount of lymphoid tissue in the walls of these parts of the digestive tube. From the body and tip of the vermiform appendix eight to fifteen vessels ascend between the layers of its mesentery, one or two being interrupted in the lymph gland which lies in this peritoneal fold. They unite to form three or four vessels, which end partly in the lower and partly in the upper lymph glands of the ileocolic chain. The vessels from the root of the vermiform appendix and from the cæcum comprise an anterior and a posterior group. The anterior vessels pass in front of the cæcum, and end in

FIG. 812.—The lymph vessels and glands of the colon. (Jamieson and Dobson.)



the anterior ileocolic lymph glands and in the upper and lower lymph glands of the ileocolic chain ; the posterior vessels ascend over the back of the cæcum and terminate in the posterior ileocolic lymph glands and in the lower lymph glands of the ileocolic chain.

Lymph vessels of the colon (fig. 812).—The lymph vessels of the ascending and transverse parts of the colon end in the superior mesenteric lymph glands, after traversing the right colic and middle colic lymph glands. Those of the descending and pelvic parts of the colon are interrupted by the small lymph glands on the branches of the left colic arteries, and ultimately end in the preaortic lymph glands around the origin of the inferior mesenteric artery.

(*c*) The *lymphatic drainage of the rectum and anal canal*.—The lymph vessels of the *anal canal* accompany the inferior rectal (inferior hæmorrhoidal) vessels across the ischiorectal fossa, run with the internal pudendal vessels through the pudendal canal, and open into the internal iliac lymph glands. The lymph vessels from the *lower part of the rectum* join in a plexus on the levator ani, and then enter the internal iliac lymph glands ; those from the *upper part of the*

rectum accompany the superior rectal vessels, and, after traversing the pararectal lymph glands, enter the lymph glands near the bifurcation of the common iliac artery; vessels pass from the highest pararectal lymph glands to the lymph glands in the pelvic mesocolon, and the efferents of these glands end in the pre-aortic lymph glands around the origin of the inferior mesenteric artery.

The *lymph vessels of the anus* pass forwards and end with those of the skin of the perineum and scrotum in the superficial inguinal lymph glands.

B. The Lateral Aortic Lymph Glands and their Area of Drainage.

The lateral aortic lymph glands lie on each side of the abdominal aorta in front of the medial margin of the Psoas major, the crus of the Diaphragm and the sympathetic trunk. On the right side some members of the group lie to the lateral side of the inferior vena cava and in front of the vessel near the termination of the right renal vein. Afferents reach the lateral aortic glands from the structures supplied by the lateral and dorsal branches of the aorta and from the outlying lymph glands associated with the iliac arteries and their branches. Efferents from the lateral aortic lymph glands on each side form the *lumbar trunk*, and the right and left lumbar trunks terminate in the cisterna chyli. A few efferents may pass to the pre-aortic and retro-aortic groups.

The lymph vessels from the kidney and the abdominal portion of the ureter, from the posterior abdominal wall, from the testis in the male, and from the ovary, the uterine tube and the upper part of the uterus in the female all pass directly to the lateral aortic lymph glands without being interrupted by any intermediary group. The lymph vessels from the pelvis and most of the pelvic viscera and from the lateral and anterior parts of the abdominal wall pass first through outlying groups which are associated for the most part with the iliac arteries and some of their branches. They include the following groups:

Common iliac.	Inferior epigastric.
External iliac.	Circumflex iliac.
Internal iliac.	Sacral.

The *common iliac lymph glands*, four to six in number, are grouped behind and on the sides of the common iliac artery, one or two (subaortic) being placed below the bifurcation of the aorta in front of the fifth lumbar vertebra or the promontory of the sacrum. They receive afferents from the external and internal iliac lymph glands, and send their efferents to the lateral aortic group.

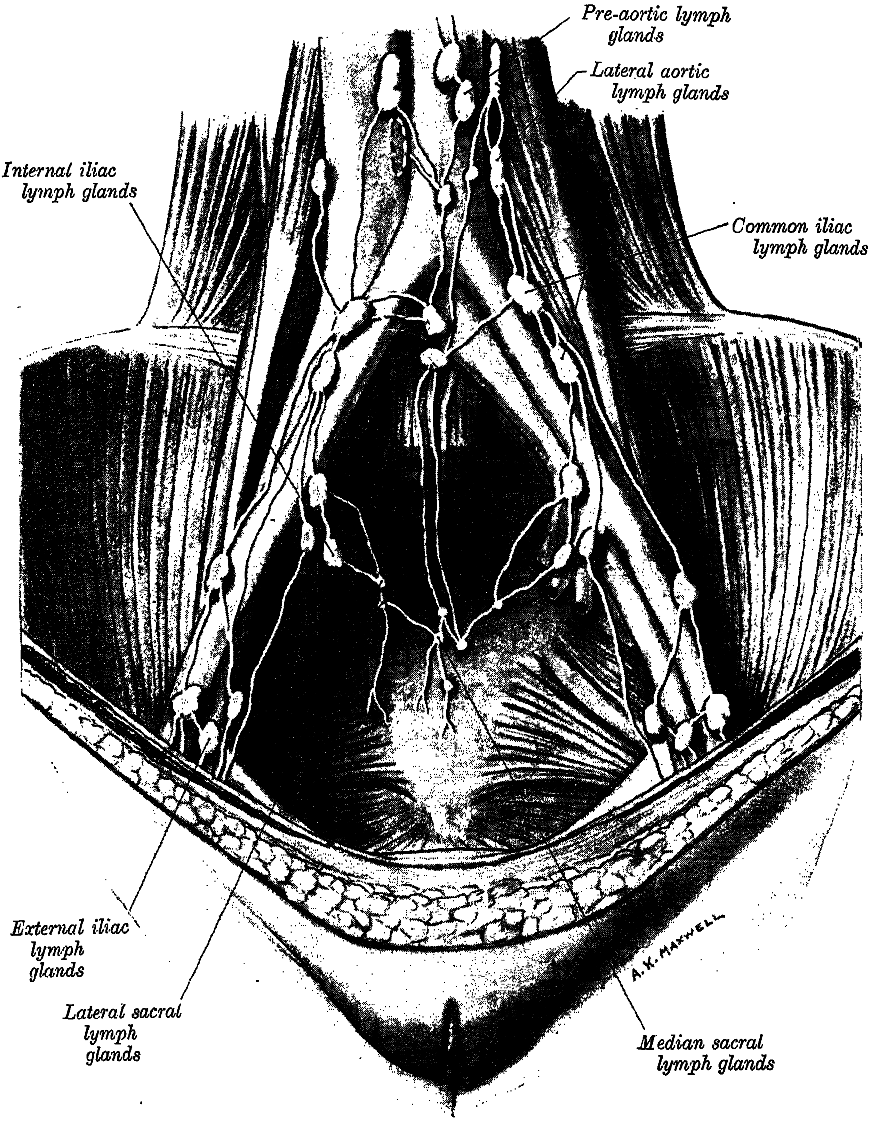
The *external iliac lymph glands*, about eight to ten in number, lie along the external iliac vessels. They are usually in three groups, one on the lateral side, another on the medial side, and a third in front of the vessels, but the last-named group is inconstant. They receive afferents from the inguinal lymph glands (p. 862), from the deeper layers of the infra-umbilical part of the abdominal wall, from the deep part of the adductor region of the thigh, from the glans penis vel clitoridis, the membranous urethra, the prostate, the fundus of the urinary bladder, the cervix uteri and part of the vagina. Their efferents pass to the common iliac lymph glands. The *inferior epigastric* and the *circumflex iliac lymph glands*, which are associated with the vessels of the same names and drain the corresponding areas, are outlying members of the external iliac group. They are inconstant in number.

The *internal iliac lymph glands* surround the internal iliac vessels. They receive afferents from all the pelvic viscera, from the deeper parts of the perineum, and from the muscles of the buttock and back of the thigh. Their efferents pass to the common iliac lymph glands. The *sacral lymph glands*, which are placed along the median and lateral sacral vessels, and the *obturator lymph gland*, which is sometimes present in the obturator canal, are outlying members of the internal iliac group.

1. **The lymphatic drainage of the urinary tract.**—(*a*) The *kidney*.—The

lymph vessels of the kidney begin in three plexuses : one in the substance of the organ between and around the renal tubules ; a second beneath the fibrous capsule ; and a third which communicates freely with the subcapsular plexus, in the renal fat. The collecting vessels from the intrarenal plexus form four or five trunks which follow the renal vein and end in the lateral aortic lymph glands ; as they issue from the hilum they are joined by the collecting

FIG. 813.—The lymph glands of the pelvis. Semi-diagrammatic.

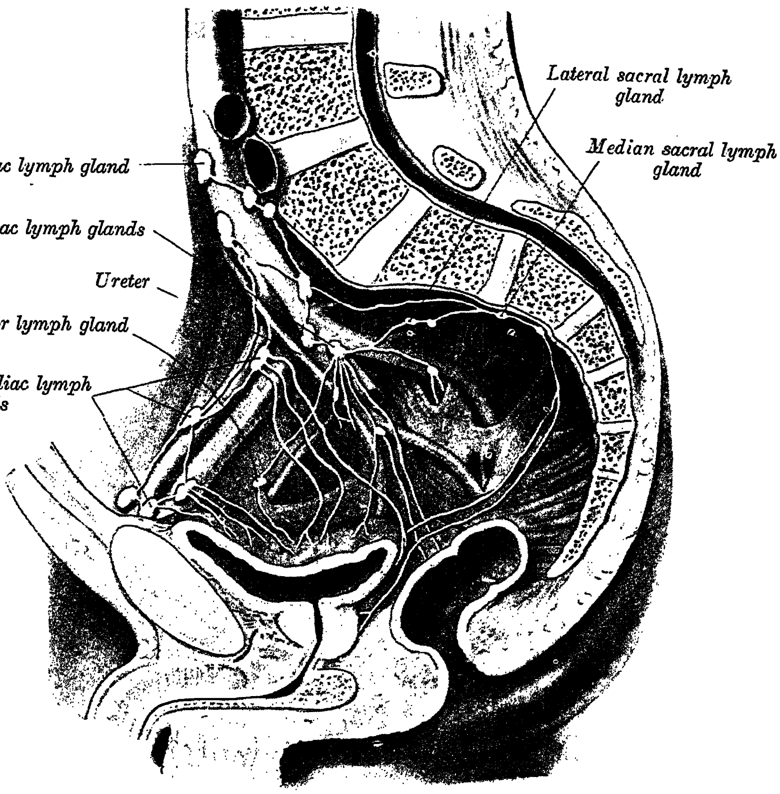


vessels from the subscapular plexus. The plexus in the renal fat drains directly into the lateral aortic lymph glands.

(*b*) The *ureter*.—The lymph vessels of the ureter begin in submucous, intramuscular and adventitial plexuses which communicate with each other. The collecting vessels from the upper part of the ureter may join the renal collecting vessels or may pass directly to the lateral aortic lymph glands near the origin of the testicular (or ovarian) artery ; those from the succeeding part pass to the common iliac lymph glands ; and those from the pelvic part of the ureter may end in the common, the external or the internal iliac lymph glands.

(c) The *bladder*.—The lymph vessels of the bladder take origin in three plexuses—a submucous,* an intramuscular and an extramuscular. The collecting vessels, nearly all of which end in the external iliac lymph glands, are arranged in three sets : the vessels from the region of the trigone emerge on the base of the bladder and run upwards and laterally ; those from the superior surface converge on the posterolateral angle and then pass upwards and laterally across the lateral umbilical ligament to reach the external iliac glands (one of the vessels of this set may go to the internal or common iliac group) ; those from the inferolateral surface pass towards its upper part and then run with those from the superior surface. Minute nodules of lymphoid tissue may be found along the course of the lymph vessels of the bladder.

FIG. 814.—The lymphatic drainage of the urinary bladder. Semi-diagrammatic.



(d) The *urethra*.—(i) The vessels from the prostatic and membranous parts in the male, and from the whole urethra in the female, pass mainly to the internal iliac lymph glands ; a few may end in the external iliac glands. The vessels from the membranous part accompany the internal pudendal artery.

(ii) The vessels of the spongy urethra in the male accompany those of the glans penis and end in the deep inguinal lymph glands (p. 862). Some may terminate in the superficial inguinal glands, and others may pass along the inguinal canal to reach the external iliac group.

2. **The lymphatic drainage of the male reproductive organs.**—(a) The *testis*.—The lymph vessels of the testis commence in two plexuses—a superficial, under the tunica vaginalis, and a deep, in the substance of the testis and in the epididymis. Four to eight collecting trunks ascend in the spermatic cord and accompany the testicular vessels as they lie on the psoas major muscle ; they end in the lateral aortic and pre-aortic lymph glands.†

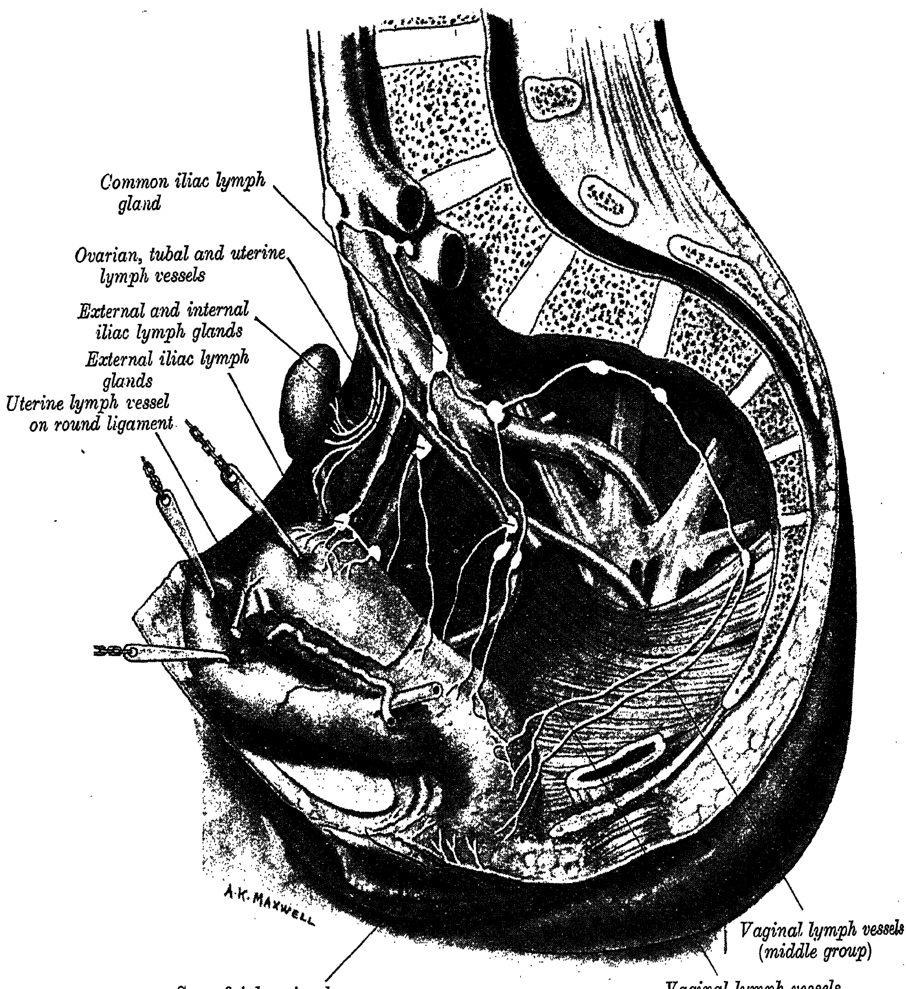
* See *Médecine opératoire des voies urinaires*, J. Albarran, Paris, 1909 ; and *Anatomie des lymphatiques de l'homme*, H. Rouvière, Paris, 1932.

† "The Lymphatics of the Testicle," by J. K. Jamieson and J. F. Dobson, *Lancet*, February 19th, 1900.

(*b*) The *vas deferens, seminal vesicle and prostate.*—The collecting vessels from the vas deferens end in the external iliac lymph glands. Those from the seminal vesicle go to both the internal and external iliac groups.

The prostatic lymph vessels terminate chiefly in the internal iliac and sacral lymph glands ; a trunk from the posterior surface passes with the lymph vessels of the bladder to the external iliac glands, and another from the anterior surface gains the internal iliac group by joining the lymph vessels of the membranous urethra.

FIG. 815.—The lymphatic drainage of the female reproductive organs. Semi-diagrammatic. (After Cunéo and Marcille.)



(*c*) The *scrotum and penis.*—The skin covering these parts is drained by vessels which, together with those of the whole of the perineal skin, pass along the course of the external pudendal blood-vessels to the superficial inguinal lymph glands. The lymph vessels of the glans penis pass to the deep inguinal and external iliac groups.

3. **The lymphatic drainage of the female reproductive organs.**—(*a*) The *ovary.*—The lymph vessels of the ovary, like those of the testis, ascend along the ovarian artery to the lateral aortic and pre-aortic lymph glands.

(*b*) The *uterus and uterine tube.*—The lymph vessels of the uterus comprise two sets : a superficial, beneath the peritoneum, and a deep, in the substance of the uterine wall. The collecting vessels from the cervix pass in three

directions: laterally in the parametrium to the external iliac lymph glands; posterolaterally to the internal iliac glands; and backwards in the sacrogenital fold to the sacral glands. Most of the vessels from the body and fundus of the uterus and from the uterine tube accompany those of the ovary to the lateral aortic and pre-aortic glands; a few, however, pass to the external iliac glands. The region near the point of entry of the uterine tube is drained by vessels which accompany the round ligament and so reach the superficial inguinal lymph glands. The lymph vessels of the uterus enlarge greatly during pregnancy.

(c) The *vagina.*—The lymph vessels of the vagina anastomose with those of the cervix uteri, the rectum and the vulva. They are in three groups, but the areas drained by the three sets are not sharply demarcated. The vessels from the upper part accompany the uterine artery to the external iliac lymph glands. The middle part is drained by vessels which accompany the vaginal artery and end in the external iliac glands. The vessels of the vagina below the hymen, the vulva, and the skin of the perineum as a whole pass to the superficial inguinal lymph glands.

4. The **lymphatic drainage of the abdominal wall.**—The lymph vessels of the abdominal wall are in two sets: superficial, in the superficial fascia; and deep, draining the muscles, etc.

The *superficial lymph vessels* accompany the superficial blood-vessels. Those from the loin and buttock run with the superficial circumflex iliac vessels, and those from the skin of the anterior wall below the umbilicus with the superficial epigastric vessels. Both sets pass to the superficial inguinal lymph glands. The part above the umbilicus is drained by vessels most of which run obliquely upwards to end in the pectoral and subscapular groups of the axillary lymph glands; a few end in the internal mammary lymph glands (p. 876).

The *deep lymph vessels* accompany the deep arteries. Those from the posterior abdominal wall pass directly, along the course of the lumbar arteries, to the lateral aortic and retro-aortic lymph glands; those from the upper part of the anterior abdominal wall run with the superior epigastric vessels to reach the internal mammary lymph glands; those of the lower part end in the circumflex iliac, inferior epigastric, and external iliac lymph glands. The lymph vessels of the pelvic wall follow the internal iliac artery and its parietal branches and end in the iliac or lateral aortic lymph glands.

THE LYMPHATIC DRAINAGE OF THE THORAX

The lymphatic drainage of the thorax may be considered under two headings: (*A*) drainage of the thoracic walls, and (*B*) drainage of the thoracic contents, and it should be noted that the glands on the lymphatic pathways of the thorax cannot be divided into terminal and outlying groups, as, with a few exceptions, the lymph glands concerned drain into the thoracic duct or the right lymphatic duct or one of their larger tributaries.

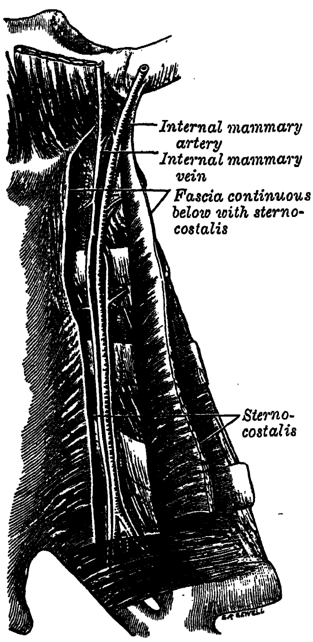
A. Lymphatic Drainage of the Thoracic Walls.

1. The *superficial tissues.*—The superficial lymph vessels of the thoracic wall ramify beneath the skin and converge on the axillary lymph glands. Those over the trapezius and latissimus dorsi run forwards and unite to form about ten or twelve trunks which end in the subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mammary gland, run backwards, and those over the serratus anterior upwards, to the pectoral group. Others near the lateral margin of the sternum pass inwards between the rib cartilages and end in the internal mammary lymph glands, while the vessels of opposite sides anastomose across the front of the sternum. A few vessels from the upper part of the pectoral region ascend over the clavicle to the inferior deep cervical lymph glands.

2. The *deeper tissues*.—The lymph vessels from the deeper tissues of the thoracic walls drain mainly into three sets of glands—the internal mammary, the intercostal and the diaphragmatic.

(*a*) The **internal mammary lymph glands** (sternal lymph glands) are four or five in number on each side, and are placed (fig. 816) at the anterior ends of the intercostal spaces, by the side of the internal mammary artery.* They derive afferents from the medial part of the mammary gland, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the upper surface of the liver through a small group of lymph glands which lies behind the xiphoid process, and from the deeper parts of the anterior portion of the thoracic wall. Their efferents usually unite to form a single trunk; this may open directly into the junction of the internal jugular and subclavian veins, or that of the right side may join the right subclavian trunk, and that of the left the thoracic duct.

FIG. 816.—The right sternal or internal mammary lymph glands (E. P. Stibbe).



(*b*) The **intercostal lymph glands** lie in the posterior parts of the intercostal spaces and in relation to the heads and necks of the ribs. They receive the deep lymph vessels from the postero-lateral aspect of the chest; some of these vessels are interrupted by small lateral intercostal lymph glands. The efferents of the lymph glands in the lower four or five spaces unite to form a trunk which descends and opens either into the cisterna chyli or into the commencement of the thoracic duct. The efferents of the lymph glands in the upper spaces of the left side end in the thoracic duct; those of the corresponding right spaces, in the right lymphatic duct.

(*c*) The **diaphragmatic lymph glands** lie on the thoracic surface of the diaphragm, and consist of three sets, anterior, right and left lateral.

The *anterior* set comprises (*a*) two or three small lymph glands behind the base of the xiphoid process, which receive afferents from the convex surface of the liver, and (*b*) one or two lymph glands on each side near the junction of the seventh rib with its cartilage, which receive lymph vessels from the front part of the Diaphragm. The efferent vessels of the anterior set pass to the internal mammary lymph glands.

The *lateral* sets consist of two or three lymph glands on each side close to where the phrenic nerves enter the Diaphragm. On the right side some of the lymph glands of this group lie within the fibrous wall of the pericardium on the front of the termination of the inferior vena cava. The afferents of this set are derived from the middle part of the Diaphragm, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal lymph glands.

The *posterior* set consists of a few lymph glands situated on the back of the crura of the Diaphragm, and connected on the one hand with the lumbar lymph glands, and on the other with the posterior mediastinal lymph glands.

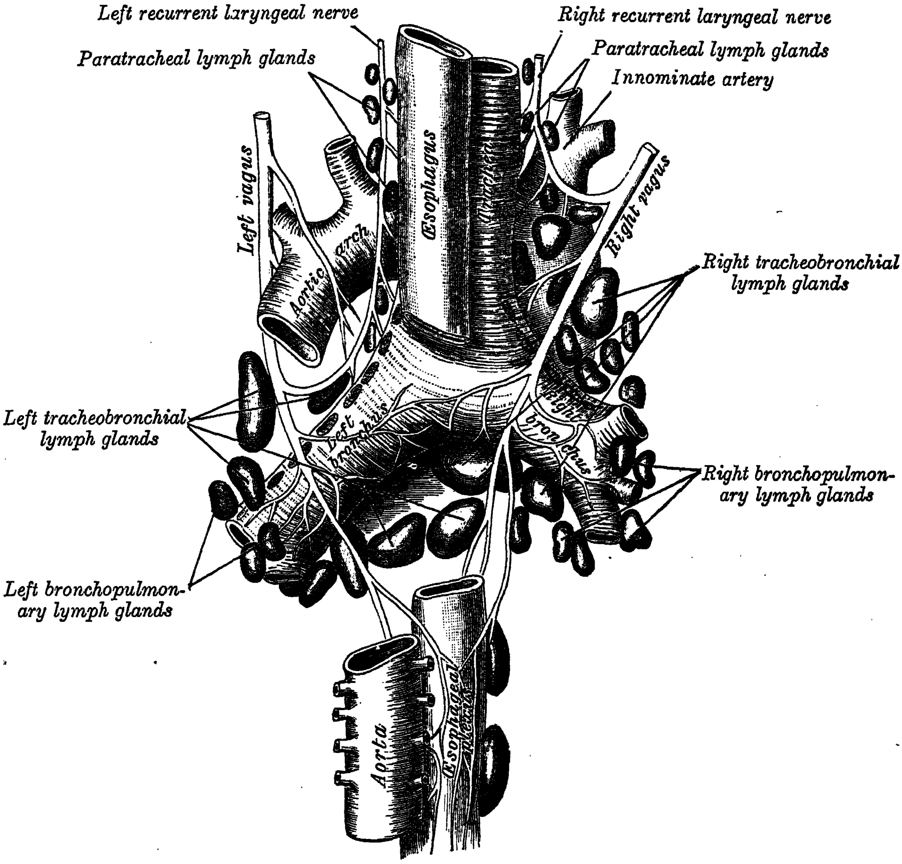
The collecting lymph vessels from the deeper tissues comprise:

(*a*) The lymph vessels of the muscles which lie on the ribs: most of these end in the axillary lymph glands, but some from the Pectoralis major pass to the internal mammary lymph glands. (*b*) The intercostal lymph vessels which drain the Intercostales and parietal pleura; those from the anterior half of the thoracic wall and pleura end in the internal mammary lymph glands; those from the posterior half, in the intercostal lymph glands. (*c*) The lymph vessels of the Diaphragm, which form two plexuses, one on its thoracic and another on its abdominal surface; these plexuses anastomose freely with each other, and

* E. P. Stibbe, *Journal of Anatomy*, vol. lii.

are best marked on the parts covered respectively by the pleuræ and peritoneum. *The plexus on the thoracic surface* unites with the lymph vessels of the costal and mediastinal parts of the pleura, and its efferents consist of three groups: anterior, passing to the anterior diaphragmatic lymph glands, which lie near the junction of the seventh rib with its cartilage; middle, to the lymph glands on the œsophagus and to those around the termination of the inferior vena cava; and posterior, to the lymph glands which surround the aorta at the point where this vessel leaves the thoracic cavity. *The plexus on the abdominal surface* is composed of fine vessels, and anastomoses with the lymph vessels

FIG. 817.—The tracheobronchial lymph glands. (From a figure designed by M. Hallé.)



of the liver and, at the periphery of the Diaphragm, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of lymph glands on the trunk of the corresponding phrenic artery, while others end in the right lateral aortic lymph glands. Those from the left half of the plexus pass to the pre-aortic and lateral aortic lymph glands and to the lymph glands on the terminal portion of the œsophagus.

B. Lymphatic Drainage of the Thoracic Contents.

The lymph from the thoracic viscera traverses one or other of three sets of lymph glands, viz. innominate, posterior mediastinal and tracheobronchial, before entering the thoracic duct, the right lymphatic duct or another lymph vessel which itself enters one of the great veins at the root of the neck.

The **innominate lymph glands** (anterior mediastinal lymph glands) are placed in the anterior part of the superior mediastinum, in front of the innominate veins and the large arterial trunks which arise from the aortic arch. They

receive afferents from the thymus and pericardium, and from the lateral diaphragmatic lymph glands; their efferents unite with those of the tracheobronchial lymph glands, to form the right and left bronchomediastinal trunks.

The **posterior mediastinal lymph glands** lie behind the pericardium in relation to the œsophagus and descending thoracic aorta. Their afferents are derived from the œsophagus, the posterior part of the pericardium, the Diaphragm, and, occasionally, the left lobe of the liver. Their efferents mostly end in the thoracic duct, but some join the tracheobronchial lymph glands.

The **tracheobronchial lymph glands** (fig. 817) form five main groups, and include some of the largest lymph glands in the body: (*a*) *paratracheal*, at the sides of the thoracic part of the trachea; (*b*) *superior tracheobronchial*, in the angles between the lower part of the trachea and bronchi; (*c*) *inferior tracheobronchial* in the angle between the two bronchi; (*d*) *bronchopulmonary*, in the hilum of each lung; and (*e*) *pulmonary*, in the lung substance, on the larger branches of the bronchi. These groups are not sharply demarcated from one another. The pulmonary lymph glands become continuous at the hilum of the lung with the bronchopulmonary glands, and they in turn are continuous with the inferior and superior tracheobronchial glands, while the latter are continuous with the paratracheal group. The afferents of the tracheobronchial lymph glands drain the lungs and bronchi, the thoracic part of the trachea, and the heart; some of the efferents of the posterior mediastinal lymph glands also end in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the internal mammary and innominate lymph glands to form the *right* and *left bronchomediastinal trunks*. The right bronchomediastinal trunk may join the right lymphatic duct, and the left the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

Applied Anatomy.—In all town-dwellers there are continually being swept into these lymph glands from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. In tuberculosis of the lungs these lymph glands are practically always infected; they enlarge, being filled with tuberculous deposits that may soften, or become fibrous, or calcify. Not infrequently an enlarged tuberculous lymph gland perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute pulmonary tuberculosis, the infecting gland-substance being rapidly spread throughout the bronchial system by the coughing induced by its presence in the air-passages.

1. The *lymphatic drainage of the heart.*—The lymph vessels of the heart consist of two plexuses: (*a*) deep, immediately under the endocardium, and (*b*) superficial, subjacent to the visceral pericardium. The deep plexus opens into the superficial, the efferents of which form left and right collecting trunks. The *left* trunks, two or three in number, ascend in the anterior interventricular groove, receiving, in their course, vessels from both ventricles. On reaching the atrioventricular (coronary) sulcus they are joined by a large trunk from the diaphragmatic surface of the heart, and then unite to form a single vessel, which ascends between the pulmonary artery and the left atrium, and ends, usually, in one of the inferior tracheobronchial lymph glands. The *right* trunk receives its afferents from the right atrium and from the right border and diaphragmatic surface of the right ventricle. It runs upwards in the atrioventricular groove, close to the right coronary artery, and then ascends in front of the ascending aorta to terminate in one of the innominate lymph glands, usually to the left of the median plane.

2. The *lymphatic drainage of the lungs and pleuræ.*—The lymph vessels of the lungs originate in two plexuses, a superficial and a deep. The superficial plexus is placed beneath the pulmonary pleura; the deep accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two networks—a submucous, beneath the mucous membrane, and a peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls of which there are no traces of lymph vessels. The superficial efferents turn round the borders of the lungs and the margins of their fissures, and converge to end in the bronchopulmonary lymph glands; the deep efferents

are conducted to the hilum along the pulmonary vessels and bronchi, and end, for the most part, in the bronchopulmonary lymph glands. No free anastomosis occurs between the superficial and deep lymph vessels of the lungs, except in the region of the hilum. In the peripheral parts of the lung small connecting channels do exist between the superficial and the deep lymph vessels and, although they are difficult to demonstrate in injected specimens, they are capable of becoming dilated so as to direct the lymph flow from the deep to the superficial vessels, when the outflow from the deep vessels is obstructed by disease of the lung or pulmonary glands. At the bottom of the fissures the lymph vessels of the adjoining lobes communicate with one another, so that although there is a general tendency for the lymph vessels from the upper lobes of the lungs to pass to the superior tracheobronchial lymph glands and for those from the lower lobes to join the inferior tracheobronchial group, these connexions are not exclusive.

The lymph vessels of the pleura consist of two sets—one in the visceral and another in the parietal part of the membrane. Those of the visceral pleura drain into the superficial efferents of the lung, while those of the parietal pleura have three modes of ending, viz.: (*a*) those of the costal portion join the lymph vessels of the internal intercostal muscles and so reach the internal mammary lymph glands; (*b*) those of the diaphragmatic part are drained by the efferents of the diaphragm; while (*c*) those of the mediastinal portion end in the posterior mediastinal lymph glands.

3. The *lymphatic drainage of the thymus.*—The lymph vessels of the thymus end in the innominate, tracheobronchial, and internal mammary lymph glands.

4. The *lymphatic drainage of the œsophagus.*—The lymph vessels of the œsophagus form a plexus round that tube, and the collecting vessels from the plexus drain into the posterior mediastinal lymph glands.

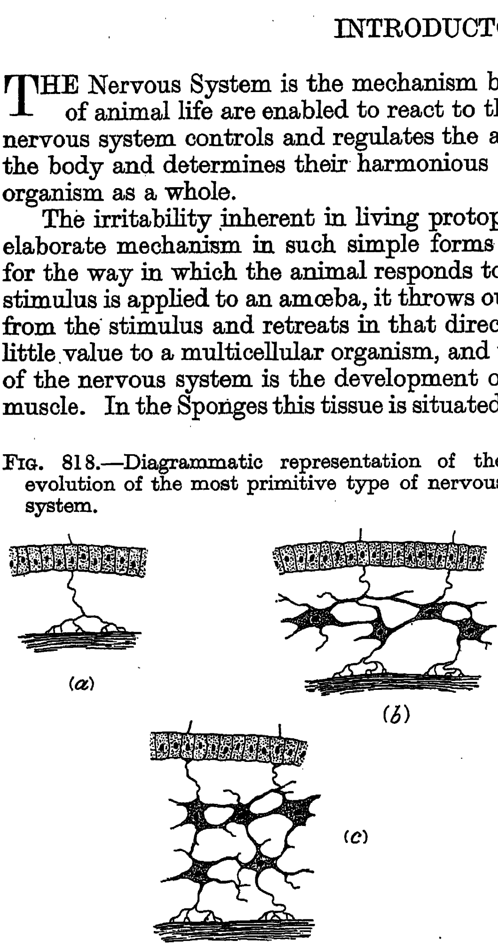
NEUROLOGY

INTRODUCTORY

THE Nervous System is the mechanism by which all, save the lowest, forms of animal life are enabled to react to their environment. In addition, the nervous system controls and regulates the activities of all the other systems of the body and determines their harmonious co-operation, for the benefit of the organism as a whole.

The irritability inherent in living protoplasm obviates the necessity for an elaborate mechanism in such simple forms as the amœba, and is responsible for the way in which the animal responds to stimulation. When a mechanical stimulus is applied to an amœba, it throws out pseudopodia on the side removed from the stimulus and retreats in that direction. Such a reaction would be of little value to a multicellular organism, and the first step towards the evolution of the nervous system is the development of a contractile tissue akin to plain muscle. In the Sponges this tissue is situated close to the surface and it responds to direct stimulation, but this arrangement provides for the possibility of localised movements only. In addition to the development of a contractile tissue (or *effector* apparatus) a mechanism must be developed for the reception of stimuli (*receptor* apparatus) and for their transmission to the whole effector apparatus, before generalised movements, which constitute a notable advance along the path of evolution, can become possible.

FIG. 818.—Diagrammatic representation of the evolution of the most primitive type of nervous system.



The cuticle is developed in order to protect the more delicate vital tissues of the animal against its environment, and it is not surprising to find that some of the ectodermal cells become specialised so as to enable them to appreciate alterations in the environment. The most primitive of these sensory cells possess two processes, of which the one projects from the surface of the cuticle and the other grows inwards to establish contact with the effector (fig. 818, *a*). Many of these primitive sensory cells migrate more deeply into the subcuticular tissues, leaving their peripheral processes in the ectodermal layer, where they may lie free or may arborise around the bodies of other sensory cells (fig. 818, *b*). In Cœlenterata, which exhibit the simplest form of nervous system, sensory cells are scattered over the cuticle and are linked up to a subcuticular ganglion cell plexus, the constituents of which are connected both to the effector apparatus and to one another. Such an arrangement enables a localised stimulus to bring about a generalised response; and, in addition, it provides for the correlation of a number of incoming stimuli and for the co-ordination of the outgoing response (fig. 818, *c*). This diffuse type of nervous system, though admirably adapted to the needs of such an animal as Hydra, whose movements, though generalised, are limited in character, gives way to a centralised arrangement in higher forms, where the motor possibilities are much more numerous and varied.

In the segmented types, the diffuse ganglion cell plexus of the Cœlenterata is separated into an appropriate number of segmental ganglia, which are connected not only to the receptors and effectors of their own segments but also to one another. Incoming stimuli can be distributed and correlated so as to bring about a co-ordinated response affecting a large number of segments and, as a result of the centralisation, the efficiency and the speed of the response are greatly increased.

In these simpler forms of nervous system the response to stimulation is immediate, and the same stimulus, repeated under the same conditions, always provokes the same response. The behavioural reactions of such animals are therefore stereotyped in charater, for they have not acquired the power of inhibition or the ability to register past experience, and plasticity of behaviour is impossible in the absence of these two factors.

With the evolution of vertebrates the nervous system underwent further changes, the most important of which was the development of a suprasegmental controlling centre, namely the brain, already foreshadowed in annelid worms by the large ganglia found in the head region. Owing to the elongated form of the body and the mode of progression, it is the head end of the animal which is subject to the greatest number of afferent impressions, and this number is enormously increased by the development of the olfactory and of the visual apparatus in the same situation. These factors determined the enlargement of the cephalic end of the nervous system, and its further growth followed, in the first place, from the necessity to link up with the rest of the nervous system in order that olfactory, visual and other stimuli received by the brain might be able to produce an effector response involving any part or even the whole of the motor system. The power to delay the immediate localised reactions to local stimuli in any part of the body, in view of contrary stimuli coming from the head region, became urgently necessary in order to allow time for the complete correlation of afferent impressions from all sources. The acquisition of this power of inhibition was an enormous step forward in mental development. The animal ceased, partially at least, to react instantaneously and reflexly to all incoming stimuli, and the interval of time so introduced enabled the ultimate response to take on a purposive character. At this stage in the evolution of the nervous system a localised stimulus may be followed by one of several results. It may produce an immediate, local response, an immediate general response, a delayed response, or the response may be inhibited completely.

The acquisition of the power to register past experience is the last and greatest step forward in mental development, and it has only been rendered possible by additional growth of the brain and the establishment of association areas in the cortex. This new acquisition of the nervous system is well developed in the mammalia, and the higher an animal is in the evolutionary scale the more numerous are its association areas and their connexions. The registration of past experience exerts a very profound influence on behaviour, endowing it with greater plasticity and increasing the complexity of all behavioural reactions. The dominance of man in the animal world is to be attributed to a further elaboration of the association areas, which enables him to benefit not only by his own past experience, but also, through the medium of education, by the past experience of others.

The Functional Components of the Nervous System

The definition of the nervous system which was given at the beginning of this section covers two spheres of activity. It is through the nervous system that an animal is enabled to react to alterations in or to stimuli from its external environment, and it is through the nervous system that all the other systems of the body are governed and controlled, so that their activities are directed towards the good of the animal as a whole. These two components of the nervous system are designated the *somatic* and the *splanchnic* or *visceral components*, and they have much in common. Both components are provided with a series of receptors and of effectors, and the translation of a stimulus

applied to a receptor into an effector response is brought about by the mechanism of the nervous system which has already been outlined.

The **somatic component** deals with the reception, translation and transmission of stimuli which originate in the somatic receptors and result in alterations in the locomotor apparatus of the body. It can be subdivided into an *afferent* or *centripetal* and an *efferent* or *centrifugal* side. The somatic receptors are formed by a series of end-organs, situated in or close to the skin, in the muscles, tendons and joints (p. 1216). The receptors found in or close to the skin receive their stimuli from the external environment. The term *exteroceptive* is applied to the variety of sensibility to which they give rise. Painful, tactile, thermal, pressure, olfactory, visual and auditory stimuli are all exteroceptive in character. The receptors found in the muscles, tendons and joints have their source of stimulation within the body and are independent of the external environment. The variety of sensibility to which they give rise is termed *proprioceptive*. Sensations of movements, both active and passive, and sensations of posture are proprioceptive in character. These constituents of proprioceptive sensibility, like all the constituents of exteroceptive sensibility, succeed in reaching consciousness, on account of the fact that they ultimately reach the cerebral cortex or the thalamus. There are, however, constituents of proprioceptive sensibility which never intrude into consciousness. They are responsible for the muscular adjustments which are constantly necessary during the performance of any movement, however simple.

The *somatic efferent component* includes the effector apparatus of the body and the series of neurones which activate them. It may be brought into play either by the exteroceptive or by the proprioceptive constituents of the somatic afferent component.

The **splanchnic** *component* comprises that portion of the nervous system which regulates and controls the activities of the blood-vessels, the secretory glands and the viscera. Like the somatic component it can be subdivided into an afferent and an efferent side. Special end organs are associated with the reception of stimuli in the walls of the viscera, and the effector apparatus is represented by the glandular epithelial cells and the involuntary muscle of the viscera and the blood-vessels. Under normal conditions the splanchnic component of the nervous system is constantly at work, but its activities are carried out without intruding into consciousness. When all the viscera are working efficiently and harmoniously a characteristic feeling of well-being is experienced. It is uncertain whether this is to be regarded as the appearance in consciousness of the splanchnic afferent component, but, if so, it is necessary to postulate the existence of splanchnic centres in the forebrain, and evidence is accumulating to show that such centres do actually exist (p. 966). That, under abnormal conditions, the activities of the splanchnic component do intrude into consciousness is a matter of everyday observation. The occurrence of pain as a sign of such conditions probably indicates that the neurones constituting the splanchnic afferent component are linked up by means of collaterals with the neurones of the somatic afferent component. Stimuli which give rise to tactile or painful impressions when applied to the skin or subcutaneous tissue do not give rise to similar impressions when applied to the viscera, and yet pathological conditions, especially those leading to increased tension of the muscular walls of viscera, can and do give rise to pain. Whether such visceral pain is due to the passage of painful stimuli along the visceral afferent pathways or whether it is due to the spread of abnormal stimuli from the visceral to the somatic afferent pathways by means of collaterals cannot be decided satisfactorily.

The activities of these two great components of the nervous system are the basis of the conscious life. From the correlation and association of the impulses which stream into the nervous system from the afferent components are built up those sensory combinations which confer the power of controlling behaviour in the light of past experience and constitute the phenomenon of memory. The co-ordinated impulses which pass out along the efferent components and result in positive reactions, or in the inhibition of such reactions, are all dependent on the efferent components and constitute the behaviour of the individual. Behaviour can only manifest itself through the effector

apparatus, and the more it is influenced by past experience the more purposeful does it become. Throughout the whole of evolution there has been a steady increase in the purposive character of behaviour, due to the elaboration of the connexions within a centralised nervous system.

The constituents of the somatic afferent component have been analysed still further. Head and other investigators have examined the effects of sections of peripheral nerves and posterior nerve roots, and the phenomena associated with the return of sensation after division followed by suture, and after crushing without division. As a result of his observations Head divided general sensibility into (*a*) cutaneous and (*b*) deep sensibility, and he further differentiated two varieties of cutaneous sensibility as (1) epicritic and (2) protopathic. *Epicritic sensibility* localises tactile and painful stimuli, differentiates neighbouring degrees of temperature and appreciates very light touch. It is discriminative in quality and is abolished when the post-central gyrus of the cortex is destroyed. *Protopathic sensibility* recognises tactile and painful stimuli, but has no power of localisation and can distinguish between extremes of temperature only. It is not abolished when the cerebral cortex is destroyed, for it can reach consciousness in the thalamus. *Deep sensibility* includes all the varieties of proprioceptive sensibility and, in addition, responds to, and localises, pressure stimuli of all kinds.*

Stopford has analysed deep sensibility into two varieties analogous to the epicritic and protopathic components of cutaneous sensibility. He recognises a finer element, which appreciates sensations of posture, and localises accurately both pressure and pressure pain, and a cruder element which recognises pressure and pressure pain without any power of localisation.

There is, then, in both cutaneous and deep sensibility, a finer, discriminative element which requires for its full appreciation that the cortex of the postcentral gyrus should be intact, and a cruder element which can reach consciousness in the thalamus. These two elements, as will be seen later, travel by different pathways in the spinal cord, and the pathway followed by the cruder element is, as might have been guessed, phylogenetically the older of the two. Kappers has suggested the terms *gnostic* and *vital* for these two elements. Gnostic sensibility is of predominant importance for the intellectual life and vital sensibility for the animal life.

The Structure of the Nervous System

Nerve cells constitute the units of structure in the nervous system. They exhibit a remarkable range of variation, dependent, apparently, on the particular functions with which they are associated, but although they may and do vary in the details of their structure, in size and in shape, they all possess certain features in common. Nerve cells are specialised to enable them to receive and to transmit nervous impulses and, with certain exceptions to be noted later, they are provided with a *cell body*, one or more receiving processes or *dendrites*, and one transmitting process or *axon*. The precise character of a nervous impulse is uncertain, but it possesses many properties which suggest an analogy with an electrical current and, fortunately, for a clear understanding and appreciation of the anatomy of the nervous system definite knowledge on this point is not essential.

The *cell body* or *cyton* is provided with a limiting membrane, which may serve to insulate it from its surroundings. In certain situations, e.g. sympathetic ganglia and the posterior nerve root ganglia of the spinal nerves, the membrane is surrounded by a nucleated capsule (fig. 819), which is structurally continuous with the neurolemma sheath of the axon. The Golgi apparatus, which has been described as a regular feature of many of the cells of the body (p. 2), was first demonstrated in nerve cells. A system of fine intracytoplasmic

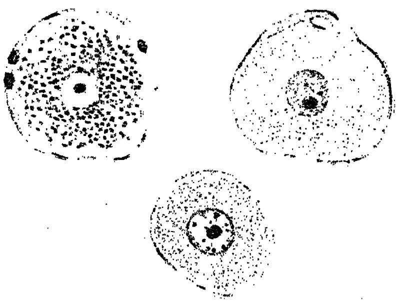
* Many neurologists regard the phenomena associated with the return of sensation as pathological in character, or as dependent on changes which accompany regeneration, but, on the whole, the balance of the available evidence supports the view that there are two distinct elements in general sensibility. For a full discussion of these views and a list of references to the literature, see *Sensation and the Sensory Pathway*, by J. S. B. Stopford, London, 1930.

canals, first described by Holmgren, is present in some ganglion cells.* Two positive features, which are not found elsewhere, serve to differentiate nerve cells from the cells of all other tissues. (1) The presence in the cytoplasm of a number of granules which stain deeply with basic anilin dyes and are known as *Nissl's bodies* or *spindles* (fig. 50). (2) The presence in the cytoplasm of a number of *neurofibrils* (p. 39).

A very important negative feature also helps to differentiate nerve-cells from other cells in the body. Owing to the high degree of specialisation which they have attained nerve-cells have lost the power of reproduction, and as a result the centrosome, which plays such an important part in the process of cell division, is conspicuous by its absence.

The nucleus of the nerve-cell is large and usually spherical in shape, but it presents no differentiating features and is probably concerned with the metabolic processes of the cell and has no direct influence on its special functional activities.

FIG. 819.—Three types of nerve-cells from a spinal ganglion of a cat. Stained with hæmatoxylin and eosin. ×350. (The nuclei of the cells lining the capsule are shown in the left-hand figure only.)



It will be seen, therefore, that apart from the possession of Nissl's bodies and neurofibrils and the loss of the centrosome, the cell body of a nerve-cell does not differ markedly from the cells of other tissues in the body. The processes with which it is provided are, however, in nearly all varieties of nerve-cells, a very striking and characteristic feature. The **dendrites** are characterised by the repeated and irregular manner in which they divide into branches. These branches begin to arise close to the cell body, and their terminal filaments rarely extend beyond its immediate neighbourhood. They are always confined to the grey substance of the nervous system or of the various ganglia. They represent extensions of the cytoplasm of the nerve-cell, and they therefore contain Nissl's bodies in addition to neurofibrils. A large Nissl's body is situated at the *bifurcation cone*, the point of origin of the first branch, and, owing to the reduction in size due to repeated branching, the Nissl's bodies become progressively smaller as the dendrites are traced towards their terminal arborisations. Numerous minute swellings, the significance of which is uncertain, are found studded along the dendrites and their branches.

No difficulty need be experienced in distinguishing the **axon**. The area of the cell body from which it arises forms a slight surface projection, termed the *implantation cone* or *cone of origin*, and is devoid of Nissl's bodies. The neurofibrils converge on the implantation cone and enter the axon, forming practically the whole of its bulk. The axon may give off one or more *collaterals* soon after leaving the cell, but these come off at right angles to its course and are readily distinguished from the branching of a dendrite. The axon is, as a rule, very much longer than the dendrites and may extend as much as 100 cm. from its origin before it breaks up into a terminal arborisation, the form of which depends in part on the function of the parent cell. Where this terminal arborisation is not related to an actual effector it ends in relationship with the dendrites or body of another nerve-cell. In the majority of cases the ends of the axon interlace with the branches of the dendrites of another cell, and this intimate relationship is termed a *synapse*. The structure of the axon and its medullary and neurolemma sheaths is described in detail on pp. 40-42. The neurolemma sheath plays a very important part in the regeneration of nerve-fibres, and it must be noted that those fibres which do not extend beyond the central nervous system are devoid of a neurolemma sheath, although they are usually myelinated. Some of the axons of the grey matter of the brain and spinal cord are entirely naked. They are very fine and threadlike and never extend far from their parent cells. Another variety of nerve-fibre is

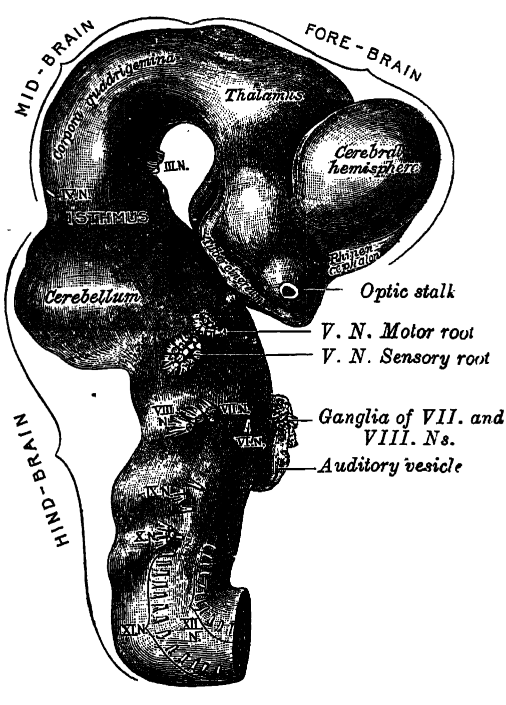
* See footnote on p. 885.

found in the sympathetic system. These axons are unmyelinated but are provided with nucleated neurolemma sheaths (Remak's fibres).

The neurone includes the cell body and all of its processes. Waldeyer's *Neurone Theory* holds that each neurone is an independent unit and that, although nervous impulses pass from one neurone to another at a synaptic junction, there is no structural continuity between them. This view has been attacked from time to time, but it still receives very general support from neurologists. Striking evidence in its favour can be obtained by observing the effects of injury or disease of the cell body. The Nissl's bodies undergo chromatolysis and eventually disappear not only from the cell body but also from the dendrites. The neurofibrils become swollen and hypertrophied at first, and later they break up and may disappear completely, a degenerative process which the dendrites and the axon share with the cell body. These changes, however, are strictly limited to the neurone concerned and do not extend beyond synaptic junctions. Again, section of the axon is followed by degenerative changes, usually of a transient character, in the cell body. They include the fragmentation of the Golgi apparatus and its displacement towards the periphery of the cell.* Each neurone, therefore, can be regarded as an independent structural unit, but functionally neurones are interdependent on one another to a remarkable extent, and every nervous impulse passes through a series of neurones before it reaches the appropriate effector.

It should be observed that two features in the anatomy of the nerve-cell, (1) the profusion of its dendrites and (2) the collaterals given off by its axon, facilitate the correlation and association of afferent impressions and the co-ordination of efferent impulses, which are the essential factors in mental development. By the profusion of the branches of its dendrites the cell is brought into functional relationship with a large number of other cells, and by means of the collaterals given off by its axon the cell is able to discharge its stimuli into a large number of different channels.

Fig. 820.—The brain of a human embryo about 10·2 mm. long. Right lateral aspect. (From a model by His.)



The Parts of the Nervous System

We have seen already (p. 60) that even prior to the closure of the neural tube three primary enlargements occur at its cephalic end. After the closure of the tube these enlargements constitute the three primary cerebral vesicles and, by further development and growth, they give rise to the brain. From the cephalic portion of the *prosencephalon*, or forebrain, two symmetrical diverticula arise during the fourth week of intra-uterine life to form the cerebral hemispheres, and their cavities persist throughout life as the lateral ventricles of the brain. The enormous expansion and thickening which the walls of these two vesicles undergo is characteristic of the mammalia and especially of man, and gives rise to the cortex or pallium and the corpus striatum. Together with the lamina terminalis, the anterior blind

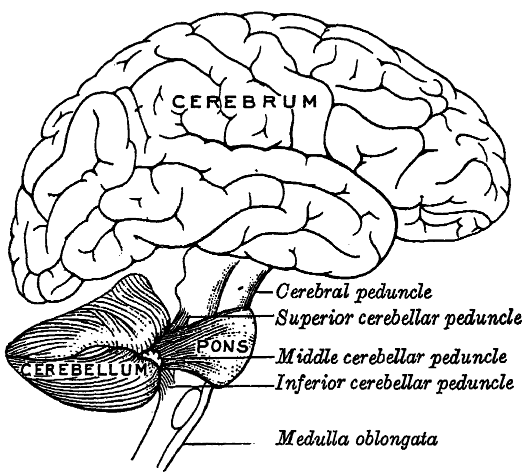
* See a paper by W. G. Penfield, "The Golgi Apparatus and its Relationship to Holmgren's Trophospongium in Nerve-cells," *Anat. Record*, vol. 22.

end of the original tube, which serves to connect them, and certain structures on the base of the brain to be described later, the cerebral hemispheres constitute the *telencephalon*. The caudal part of the prosencephalon constitutes the *diencephalon*. Its lateral walls become greatly thickened and form the thalami, while its cavity, reduced to a deep slit, forms the third ventricle of the brain. The growth of the diencephalon is quite overshadowed by the growth of the cerebral hemispheres, and it becomes completely hidden from surface view. The *mesencephalon*, as contrasted with the prosencephalon and the rhombencephalon, undergoes remarkably few changes. The thickening of its walls reduces its vesicle to a short canal—the aqueduct of the mid-brain—which connects the caudal end of the third to the cranial end of the fourth ventricle.

The *rhombencephalon*, or hind-brain, becomes subdivided into a cephalic portion, termed the *metencephalon*, and a caudal portion, termed the *myelencephalon*. From the lateral walls and floor plate of the cephalic portion the pons is developed, while its originally thin roof plate becomes invaded by the cells of the rhombic lip (p. 112), and converted into the cerebellum. The caudal portion gives rise to the medulla oblongata. The cavity of the vesicle of the hind-brain becomes the fourth ventricle of the brain, communicating in front with the third ventricle through the aqueduct of the mid-brain, and behind with the central canal of the spinal cord.

These derivatives of the three primary cerebral vesicles, viz. the *cerebrum* (telencephalon plus diencephalon), the *mid-brain*, the *pons* and *cerebellum* and the *medulla oblongata*, lie within the cavity of the cranium and together constitute the *brain*.

FIG. 821.—A scheme showing the connexions of the several parts of the brain. (After Schwalbe.)



The remainder of the neural tube gives rise to the *spinal cord*, which still retains a vestige of its original tubular character in its central canal.

The mid-brain, pons and medulla oblongata, connect the cerebrum above, to the spinal cord below, and may be termed collectively the *brain-stem*.

The brain and the spinal cord constitute the *central nervous system*, and are situated in the central axis of the body. The nerves which arise from the brain (twelve pairs of cranial nerves) and from the spinal cord (thirty-one pairs of spinal nerves) together form the *peripheral nervous system*.

It has already been indicated that the nervous system as a whole is subdivisible into a somatic and a visceral mechanism, and the components of these two mechanisms contribute both to the central and to the peripheral nervous system.

The somatic components of the central and peripheral nervous systems may be grouped together under the term '*cerebro-spinal system*,' in contradistinction to the '*autonomic system*,' which comprises all the components of the visceral mechanism. The autonomic system, however, includes two ganglionated nerve trunks (the sympathetic trunks), which lie on the ventrilateral aspect of the vertebral column extending from the atlas to the coccyx, where these two trunks fuse in an unpaired ganglion (the ganglion impar). These two trunks receive their visceral efferent components from a strictly limited region of the spinal cord which extends from the first (sometimes the second) thoracic to the second or third lumbar segment. Visceral efferent components, however, are distributed directly by certain of the cranial nerves (third, seventh, ninth, tenth and eleventh) and by the second, third and frequently the fourth sacral nerves. It has been found experimentally that the

visceral efferent components of these cranial and sacral nerves are usually functionally antagonistic to the visceral efferent components of the sympathetic trunks, and that they may react differently to certain pharmacological agents. The autonomic system has therefore been divided into two constituent parts, the *sympathetic* and the *parasympathetic*. The former comprises the two ganglionated trunks, and their numerous subsidiary ganglia and their branches. The parasympathetic system comprises the craniosacral outflow of visceral efferent components together with such visceral afferent components as they may convey in addition. Small ganglia, which may be situated on the walls of the viscera concerned, are placed in the course of the efferent parasympathetic fibres.

It is characteristic of the autonomic system that the efferent fibres from the central nervous system do not, like the nerves of the cerebrospinal nervous system, pass direct to the effectors, but terminate in a ganglion where they are relayed. It is customary, therefore, to use the terms 'preganglionic and postganglionic' fibres with reference to the last stages in the path to the visceral effectors. The afferent fibres of the autonomic system, however, are strictly comparable to the afferent fibres of the cerebrospinal system. They traverse the ganglia without interruption and eventually reach the ganglion on the sensory root of a spinal or cranial nerve where their parent cells are situated.

THE CENTRAL NERVOUS SYSTEM

It is now possible to commence the detailed study of the structures which constitute the central nervous system. They include the spinal cord (medulla spinalis), the medulla oblongata, the pons, the cerebellum, the mid-brain and the cerebrum. It will be found convenient to commence with the study of the spinal cord, which represents the simplest and most primitive part of the central nervous system, and, although it contains the terminals of the great efferent pathways, it also contains the origins and early stages of a number of the great afferent pathways.

THE SPINAL CORD

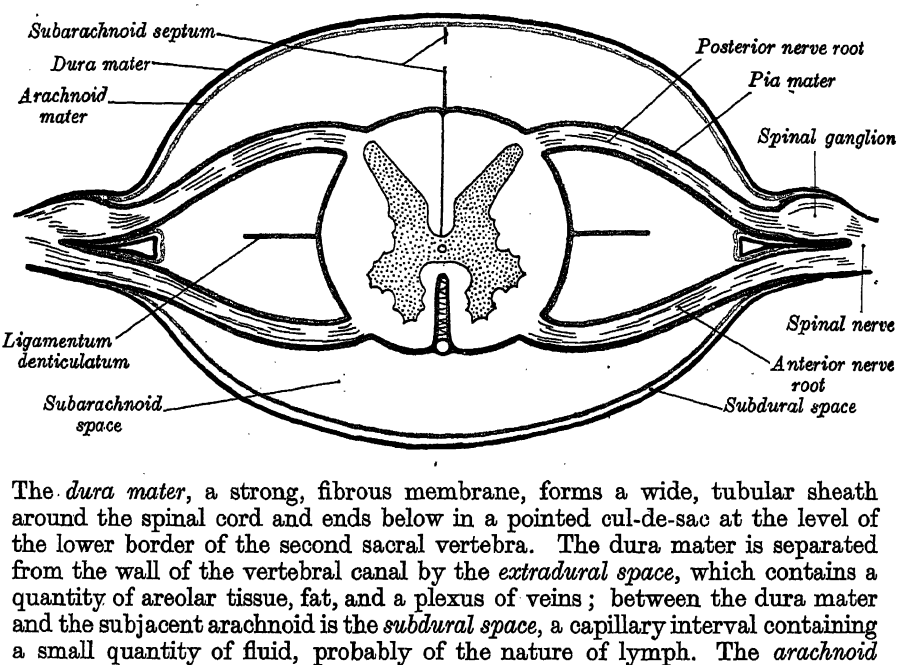
The **spinal cord** [medulla spinalis] is the elongated, nearly cylindrical, part of the central nervous system which occupies the upper two-thirds of the vertebral canal. Its average length in the male is 45 cm.; its weight is about 30 gms. It extends from the level of the upper border of the atlas vertebra to that of the lower border of the first lumbar vertebra, or upper border of the second. Above, it is continuous with the brain; below, it tapers off rapidly into a conical extremity (fig. 824) termed the *conus medullaris*, from the apex of which a delicate non-nervous filament, named the *filum terminale*, descends as far as the first segment of the coccyx (fig. 822).

The position of the spinal cord varies with the movements of the vertebral column, its lower extremity being raised slightly when the column is flexed. It also varies at different periods of life: in early fœtal life the spinal cord is as long as the vertebral canal, but after the embryo has attained a length of

30 mm. the vertebral column begins to grow more rapidly than the spinal cord, and the latter gradually assumes a higher position within the vertebral canal. The chief part of this upward migration occurs during the first half of fœtal life, so that by the twenty-fifth week of fœtal life the lower end of the spinal cord has ascended from the level of the second coccygeal vertebra to that of the third lumbar vertebra, i.e. a distance of nine segments, and there remain but two segments before the adult position is reached (Streeter). In the early embryo the nerve-roots pass transversely outwards to their respective intervertebral foramina, but owing to the relative inequality in the rates of growth of the spinal cord and vertebral column, the nerve-roots become more and more oblique in direction, so that in the adult the lumbar and sacral nerve-roots descend almost vertically to reach their foramina. From the appearance these nerve-roots present at their attachment to the spinal cord and from their great length they are collectively termed the *cauda equina* (fig. 824).

The brain and the spinal cord are ensheathed by three protective membranes separated from each other by spaces. The membranes are named from without inwards the dura mater, the arachnoid mater, and the pia mater (fig. 823).

FIG. 823.—A transverse section through the spinal cord and its membranes. Diagrammatic.



The *dura mater*, a strong, fibrous membrane, forms a wide, tubular sheath around the spinal cord and ends below in a pointed cul-de-sac at the level of the lower border of the second sacral vertebra. The dura mater is separated from the wall of the vertebral canal by the *extradural space*, which contains a quantity of areolar tissue, fat, and a plexus of veins; between the dura mater and the subjacent arachnoid is the *subdural space*, a capillary interval containing a small quantity of fluid, probably of the nature of lymph. The *arachnoid mater* is a thin, transparent sheath which ends at the lower border of the second sacral vertebra; it is separated from the pia mater by the *subarachnoid space*, which contains cerebrospinal fluid. The *pia mater* closely invests the spinal cord and sends some delicate septa into its substance; from each side of the pia mater a fibrous band, named the *ligamentum denticulatum*, projects into the subarachnoid space, and is attached by a series of pointed processes to the inner surface of the dura mater.

A detailed description of these membranes is given on pp. 1023 to 1030.

Thirty-one pairs of spinal nerves spring from the spinal cord, each nerve having an anterior and a posterior root, the latter being distinguished by the presence of an oval swelling, termed the *spinal ganglion*. Each root consists of several bundles of nerve-fibres, and at its attachment extends for some distance along the side of the spinal cord. The pairs of spinal nerves are grouped as follows: cervical 8, thoracic 12, lumbar 5, sacral 5, coccygeal 1, and, for convenience of description the spinal cord is divided into cervical, thoracic, lumbar, and sacral regions, corresponding with the attachments of the different groups of nerves.

Although no trace of transverse segmentation is visible on the surface of the spinal cord, it is convenient to regard it as being built of a series of superimposed *spinal segments* or *neuromeres*, to each of which is attached a pair of spinal nerves.

The *filum terminale* (figs. 824, 825) is a delicate filament, about 20 cm. long, continued downwards from the apex of the conus medullaris. Its upper part, or *filum terminale internum*, about 15 cm. long, is continued within the tubular sheath of dura and arachnoid mater, and reaches as far as the lower border of the second sacral vertebra. It is surrounded by the nerve-roots forming the cauda equina,

FIG. 824.—The cauda equina and filum terminale seen from behind. The dura mater has been opened and spread out, and the arachnoid mater has been removed.

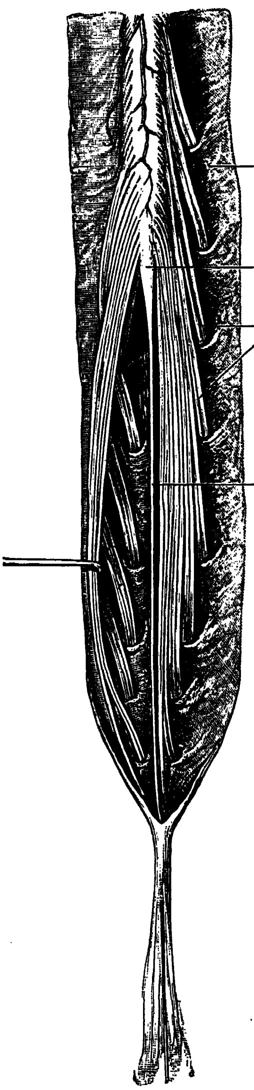


FIG. 825.—Diagrams of the spinal cord.

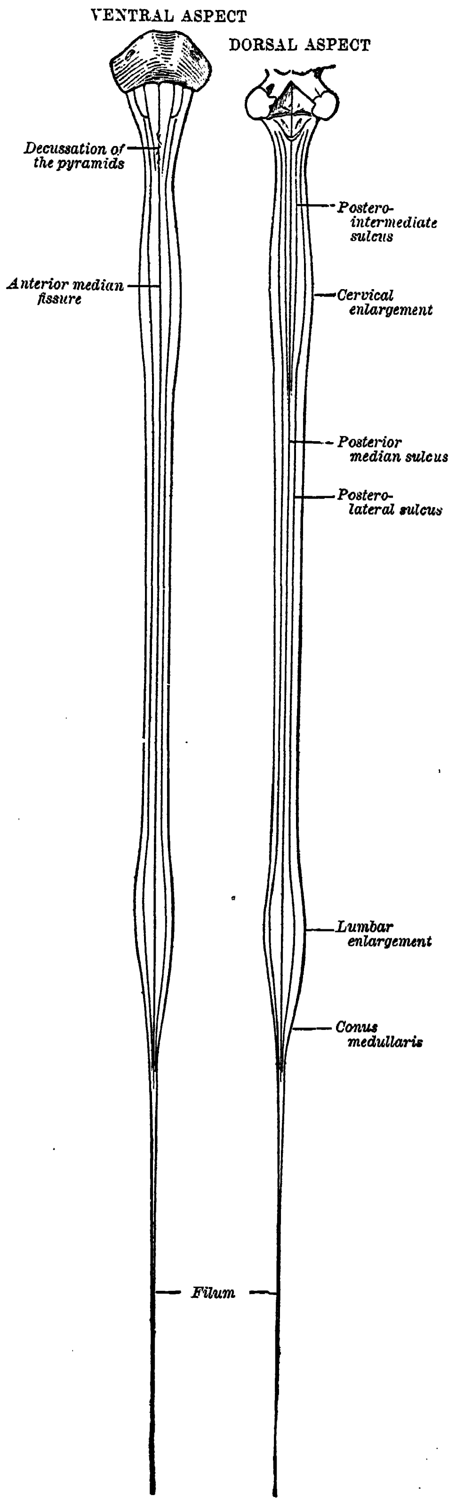
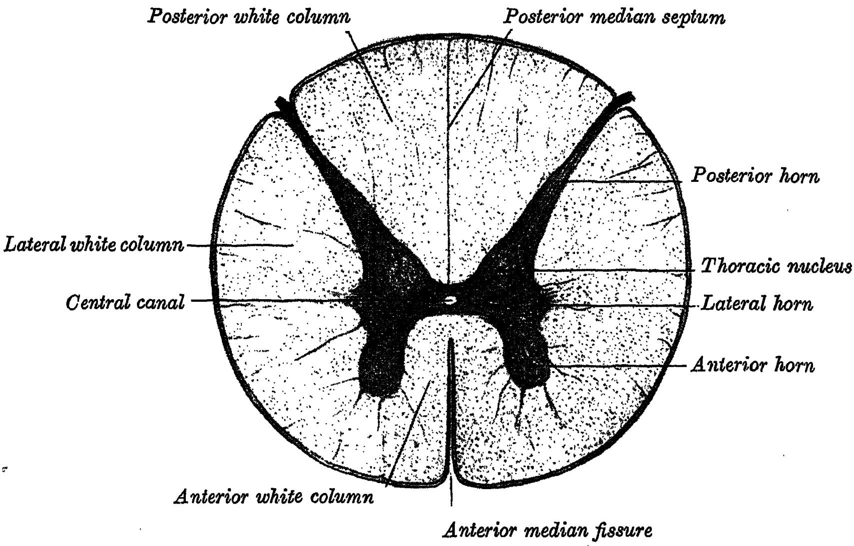


but can be readily distinguished from them by its bluish-white colour. Its lower part, or *filum terminale externum*, is closely invested by, and adherent to, the dura mater ; it descends from the apex of the tubular sheath of dura mater and is attached to the back of the first segment of the coccyx. The filum terminale consists mainly of fibrous tissue, continuous above with that of the pia mater, but adhering to the outer surface of its upper part are a few strands of nerve-fibres which probably represent the nerve-roots of rudimentary second and third coccygeal nerves ; further, the central canal of the spinal cord is continued downwards into it for 5 or 6 cm.

Enlargements.—The spinal cord is not quite cylindrical, being slightly flattened from before backwards ; it also presents two swellings or enlargements, an upper or cervical, and a lower or lumbar (fig. 825).

The *cervical enlargement* is the more pronounced, and corresponds with the attachments of the large nerves of the upper limbs. It extends from the third cervical to the second thoracic vertebra, its maximum circumference (about 38 mm.) being at the level of the roots of the sixth pair of cervical nerves.

FIG. 826.—A transverse section through the mid-thoracic region of the spinal cord. ×8.



The *lumbar enlargement* corresponds with the attachments of the nerves of the lower limbs. It begins at the level of the ninth thoracic vertebra, and reaches its maximum circumference—about 33 mm.—opposite the last thoracic vertebra, below which it tapers rapidly into the conus medullaris.

Fissures and sulci (fig. 826).—An anterior median fissure and a posterior median septum incompletely divide the spinal cord into two symmetrical parts, which are joined across the median plane by a commissural band of nervous matter.

The *anterior median fissure* has an average depth of about 3 mm., but is deepest in the lower part of the spinal cord. It contains a reticulum of pia mater, and its floor is formed by a transverse band of white matter, termed the *anterior white commissure*, which is perforated by blood-vessels on their way to or from the central part of the spinal cord.

The *posterior median sulcus* is very shallow ; from it a septum of neuroglia reaches rather more than half-way into the substance of the spinal cord ; this septum varies in depth from 4 to 6 mm., but diminishes considerably as it is traced downwards.

On each side of the posterior median sulcus, and at a short distance from it, the posterior nerve-roots are attached along a vertical furrow (B.N.A. *posterolateral sulcus*). The portion of the spinal cord which lies between this and the posterior median septum is named the *posterior white column* (posterior

funiculus). In the cervical and upper thoracic regions the surface of this white column presents a longitudinal furrow (B.N.A. *postero-intermediate sulcus*) : this marks the position of a septum which extends into the posterior white column and subdivides it into two fasciculi—a medial, named the *fasciculus gracilis* ; and a lateral, the *fasciculus cuneatus* (fig. 831).

The portion of the spinal cord between the posterolateral sulcus and the anterior median fissure is termed the *anterolateral region.* The anterior nerve-roots, unlike the posterior, are not attached in linear series, and their positions of exit are not marked by a sulcus ; they arise by separate bundles which spring from the anterior grey column and, passing forward through the white matter, emerge over an area of some width. The line of emergence of the most lateral of these bundles is generally taken as the dividing line which separates the anterolateral region into two parts, viz. an *anterior white column,* between the anterior median fissure and the most lateral of the anterior nerve-roots ; and a *lateral white column,* between the exit of these roots and the posterolateral sulcus. In the upper part of the cervical region a series of nerve-roots passes outwards through the lateral white column ; these unite to form the spinal root of the accessory nerve, which ascends and enters the cranial cavity through the foramen magnum (fig. 839), and conveys to the accessory nerve the fibres which supply the Sternomastoid and Trapezius.

Development of the Spinal Cord

Although the development of the spinal cord has been dealt with in a preceding section (pp. 104-108) the following summary will be found useful for a proper appreciation of the internal structure of the adult spinal cord.

The cavity of the neural tube in the region of the spinal cord becomes narrowed down to a dorsiventral slit by the growth of its lateral walls. During the fifth week of development a longitudinal groove, termed the *sulcus limitans,* appears on the inner surface of the lateral wall. This sulcus is the earliest sign of the differentiation of the wall into two functionally distinct areas. The anterior area, or *basal lamina,* contains cells which belong to the efferent pathway and are consequently motor in function ; the posterior area, or *alar lamina,* contains cells which belong to the afferent pathway. The cells in the anterior part of the basal lamina belong to the somatic efferent component, and their axons are distributed to the voluntary musculature of the body. The cells in the dorsal part of the basal lamina belong to the visceral efferent component and their axons, after being relayed in a sympathetic or parasympathetic ganglion, are distributed to the involuntary muscle of the viscera and blood-vessels. In the highest segments of the spinal cord and the hind-brain a third group of cells develops in the basal lamina and lies in an intermediate position between the two groups which have just been described. These cells distribute their axons to the voluntary muscles which develop in association with the visceral or branchial arches (fig. 840).

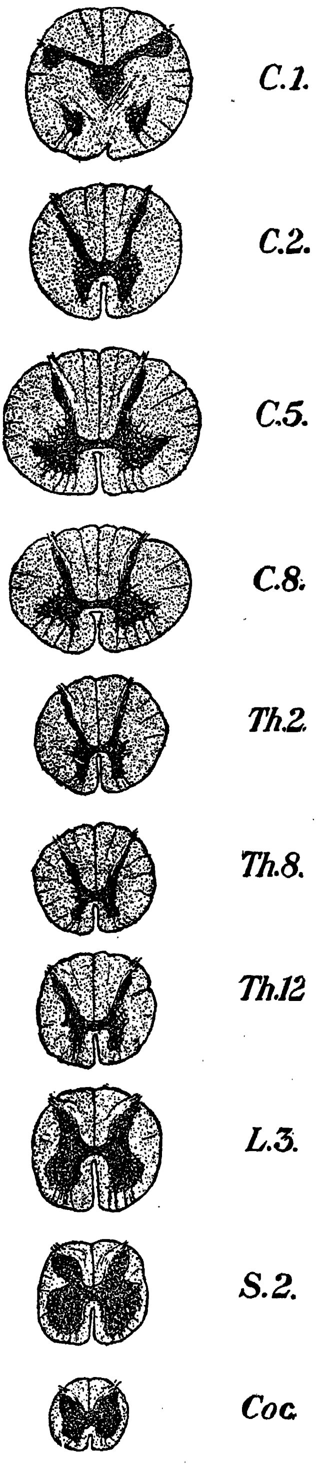
This early functional differentiation of the wall of the neural tube is reflected in the adult spinal cord, for the nerve-cells retain their primitive relationships to a very large extent, as will be seen later.

The character of the lumen of the tube undergoes a striking change during the second and third months of intra-uterine life. Dorsal to the limiting sulcus, the walls become approximated and unite with each other so that the lumen becomes obliterated in its posterior part, while its anterior part persists as a small canal. Incoming fibres from the spinal ganglia collect at first on the dorsilateral aspect of the spinal cord, but as growth proceeds and the grey matter derived from the alar lamina extends in a dorsilateral direction they come to lie at first dorsal to it and finally insinuate themselves between it and the posterior median septum.

While these changes are occurring in the alar lamina and the dorsal half of the spinal cord the cells of the basal lamina are proliferating rapidly, and the grey matter so formed extends in an anterolateral direction. The floor plate at first undergoes little change, so that, as a result of the growth of the adjoining grey matter, a surface elevation is produced on each side of

the median plane anteriorly, and further growth converts the shallow sulcus—which separates them at first—into a deep anterior median fissure (figs. 138, 823). Nerve-cells and nerve-fibres invade the floor plate and constitute the grey and white commissures.

Fig. 827.—Transverse sections through the spinal cord at different levels.



Large efferent tracts grow down from the brain into the lateral and anterior parts of the spinal cord, intervening between the surface and the derivatives of the alar and basal laminæ. Further thickening of these areas is produced by the passage into them of important ascending tracts, whose constituent fibres arise from the cells derived from the alar laminæ.

Internal Structure of the Spinal Cord

The spinal cord is composed of grey and white nervous matter, in both of which there is a supporting framework of neuroglia.

The **grey matter** [substantia grisea] is situated centrally and has the form of a fluted column which runs through its whole length. On transverse section of the spinal cord this column is seen to consist of right and left symmetrical portions connected by a transverse commissure of grey matter, the whole bearing a resemblance to the letter H. The transverse grey commissure is traversed by the central canal, which is just visible to the naked eye. Each lateral portion is shaped like a crescent with its concavity directed laterally, and, as seen on transverse section, can be divided into anterior and posterior horns * according to their relation to the transverse grey commissure.

The **anterior horn** is directed forwards and somewhat laterally. It is short but broad in proportion and fails to reach the surface of the spinal cord, from which it is separated by the anterior white column. The posterior part of the anterior horn is termed the *base*, and the anterior part the *head*, but they are not separated from each other by any definite constriction.

The **posterior horn** is directed backwards and somewhat laterally. It is long and slender, and reaches almost as far as the posterolateral sulcus, from which it is separated by a thin coating of white matter, named the *posterolateral tract*. It consists of a *base*, which is continuous with the base of the anterior horn, a constricted *neck*, and an oval or fusiform *head*, the *apex* of which is capped by a mass of translucent nervous tissue, termed the *substantia gelatinosa*. This gelatinous substance is V-shaped or crescentic in transverse section, and contains both neuroglia and nerve-cells.

A pointed projection from the lateral surface of the grey matter opposite the transverse commissure

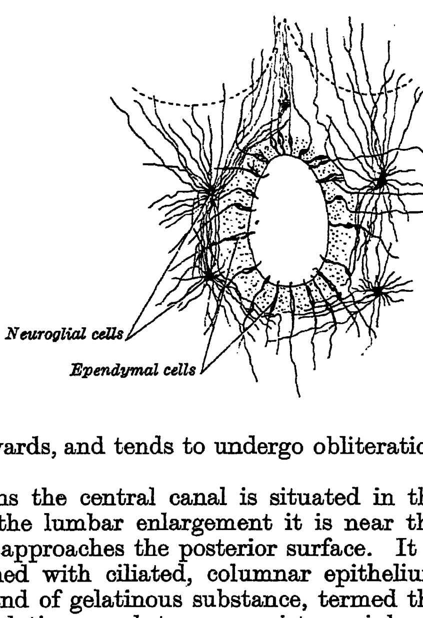
* It should be observed that the terms 'anterior horn,' 'posterior horn' and 'lateral horn' are used only with reference to transverse sections of the spinal cord. When the grey matter of the spinal cord as a whole is under consideration, the terms 'anterior grey column,' 'posterior grey column' and 'lateral grey column' are employed.

constitutes the **lateral horn**. It is easily recognisable in transverse sections through the thoracic and first lumbar segments of the spinal cord, but not elsewhere.

The limits of the grey matter are, as a rule, clearly defined, but in the cervical region strands of grey matter extend into the lateral white column, where they form a network, termed the *formatio reticularis*, opposite the base of the posterior horn. Traces of this reticular formation can be seen also in lower segments.

The quantity of grey matter and the form it presents on transverse section vary at different levels. In the thoracic region the grey matter is small in amount, not only absolutely but relatively to the surrounding white matter. In the cervical and lumbar enlargements, to which the nerves of the limbs are attached, it is greatly increased; so that in the latter, and especially in the conus medullaris, its proportion to the white matter is greater than elsewhere (fig. 829). In the cervical region the posterior horn is comparatively narrow, while the anterior horn is broad and expanded; in the thoracic region, the anterior and posterior horns are narrow, and the lateral horn is evident; in the lumbar enlargement the anterior and posterior horns are both broad; while in the conus medullaris the grey matter assumes the form of two oval masses, one in each half of the spinal cord, connected together by a broad grey commissure. The motor nerves to the limbs arise from groups of nerve-cells which occupy the lateral parts of the broad anterior grey columns in the cervical and lumbar enlargements.

Fig. 828.—A transverse section through the central canal of the spinal cord, showing the ependymal and neuroglial cells. (Lenhossék.)



The **central canal** traverses the entire length of the spinal cord. It is continued upwards through the lower part of the medulla oblongata and opens into the fourth ventricle of the brain; below, it reaches for a short distance (5·6 cm.) into the filum terminale. In the lower part of the conus medullaris it exhibits a fusiform dilatation (the *terminal ventricle*), which has a vertical measurement of from 8 to 10 mm., is triangular on cross section with its base directed forwards, and tends to undergo obliteration after the age of forty years.

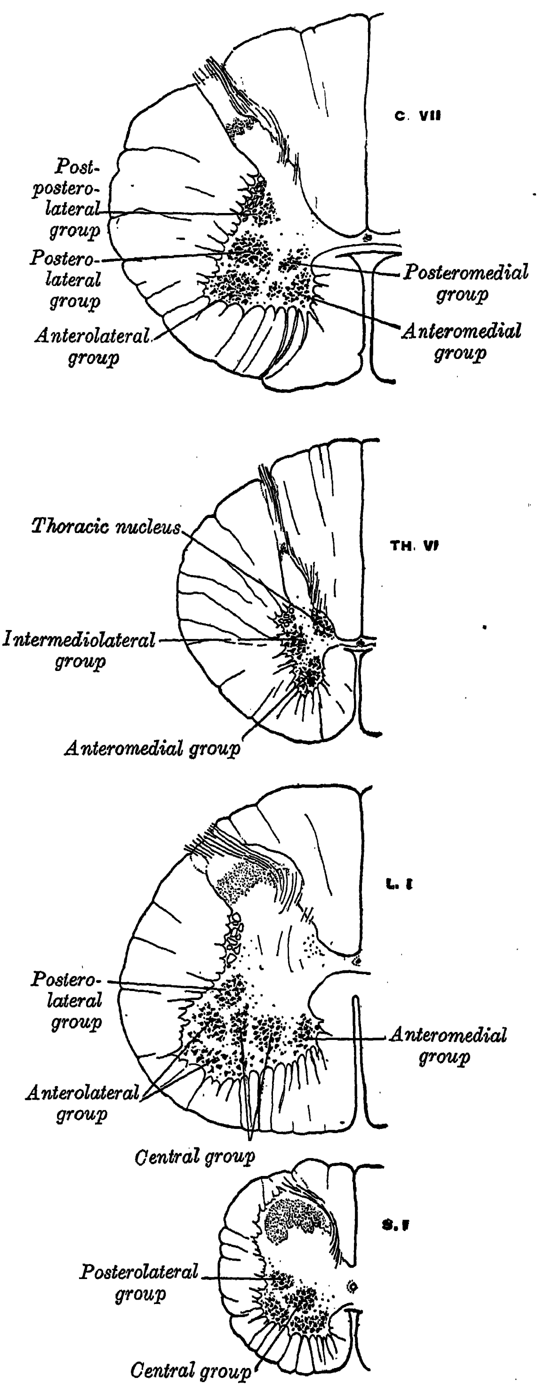
In the cervical and thoracic regions the central canal is situated in the anterior part of the spinal cord: in the lumbar enlargement it is near the middle, and in the conus medullaris it approaches the posterior surface. It is filled with cerebrospinal fluid, and lined with ciliated, columnar epithelium (*ependyma*), which is encircled by a band of gelatinous substance, termed the *substantia gelatinosa centralis*. This gelatinous substance consists mainly of neuroglia, but contains a few nerve-cells and nerve-fibres; it is traversed by processes from the deep ends of the columnar cells which line the central canal (fig. 828).

The grey matter surrounding the canal is named the *grey commissure*. The part in front of the canal is thin, and in contact with the white commissure: it contains a pair of longitudinal veins, one on each side of the median plane. The part behind the canal reaches from the central canal to the posterior median septum; it is thinnest in the thoracic region, and thickest in the conus medullaris.

The structure of the grey matter.—The grey matter of the spinal cord consists of neuroglia, nerve-cells, and nerve-fibres. Throughout the greater part of it the neuroglia is arranged in the form of a sponge-like network, but around the central canal and on the apices of the posterior horns it is condensed to form the gelatinous substance already referred to. The nerve-cells are multipolar, and vary greatly in size and shape, but they may be classified in four main types: (1) Motor cells of large size are found in the anterior grey

column throughout the whole length of the spinal cord. Their axons enter the anterior nerve-roots of the spinal nerves and are distributed to the voluntary musculature. Before leaving the spinal cord they frequently give off collaterals which re-enter and ramify in the grey matter. These large cells are derived from the ventral part of the basal lamina. (2) Motor cells of smaller size are found throughout the lateral grey column. Their axons join the anterior nerve-roots, but they are destined for a sympathetic ganglion where they are relayed to the visceral musculature. (3) Smaller cells, belonging to Golgi's type I, are found throughout the posterior grey column. Their axons, on reaching the white matter, may ascend to higher levels in the spinal cord or may reach the brain; or, they may descend to lower segments of the spinal cord: or, they may divide dichotomously into ascending and descending branches. (4) A few of the small cells found in the posterior grey column and the substantia gelatinosa belong to Golgi's type II. Their axons, therefore, do not leave the grey matter, and are usually short and confined to one segment (intrasegmental neurones). Most of these neurones are confined to one side of the spinal cord. Those whose axons terminate in the grey matter at higher or lower levels constitute *intersegmental neurones*, and serve to link up the different parts of the spinal cord to one another. Some of the axons traverse the white commissure and terminate in the grey matter of the opposite side. They are termed *crossed commissural fibres*.

Fig. 829.—Transverse sections through the spinal cord at different levels, showing the arrangement of the principal cell-columns.



Most of the nerve-cells are arranged in longitudinal columns, and they therefore appear as groups on transverse section (fig. 829).

Nerve-cells in the anterior grey column.—The nerve-cells in the anterior grey column are arranged in columns of varying length. The longest of them occupies the anteromedial portion of the anterior grey column, and constitutes in transverse sections the *anteromedial group* of the anterior horn. It extends

from the first cervical to the fourth lumbar segments and reappears again in the third and fourth sacral segments, being at its widest in the fourth and fifth cervical segments. A second collection of cells, named the *posteromedial group*, is present in the sixth and seventh cervical and absent from the succeeding two segments, and thereafter extends from the second thoracic to the first lumbar segment, lying immediately posterior to the anteromedial group. There is strong presumptive evidence, from the position and extent of these two columns, for supposing that they innervate the muscles of the trunk, and that the enlargement of the anteromedial group in the fourth and fifth cervical segments indicates the cells of origin of the phrenic nerve.

The other cell-groups in the anterior grey column are more localised and are found in the upper cervical region, and in the cervical and lumbar enlargements. A group of cells is found in the first, second and third cervical segments, lying to the lateral side of the anteromedial group and somewhat dorsal to it. These cells send their axons through the lateral white column to emerge midway between the anterior and posterior nerve-roots, where they constitute the spinal root of the accessory nerve. This group of cells probably represents the branchial (special visceral) efferent group in the basal lamina (fig. 840).

Both in the cervical and in the lumbar enlargements the anterior grey column widens out in a lateral direction, and contains groups of cells which have been classified as anterolateral, posterolateral, post-posterolateral and central. The *anterolateral group* does not extend into the first thoracic or third sacral segments, while the post-posterolateral group is only found in the eighth cervical, first thoracic and the upper three sacral segments. The central group is not present as a separate entity in the cervical enlargement, but it is present from the second lumbar down to the upper part of the second sacral segment.

The functional significance of these cell-groups is difficult to determine. It is possible that the definition of anterolateral and posterolateral groups may be associated with the primitive arrangement of the musculature of the limbs into ventral or flexor and dorsal or extensor groups.

The motor cells in the anterior grey column constitute the last neurone in the efferent pathway. Through their numerous dendrites they receive nerve impulses from a variety of sources and transmit them to the effectors, which are, in this way and at different times, brought under the control of the cerebral cortex, the cerebellum, the corpus striatum, the vestibular apparatus, etc. But the motor cells of the anterior grey column exercise a special influence of their own over the muscular apparatus apart altogether from the stimuli which they merely transmit. Destruction of the motor cells, or the division of their axons, is followed by the phenomena of muscular degeneration, *phenomena which do not result from any other lesion or combination of lesions of the nervous system*. Destruction of the great efferent pathway from the brain will cause paralysis and, after a period, atrophy of the muscle fibres, but the muscle retains its peculiar structure. This variety of control exerted by the nerve-cells of the anterior grey column is referred to as *idiodynamic control*. It must be remembered, however, that these cells, when cut off from all other sources of stimulation, are not themselves able to generate impulses which throw the effector into a state of contraction.

For local reflexes the anterior column cells stand in connexion with posterior column cells of the same segment, and the constant stream of impulses which they receive from this source is responsible for the reflex activity of muscle fibres and for their normal myotonus. Section of the posterior nerve-roots interrupts the intrasegmental reflex arc and, therefore, abolishes both these forms of activity.

Volitional control is exercised by the cerebrospinal (pyramidal) tract acting through the dendrites of the cells in the anterior grey column. But in order that the muscles may respond rapidly and effectively to volitional control they must be in a state of ' ideal tonus,' and this condition is brought about by the influence of the cerebrospinal tract. Destruction of this great motor pathway results, therefore, not only in the paralysis of all volitional movement but also in hypertonicity of the affected muscles. This increase in muscle tonus is due to the loss of the inhibitory control exercised by the cortex. Spasticity of a paralysed limb is characteristic of an upper motor neurone lesion.

Synergic control is exercised by the cerebellum and is essential for co-ordination of different muscles and muscle groups during the performance of volitional movements. The efferent pathway from the cerebellum passes to the red nucleus in the mid-brain and

then travels by the rubrospinal tract to the cells in the anterior grey column. The interruption of this pathway leads to muscular incoordination during the performance of voluntary movements, which are then carried out in a jerky and exaggerated manner.

The corpus striatum may possibly exercise control over automatic associated movements (p. 1013); its efferent pathway runs through the red nucleus and the rubrospinal tract. In some cases of hemiplegia, a patient, paralysed in the upper and lower limbs of the same side so far as volitional control is concerned, may, especially on yawning when waking from sleep, stretch both arms above his head. This movement is carried out unconsciously and always in association with the limb of the opposite side; it has been explained as an automatic associated movement inaugurated by the corpus striatum.

The vestibular apparatus controls unconscious equilibratory movements. The efferent pathway runs direct from the lateral nucleus of the vestibular nerve to the cells in the anterior grey column in the vestibulospinal tract.

Nerve-cells in the lateral grey column.—The cells in this column constitute a single group, named the *intermediolateral group*. It extends from the first

Fig. 830.—A scheme showing the mode of distribution of the nerve-cells in the grey matter. (Testut.)

Nerve-cell of anterior horn, the axon of which is passing into the posterior nerve-root. 7. Cells of substantia gelatinosa centralis. 8. Solitary cell. 9. Cells of Golgi. 10. Cells of origin of the anterior spino-cerebellar tract. 11. Anterior root. 12. Posterior root. 13. Spinal ganglion.

thoracic to the first lumbar segment and reappears again in the second, third and fourth sacral segments. In the longer upper part of its extent this cell-group is responsible for the surface projection of the lateral grey column, and its axons pass out in the anterior nerve-roots, and traverse the white rami communicantes to reach the sympathetic gangliated trunk. Finally they are distributed to glands and cardiac or unstriped muscle. In the sacral part of its extent this cell-group is overshadowed by the large posterolateral group and so produces no surface projection. Its axons traverse the anterior nerve-roots and anterior primary rami of the corresponding sacral nerves and eventually constitute the 'pelvic splanchnic nerves' (p. 1138), which represent the sacral contribution to the parasympathetic system.

It should be remembered that this cell-group is a derivative of the dorsal part of the basal lamina (fig. 840), and it retains the same relative position in the adult.

Nerve-cells in the posterior grey column.—1. The *thoracic nucleus* (nucleus dorsalis) occupies the medial part of the base of the posterior grey column, and appears on transverse section as a well-defined oval area (figs. 829, 830). It begins below at the level of the first or second lumbar nerve, and reaches its maximum size opposite the twelfth thoracic nerve. It diminishes in size above the level of the ninth thoracic nerve, and ends opposite the last cervical or first thoracic nerve. Its cells are of medium size, and oval or pyriform in shape; most of their axons pass into the peripheral part of the lateral white column of the same side, and there ascend, under the name of the *posterior spino-cerebellar tract*; a few cross to the opposite side and ascend in the *anterior spino-cerebellar tract*. In the upper cervical region, and again in the middle and lower sacral regions, the posteromedial part of the base of the posterior grey column is occupied by a group of small cells. These two groups are known as the *cervical* and *sacral nuclei*, but, although they occupy the same relative position as the thoracic nucleus, the structure of their cells and the arrangement of the Nissl's bodies show little in common with it, and apparently no close functional relationship exists between them.

2. *Nerve-cells in the substantia gelatinosa.*—These are arranged in three zones: a posterior or marginal, of triangular or fusiform cells; an intermediate, of small fusiform cells; and an anterior, of star-shaped cells. The axons of these cells pass into the lateral and posterior white columns, and there pursue a vertical course. Some of the cells in the anterior zone belong to Golgi's type II, their short axons being confined to the grey matter.

3. *Solitary cells* of varying form and size are scattered throughout the posterior grey column. Some of these are grouped to form an ill-defined *posterior basal column*, lateral to the thoracic nucleus. The axons of the cells of this column pass partly to the posterior and lateral white columns of the same side, and partly through the white commissure to the lateral white column of the opposite side. Before leaving the grey matter, a considerable number run longitudinally for a varying distance in the head of the posterior grey column, forming what is termed the *longitudinal fasciculus* of the posterior column.

A few star-shaped or fusiform nerve-cells of varying size are found in the substantia gelatinosa centralis. Their axons pass into the lateral white column of the same, or of the opposite, side.

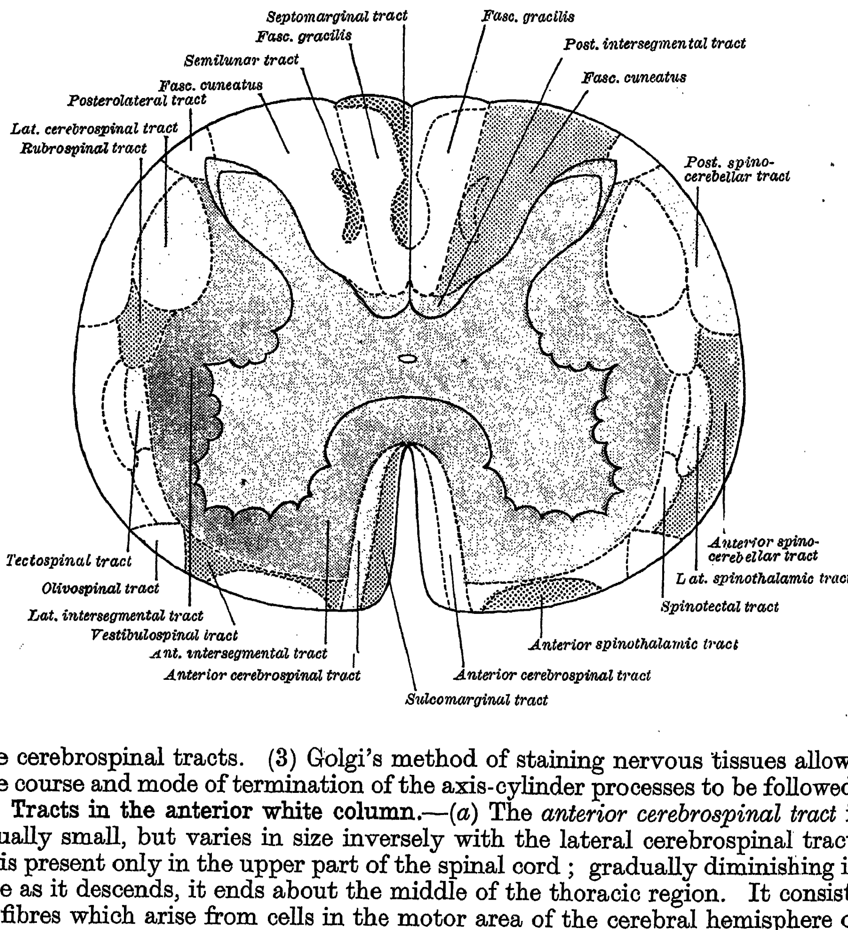
The nerve-fibres in the grey matter form a dense interlacement among the nerve-cells. This interlacement is formed partly of axons which pass from the cells in the grey matter to enter the white columns or the anterior nerve-roots; partly of the axons of Golgi's cells type II, which ramify only in the grey matter; and partly of collaterals from the nerve-fibres in the white columns, which, as already stated, enter the grey matter and ramify within it.

The **white matter** [substantia alba] of the spinal cord surrounds the grey matter, and consists chiefly of medullated nerve-fibres. The nerve-fibres are arranged in three white columns: anterior, lateral, and posterior. The anterior white column lies between the anterior median fissure and the most lateral of the anterior nerve-roots; the lateral, between these nerve-roots and the postero-lateral sulcus; and the posterior, between the posterolateral sulcus and the posterior median septum (fig. 831). The nerve-fibres vary in thickness; the thinnest are found in the fasciculus gracilis, the posterolateral tract (p. 901), and the central part of the lateral white column; the thickest are situated in the anterior white column, and in the peripheral part of the lateral white column. Some of the nerve-fibres run more or less transversely, as for example those which cross the median plane in the white commissure, but the majority pursue a longitudinal course and are divisible into (1) those connecting the spinal cord with the brain and conveying impulses to or from the latter, and (2) those which are confined to the spinal cord, and link together its different segments (i.e. intersegmental or association fibres).

Nerve-fasciculi or tracts.—The longitudinal fibres are grouped into more or less definite bundles or tracts. These are not recognisable from one another in the natural state, for the individual tracts are not surrounded by special sheaths, and their identity has been established by the following methods. (1) A. Waller discovered that if a bundle of nerve-fibres is cut, the portions of the fibres which are separated from their cells rapidly degenerate and become

atrophied. This is known as *Wallerian degeneration.** Similarly, if a group of nerve-cells is destroyed, the fibres arising from them undergo degeneration. Thus, if the motor cells of the cerebral cortex are destroyed, or if the fibres arising from these cells are severed, a *descending degeneration* from the seat of injury takes place in the fibres. In the same manner, if a spinal ganglion is destroyed, or the fibres which pass from it into the spinal cord be cut, an *ascending degeneration* occurs in these fibres above the lesion. (2) In the early stages of the development of the nervous system, the nerve-fibres are naked axis-cylinders ; groups of nerve-fibres acquire their medullary sheaths at different periods ; hence the fibres can be grouped according to the dates at which they receive these sheaths. The first fibres to acquire medullary sheaths are those of the nerve-roots and of the intersegmental tracts, the last, those of

FIG. 831.—A diagram of the principal tracts of the white matter of the spinal cord.



the cerebrospinal tracts. (3) Golgi's method of staining nervous tissues allows the course and mode of termination of the axis-cylinder processes to be followed.

Tracts in the anterior white column.—(*a*) The *anterior cerebrospinal tract* is usually small, but varies in size inversely with the lateral cerebrospinal tract. It is present only in the upper part of the spinal cord ; gradually diminishing in size as it descends, it ends about the middle of the thoracic region. It consists of fibres which arise from cells in the motor area of the cerebral hemisphere of the same side, and which, as they run downwards in the spinal cord, cross in succession through the white commissure to the opposite side, where they end by arborising around the motor cells in the anterior grey column. This tract is found only in man and in the anthropoid apes, but its precise significance is unknown.

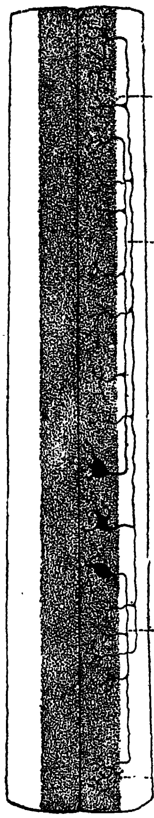
(*b*) The *vestibulospinal tract*, which is derived from the large cells of the lateral vestibular nucleus (p. 922), descends in the anterior white column ;

* Somewhat later a change, termed *chromatolysis*, takes place in the nerve-cells, and consists of the breaking down and ultimate disappearance of the Nissl's bodies. The cell-body swells, the nucleus is displaced towards the periphery of the cell, and the part of the axon still attached to the altered cell diminishes in size and atrophies. Under favourable conditions the cell may resume its normal appearance, and its axon may grow again.

its fibres end around the cells in the anterior grey column. This fasciculus is uncrossed and brings the anterior column cells under the control of the vestibular nuclei of the same side, serving as the efferent path for equilibratory control.

(c) The *anterior spinothalamic tract* is described here as one of the ascending pathways in the anterior white column, although the evidence in favour of its existence as a separate entity is not completely convincing. It has been suggested that it constitutes a pathway for the coarser elements of tactile sensibility, as distinguished from tactile discrimination (p. 883); its fibres are described as arising from cells in the posterior grey column of the opposite side of the spinal cord, ascend in the posterior white column for two or three segments and then cross in the white commissure to reach the anterior white column, in which they ascend to the thalamus.

Fig. 832.—A diagram showing in longitudinal section the intersegmental neurons of the spinal cord. The grey and white parts correspond respectively to the grey and white matter of the spinal cord. (Poirier.)



(d) A small *sulcomarginal tract** adjoins the anterior median fissure.

The remaining fibres of the anterior white column constitute the *anterior intersegmental tract* (fasciculus proprius anterior). It consists of longitudinal intersegmental fibres which arise from cells in the grey matter, and, after a longer or shorter course, re-enter the grey matter. Some of the fibres of this tract pass upwards into the medial longitudinal bundle (p. 949).

Tracts in the lateral white column.—1. Descending tracts.

(a) The *lateral cerebrospinal tract* (crossed pyramidal tract) extends throughout nearly the whole length of the spinal cord; it gradually diminishes in size as it descends, and ends about the level of the attachment of the third or fourth sacral nerves. On transverse section it appears as an oval area in front of the posterior horn and medial to the posterior spinocerebellar tract; in the lumbar and sacral regions, where the posterior spinocerebellar tract is absent, the lateral cerebrospinal tract reaches the surface of the spinal cord. Its fibres arise from cells in the motor area of the cerebral hemisphere of the opposite side. They pass downwards in company with those of the anterior cerebrospinal tract, but cross to the opposite side in the medulla oblongata and descend in the lateral white column of the spinal cord; they end by arborising around the motor cells in the anterior grey column.†

The anterior and lateral cerebrospinal tracts constitute the motor pathway of the spinal cord and have their origins in the motor cells of the cerebral cortex. They descend through the internal capsule of the cerebrum, traverse the cerebral peduncle and pons, and enter the pyramid of the medulla oblongata. In the lower part of the pyramid about two-thirds of them cross the median plane and run downwards in the lateral white column as the lateral cerebrospinal tract while the remaining fibres do not cross, but are continued into the same side of the spinal cord, where they form the anterior cerebrospinal tract. Fibres

* According to some authorities this tract is formed by the crossed fibres of the tectospinal pathway (p. 900).

† Sir E. Sharpey-Schafer (*Proc. Physiological Soc.* 1899) says it is probable that the fibres of the anterior and lateral cerebrospinal tracts are not directly related with the cells of the anterior grey column, but terminate by arborising round the cells at the base of the posterior grey column, which in turn link them to the motor cells in the anterior column, usually of several segments of the spinal cord. In consequence of these interposed neurons the fibres of the cerebrospinal tracts correspond, not to individual muscles, but to associated groups of muscles.

of this tract cross in succession through the white commissure, and thus, generally speaking, all the motor fibres from one side of the brain reach the opposite side of the spinal cord. The proportion of fibres which cross in the medulla oblongata is not a constant one, and thus the anterior and lateral cerebrospinal tracts vary inversely in size. Sometimes the former is absent, and it is then presumed that complete decussation of the motor fibres has occurred in the medulla oblongata. There is experimental and clinical evidence to show that the lateral cerebrospinal tract contains a few fibres which are derived from the cerebral hemisphere of the same side (*uncrossed lateral cerebrospinal fibres*).

(*b*) The *rubrospinal tract* is anterior to the lateral cerebrospinal tract, and on transverse section appears as a somewhat triangular area. Its fibres descend from the mid-brain, where they have their origins in the cells of the red nucleus of the tegmentum of the opposite side ; they end by forming synapses with the cells in the anterior grey column. Through this tract the cells of the anterior grey column are brought under the control of the cerebellum and the corpus striatum. The former exercises synergic control, while the latter may possibly be associated with the control of automatic associated movements (p. 1013).

(*c*) The *tectospinal tract* is anterior to the rubrospinal tract ; its fibres originate in the superior quadrigeminal body of the opposite side,* and end by forming synapses with the cells in the anterior grey column. This tract provides the efferent pathway for visual reflexes.

(*d*) The *olivospinal tract* arises in the vicinity of the olivary nucleus (inferior olivary nucleus) in the medulla oblongata and is seen only in the cervical region of the spinal cord, where it forms a small triangular area at the periphery, close to the most lateral of the anterior nerve-roots. Its fibres form synapses with the cells in the anterior grey column. The functional significance of this tract is unknown, and, in view of the uncertainty which exists with regard to its precise origin in the medulla oblongata, it is frequently termed the *bulbospinal tract*.

2. **Ascending tracts.**—(*a*) The *posterior spino-cerebellar tract* is a flattened band situated at the periphery of the posterior portion of the lateral white column ; medially it is in contact with the lateral cerebrospinal tract ; behind, with the posterolateral tract. It begins about the level of the second or third lumbar nerve, increases in size as it ascends, and finally passes to the cerebellum through the inferior cerebellar peduncle. Its fibres are the axons of the cells of the thoracic nucleus of the same side.

(*b*) The *anterior spino-cerebellar tract*, as seen on transverse section, is a crescentic, flattened tract which occupies the periphery of the lateral white column, in front of the area occupied by the posterior spino-cerebellar tract. Its constituent fibres arise in the cells of the thoracic nucleus and of the adjoining part of the posterior grey column, both from the same and from the opposite half of the spinal cord. The tract commences in the upper lumbar region and extends upwards to the upper part of the pons, where it turns downwards and backwards in the superior cerebellar peduncle to reach the cerebellum.

The spino-cerebellar tracts form, in the main, a homolateral connexion between the spinal cord and the cerebellum. They convey to the cerebellum impulses arising in the locomotor apparatus and essential for the adjustments of muscle tonus and for synergic control during the performance of voluntary movements.

(*c*) The *lateral spinothalamic tract* lies medial to the anterior spino-cerebellar tract in the lateral white column of the spinal cord (fig. 831). Its constituent fibres arise in the head of the posterior grey column of the opposite side (possibly in the substantia gelatinosa) and soon cross the median plane in the white commissure. The tract ascends through the medulla oblongata, where it comes into close relationship with the anterior spinothalamic tract. The two ascend together as the *spinal lemniscus* and reach the ventral portion of the lateral nucleus of the thalamus, where they are relayed to the cerebral cortex.

The lateral spinothalamic tract is an exteroceptive pathway, conveying painful and thermal sensibility, without any discriminative quality so far as painful sensibility is concerned. It is believed that this crude form of sensibility is carried by the non-myelinated or very finely myelinated fibres in the spinal nerves. When they enter the spinal cord they have a tendency to lie

* According to some authorities this tract arises in the superior quadrigeminal body of the same side. See footnote *, p. 899.

on the lateral side of the other fibres of the posterior nerve-root, and they constitute the *posterolateral tract*, the fibres of which soon terminate in the substantia gelatinosa or the adjoining head of the posterior grey column.

Owing to the fact that the fibres which form the lateral spinothalamic tract cross at once, decussating with the corresponding fibres of the opposite side, lesions affecting the commissural area, such as occur in the disease termed syringomyelia, will produce a bilateral loss of painful and thermal sensibilities for the particular areas involved.

(*d*) The *spinotectal tract* is placed medial to the anterior spinocerebellar tract and anterior to the lateral spinothalamic tract. Its constituent fibres arise in the posterior grey column of the opposite side and soon cross the median plane to reach the lateral white column. They ascend to the mid-brain where they terminate in the superior quadrigeminal body (superior colliculus) of the tectum. They provide a pathway for spinovisual reflexes. In this connexion it is to be remembered that the superior quadrigeminal bodies constitute a reflex centre on the visual path and are not concerned with the transmission of visual impulses to the cerebral cortex. Afferent stimuli passing up the spinotectal tract result in movements of the head and eyes towards the source of stimulation.

(*e*) The *posterolateral tract* (fasciculus dorsilateralis) is a small strand situated at the tip of the posterior grey column, close to the entrance of the posterior nerve-roots. It consists of unmyelinated and finely myelinated fibres which do not receive their medullary sheaths until near the close of fœtal life. It is usually regarded as being formed by the lateral group of the fibres of the posterior nerve-roots, which ascend for a short distance in the tract and then enter the substantia gelatinosa, where new fibres arise and pass to the lateral spinothalamic tract. There is ground for supposing that the posterolateral tract is formed by the fibres which convey crude painful and thermal sensibilities in the spinal nerves.

(*f*) The *lateral intersegmental tract* (fasciculus proprius lateralis) constitutes the remainder of the lateral white column, and is continuous in front with the anterior intersegmental tract. It consists chiefly of intersegmental fibres which arise from cells in the grey matter, and, after a longer or shorter course, re-enter the grey matter and ramify in it. Most of the fibres of the anterior and lateral intersegmental tracts are confined to the same side but some cross to the opposite side of the spinal cord. Some of the fibres of the lateral intersegmental tract are continued upwards into the brain under the name of the medial longitudinal bundle. It is believed that this intersegmental pathway may function as an alternative route for exteroceptive sensibility.

Tracts in the posterior white column.—1. Ascending tracts.

This white column comprises two large tracts, viz. the fasciculus gracilis and the fasciculus cuneatus, which are separated from each other by the posterointermediate septum.

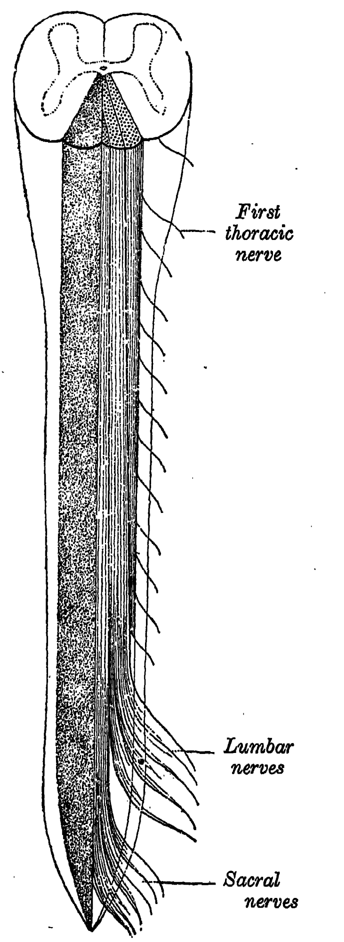
The *fasciculus gracilis* commences at the lowest limit of the spinal cord. Incoming fibres from the medial group of the fibres of the posterior nerve-roots on entering at the posterolateral sulcus divide into short descending and long ascending branches. The latter run upwards in the posterior funiculus, and as the tract ascends it receives accessions from each posterior nerve-root. The fibres which enter in the coccygeal and lower sacral regions are thrust medially by the fibres which enter at a higher level. The fasciculus gracilis, which contains fibres derived from the lower thoracic, lumbar, sacral and coccygeal segments, occupies the medial part of the posterior white column in the upper part of the spinal cord. The *fasciculus cuneatus* commences in the mid-thoracic region and derives its fibres from the posterior roots of the upper thoracic and cervical nerves and, in consequence, is placed on the lateral side of the fasciculus gracilis.

Both fasciculi are heavily myelinated, and the fibres of which they are comprised are larger in the fasciculus cuneatus than they are in the fasciculus gracilis. They ascend uncrossed to the medulla oblongata and terminate there in the nucleus gracilis and cuneatus. Relayed in these nuclei, the majority of the fibres sweep ventrally round the central grey matter (fig. 844), as the *internal arcuate fibres*, and take part in the great sensory decussation. Thereafter, as the *medial lemnisci*, they ascend on each side to the ventral portion of

the lateral nucleus of the thalamus and are there relayed to the cortex of the post-central gyrus. Through the medium of the *external arcuate* fibres (pp. 917 and 919) the remaining fibres of the posterior white column are relayed to the cerebellum.

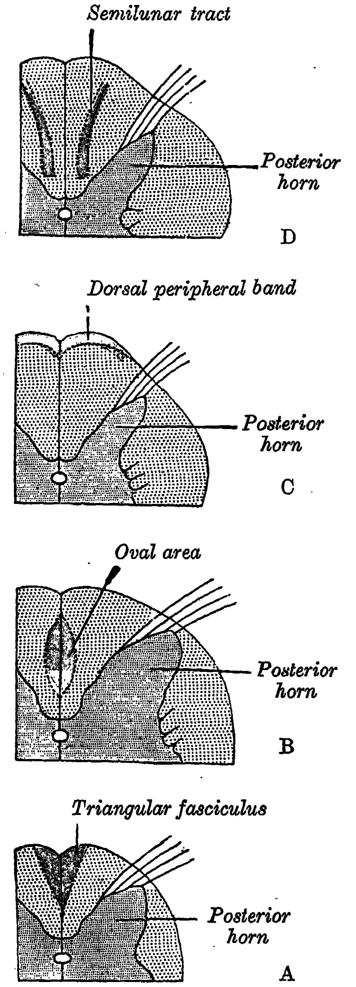
These two tracts, which occupy nearly the whole of the posterior white column, convey all the elements of deep sensibility, with the possible exception

Fig. 833.—A diagram showing the formation of the fasciculus gracilis (Poirier).



The spinal cord viewed from behind. To the left, the fasciculus gracilis is shaded. To the right, the drawing shows that the fasciculus gracilis is formed by the long ascending fibres of the posterior roots and that the sacral nerves lie next the median plane, the lumbar to their lateral side, and the thoracic still more laterally.

Fig. 834.—The descending fibres in the posterior white columns, shown at different levels. (After Testut.)



A. In the conus medullaris. B. In the lumbar region. C. In the lower thoracic region. E. In the upper thoracic region.

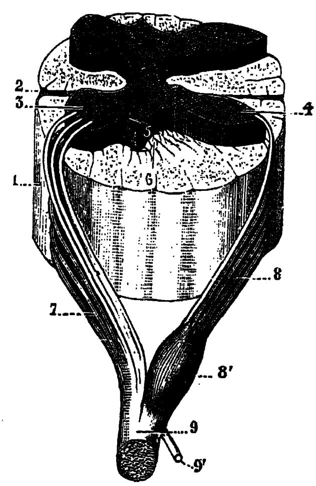
of pressure and pressure pain, and in addition they convey all the afferent fibres which are involved in discriminative sensibility. The higher forms of sensibility, which include tactile discrimination and localisation, all pass up to the medulla oblongata uncrossed in the posterior white columns, together with the fibres which convey sensations of posture and of movements, both active and passive. It is interesting to observe that the exteroceptive pathways of the lateral and anterior white columns are phylogenetically much older than the proprioceptive and discriminative pathway of the posterior white column.

2. **Descending tracts.**—The posterior white column contains some descending fibres which occupy different parts at different levels (figs. 831, 834). In the

cervical and upper thoracic regions they appear as a comma-shaped fasciculus, termed the *semilunar tract*, in the medial part of the fasciculus cuneatus, the blunt end of the fasciculus being directed forwards. In the lower thoracic region they form a *dorsal peripheral strand* on the posterior surface of the spinal cord ; in the lumbar region they are situated by the side of the posterior median septum, and appear on section as a semi-oval bundle ; in the conus medullaris they assume the form of a *triangular strand* in the posteromedial part of the fasciculus gracilis. Collectively these three strands constitute the *septomarginal tract*. These descending fibres in the posterior white column are mainly intersegmental in character and derived from cells in the posterior grey column, but some are said to consist of the descending branches of the medial divisions of the posterior nerve-roots (*vide infra*). The semilunar tract was supposed to belong to the second category, but against this view is the fact that it does not undergo descending degeneration when the posterior nerve-roots are destroyed.

Occupying the anterior or deepest part of the posterior white column is a small strand of fibres named the *posterior intersegmental tract* (fasciculus proprius posterior). It is somewhat crescentic on transverse section, and is placed between the grey commissure and the posterior white column; it is best marked in the lumbar region, but can be traced into the thoracic and cervical regions. Its fibres, which are intersegmental, are derived from the cells of the posterior grey column; they divide into ascending and descending branches which re-enter and ramify in the grey matter.

Fig. 835.—A spinal nerve with its anterior and posterior roots. (Testut.)



1. A portion of the spinal cord viewed from the left side. 2. Anterior median fissure. 3. Anterior grey column. 4. Posterior grey column. 5. Lateral grey column. 6. Formatio reticularis. 7. Anterior root. 8. Posterior root, with 8', its ganglion. 9. Spinal nerve; and 9', its posterior primary ramus.

Roots of the spinal nerves.—Each spinal nerve has two roots, an anterior and a posterior, which are attached to the surface of the spinal cord opposite the corresponding columns of grey matter (fig. 835). Medullation of their fibres precedes medullation of most of the fibres in the spinal cord (p. 898), and commences about the fourteenth week of fœtal life.

The *anterior nerve-root* consists mainly of motor fibres which are the axons of the nerve-cells in the anterior grey column, but in certain regions it contains also the efferent autonomic fibres from the cells in the lateral grey column. A short distance from their origins these axons are invested with medullary sheaths, and, passing forwards, emerge in two or three irregular rows over an area which measures about 3 mm. in width.

The *posterior nerve-root* comprises six or eight fasciculi, attached in linear series along the posterolateral sulcus. It consists of afferent fibres which arise from the nerve-cells in a spinal ganglion. Each ganglion-cell gives off a single fibre which divides in a T-shaped manner into two processes, medial and lateral. The medial processes of the ganglion-cells pass into the spinal cord as the posterior roots of the spinal nerves, while the lateral are directed towards the periphery.

As the posterior nerve-root enters the spinal cord its fibres tend to form medial and lateral bundles, which, however, are not sharply demarcated from each other. The *medial* strand passes directly into the posterior white column ; it consists of coarse fibres, which acquire their medullary sheaths between the fifth and the seventh month of intra-uterine life ; the *lateral* strand is mainly composed of fine fibres, many of which are non-medullated ; they enter the posterolateral tract (p. 901).

After entering the spinal cord, all the fibres of the posterior nerve-roots divide into ascending and descending branches, and these in their turn give

off collaterals which enter the grey matter. The descending branches are short, and soon enter the grey matter. The ascending branches are grouped into long, short and intermediate fibres; the long fibres ascend in the fasciculus cuneatus and fasciculus gracilis as far as the medulla oblongata, where they end by arborising around the cells of the cuneate and gracile nuclei; the short fibres run upwards for a distance of only 5 or 6 mm., and enter the grey matter; while the intermediate fibres, after a somewhat longer course, have a similar destination. All fibres entering the grey matter end by arborising around its nerve-cells; in the thoracic region those of intermediate length are especially associated with the cells of the thoracic nucleus. The collaterals which spring from the ascending and descending branches of the fibres of the posterior nerve-roots end by arborising around the cells in the posterior grey column; in the thoracic region many of these collaterals arborise around the cells of the thoracic nucleus and the cells of the lateral grey column.

THE PARTS OF THE BRAIN DERIVED FROM THE HIND-BRAIN OR RHOMBENCEPHALON

In the development of the spinal cord the reduction of the lumen of the neural tube into a central canal is a striking feature, and is brought about in part by the fusion of the opposed surfaces of the alar laminæ (p. 891). A similar process occurs in the hind-brain in its most caudal part only. Over the greater part of its extent the contained lumen becomes enormously widened, and the narrow roof-plate is expanded in a corresponding manner. The large cavity so formed constitutes the fourth ventricle of the brain.

The caudal portion of the hind-brain becomes the medulla oblongata, while its cephalic portion forms both the pons and the cerebellum. These three structures in the adult occupy the posterior cranial fossa. Below, the medulla oblongata passes through the foramen magnum to become continuous with the spinal cord. Above, the pons is continuous with the mid-brain, which connects it, indirectly, to the cerebrum (fig. 821). The cerebellum lies behind the pons and the medulla oblongata, and it is separated from the occipital lobes of the brain above by a fold of dura mater, named the tentorium cerebelli (p. 1024). It is connected to the brain stem by three pairs of peduncles, termed respectively the inferior, middle and superior cerebellar peduncles. The inferior cerebellar peduncles (restiform bodies) connect the cerebellum to the posterolateral aspects of the medulla oblongata: the middle cerebellar peduncles (brachia pontis) connect it to the corresponding aspects of the pons: the superior cerebellar peduncles (brachia conjunctiva) connect it to the corresponding aspects of the mid-brain.

When the medulla oblongata and the pons, on the one hand, are compared with the spinal cord on the other, it is found that, although they have many features in common, the medulla oblongata and the pons possess many features which are not found in the spinal cord. The enlargement of this part of the brain, therefore, does not indicate an enlargement of the constituent structures of the spinal cord but is to be attributed to the presence of new elements in addition to those which are present in the spinal cord.

The spinal cord shows obvious signs of its segmental origin. The metameric arrangement of its nerve-roots and the structure of its grey matter is sufficient evidence, even although the individual segments are not demarcated on its surface at any stage of its development. The structure of the medulla oblongata and of the pons shows signs of an original metamerism, but this has been profoundly altered by the superposition of a branchiomeric arrangement.

Reference to fig. 210 will show that during the fifth week of development the hind-brain lies in immediate relationship with the dorsal wall of the pharynx and the dorsal extremities of the branchial or visceral arches, and it is not surprising to find that it is from this region of the brain that the arches derive their nerve supply. In this way a branchiomeric arrangement of its constituents is strongly impressed on the medulla oblongata. It must be remembered that

the branchial apparatus in fishes constitutes the respiratory system. Oxygen-bearing water is taken into the mouth and expelled through the gill clefts, and as it flows over the pharyngeal aspects of the branchial arches, it oxygenates the blood which is circulating through them and relieves it of its carbon dioxide. This respiratory function naturally comes under the control of the hind-brain at this stage, and, at a later period in evolution, when the marine habitat was exchanged for a terrestrial one and the branchial apparatus was replaced by the pulmonary apparatus, the control of the new respiratory system remained vested in the same part of the brain. The proximity of the heart to the respiratory apparatus is essential, for the circulatory and respiratory systems must work harmoniously together. On this account the heart and the circulatory system are brought under the control and regulation of the hind-brain, which constitutes the controlling centre for the vital activities of the body.

The transition from a water to an air-breathing apparatus set free the branchial arches and their corresponding clefts and pouches, which were subsequently not allowed to atrophy and disappear in their entirety, but were adapted for new uses. The organs of the lateral line serve to convey to the fish vibrations arising in its vicinity, but these organs were not well adapted to the reception of waves in an air medium. At the headward end of the lateral line, the semicircular canals, the utricle and the saccule had developed to provide the receiving apparatus to enable the animal to maintain its equilibrium, and a further elaboration of this apparatus provided, in the cochlea, the mechanism for the perception of sound waves. New elements were therefore added to the hind-brain in connexion with this new acquisition.

The evolution of the limbs and the increased possibilities of movement which they conferred led to further changes in the structure of the hind-brain. The movements of the fish, though very generalised, are relatively simple, and their co-ordination does not call for any elaborate mechanism. Increased possibility of movement required increased powers of co-ordination in order that the animal might derive the maximum benefit. This demand was met by the growth and elaboration of the vestibular nuclei and the cerebellum, an organ which, as we have already seen, is responsible for synergic control.

To sum up, the hind-brain owes its importance to (1) its control over the heart and the respiratory apparatus ; (2) its control over the alimentary tract and its derivatives ; (3) its association with the modifications of the lateral line and branchial apparatus, which led to the acquisition, first, of the sense of hearing and, subsequently, of the power of phonation, and (4) its synergic control over the musculature of the body.

The Medulla Oblongata

The **medulla oblongata** extends from the lower margin of the pons to a transverse plane passing above the first pair of cervical nerves ; this plane corresponds with the upper border of the atlas behind, and the middle of the odontoid process of the axis in front ; at this level the medulla oblongata is continuous with the spinal cord. The anterior surface of the medulla oblongata is separated from the basilar part of the occipital bone and the upper part of the odontoid process by the membranes of the brain, and the occipito-axial ligaments. Posteriorly it is received into the fossa between the hemispheres of the cerebellum, and the upper portion of this surface forms the lower part of the floor of the fourth ventricle. The vertebral arteries pass upwards and forwards in relation to its lateral surfaces ; they then curve forwards to its anterior surface and unite at the lower border of the pons to form the basilar artery.

The medulla oblongata is somewhat piriform in shape (fig. 836), its broad extremity being directed upwards towards the pons, while its narrow lower end is continuous with the spinal cord. It measures about 3 cm. longitudinally, 2 cm. transversely at its widest part, and 1·25 cm. anteroposteriorly. The central canal of the spinal cord is prolonged into its lower half, and then opens into the cavity of the fourth ventricle ; the medulla oblongata may therefore be divided into a lower part containing the central canal, and an upper part corresponding with the lower portion of the fourth ventricle. Its anterior and posterior surfaces are marked by median fissures.

The **anterior median fissure** contains a short fold of pia mater, and extends along the entire length of the medulla oblongata; below, it is continuous with the anterior median fissure of the spinal cord; above, it ends at the lower border of the pons in a small triangular expansion termed the *foramen cæcum.* Its lower part is interrupted by bundles of fibres which cross obliquely from one side to the other, and constitute the *decussation of the pyramids.* Some fibres, termed the *external arcuate fibres,* emerge from the fissure above this decussation and curve laterally over the surface of the medulla oblongata.

FIG. 836.—The medulla oblongata, pons and mid-brain. Viewed from below.

The wall of the lateral recess of the fourth ventricle is shown in *blue,* and the choroid plexus which protrudes through the foramen of the lateral recess into the subarachnoid space is coloured *crimson.*

Note that the lateral recess covers the medial part of the flocculus and is itself partially obscured by the glossopharyngeal nerve.

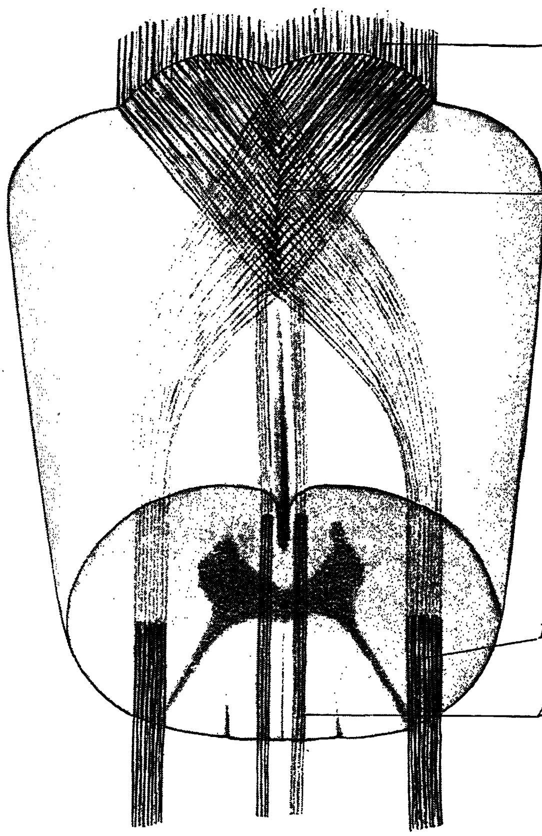
The **posterior median fissure** is a narrow groove which exists only in the closed part of the medulla oblongata; it is continuous below with the posterior median sulcus of the spinal cord, but becomes rapidly shallower from below upwards, and ends about the middle of the medulla oblongata, where the central canal expands into the cavity of the fourth ventricle.

The two fissures divide the lower part of the medulla oblongata into lateral halves which, on surface view, appear to be continuous with the halves of the spinal cord. In the upper part the halves are separated by the anterior median fissure, and by a median *raphe* which extends from the bottom of the fissure to the median sulcus of the floor of the fourth ventricle. Further, certain of the cranial nerves pass through the substance of the medulla oblongata, and are attached to its surface in series with the roots of the spinal nerves; thus, the fibres of the hypoglossal nerve correspond in position with the anterior roots of the spinal nerves, and emerge in linear series from a furrow termed the *anterolateral sulcus.* Similarly, the accessory, vagus, and glossopharyngeal

nerves are in line with the posterior roots of the spinal nerves (p. 1079), and are attached to the bottom of a sulcus named the *posterolateral sulcus*. Advantage is taken of this arrangement to subdivide each half of the medulla oblongata into anterior, middle and posterior regions. Although these three regions appear to be directly continuous with the corresponding white columns of the spinal cord, they do not contain precisely the same nerve-fibres, since some of the fasciculi of the spinal cord end in the medulla oblongata, while others alter their course in passing through it.

The **anterior region** of the medulla oblongata (fig. 836) is named the *pyramid*, and lies between the anterior median fissure and the anterolateral sulcus.

FIG. 837.—A scheme showing the decussation of the pyramids.



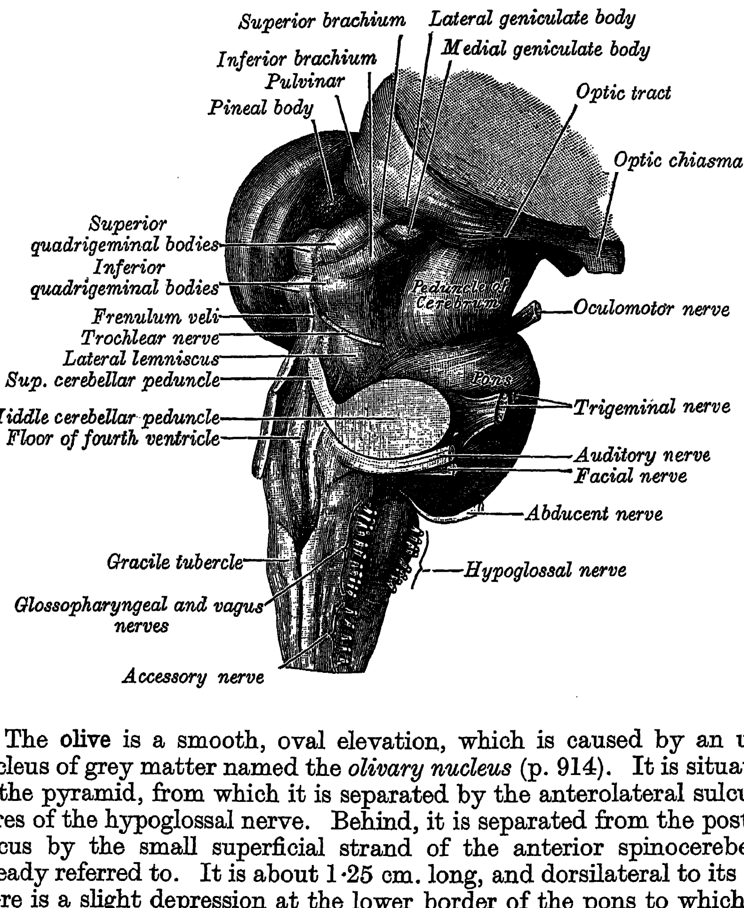
Its upper end is slightly constricted and between it and the pons the fibres of the abducent nerve emerge; below, it tapers into the anterior white column of the spinal cord, with which it appears to be directly continuous.

The two pyramids contain the motor fibres which pass from the brain to the spinal cord. When traced downwards, two-thirds or more of these fibres leave the pyramids in successive bundles, and decussate in the anterior median fissure, forming what is termed the *decussation of the pyramids*. Having crossed the median plane, they pass down in the posterior part of the lateral white column of the spinal cord as the lateral cerebrospinal tract. The remaining fibres—i.e. those in the lateral part of the pyramid—do not cross the median plane, but descend as the anterior cerebrospinal tract (fig. 837) into the anterior white column of the same side of the spinal cord.

The **lateral region** of the medulla oblongata (fig. 838) is limited in front by the anterolateral sulcus and the roots of the hypoglossal nerve, and behind by the posterolateral sulcus and the roots of the accessory, vagus, and glossopharyngeal nerves. Its upper part consists of a prominent oval mass which is

named the *olive*, while its lower part is of the same width as the lateral column of the spinal cord, and appears on the surface to be a direct continuation of it. As a matter of fact, only a portion of the lateral column of the spinal cord is continued upwards into this region, for the lateral cerebrospinal tract is derived from the pyramid of the opposite side, and most of the fibres of the posterior spinocerebellar tract leave it to enter the inferior cerebellar peduncle in the posterior region. The lateral intersegmental tract and the anterior spinocerebellar tract are continued upwards into the lateral region of the medulla oblongata. Most of these fibres dip beneath the olive and disappear from the surface; but a small strand remains superficial, and ascends between the olive and the posterolateral sulcus.

Fig. 838.—The hind-brain and the mid-brain. Posterolateral aspect.



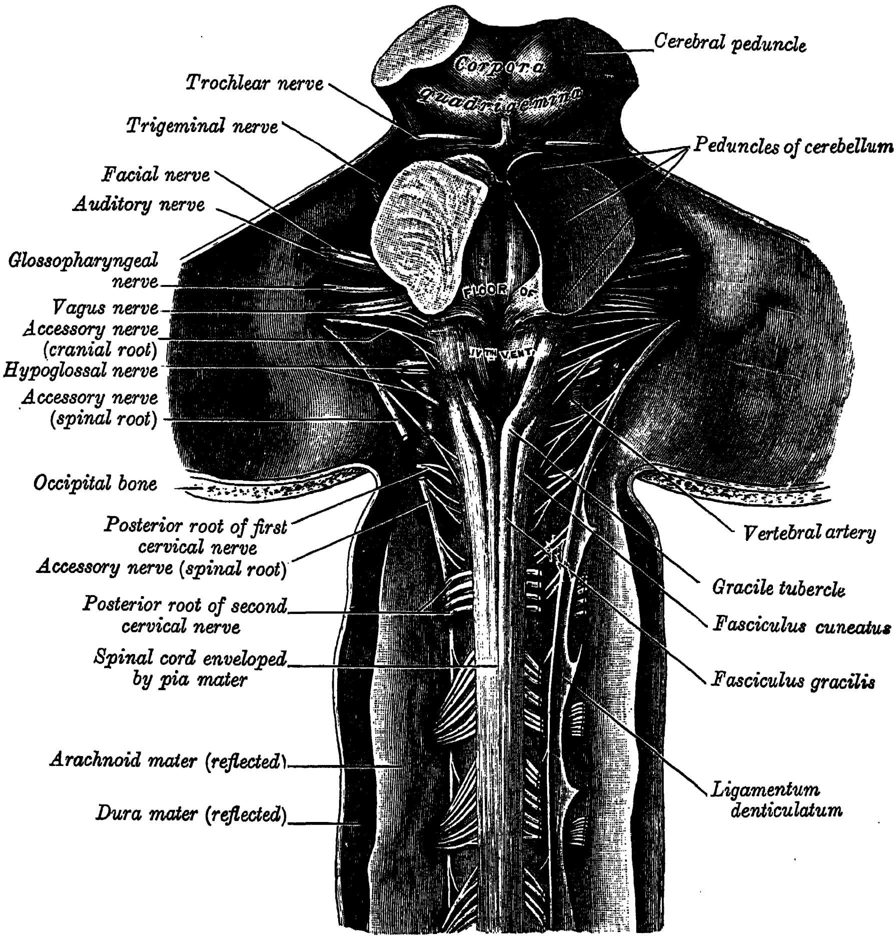
The **olive** is a smooth, oval elevation, which is caused by an underlying nucleus of grey matter named the *olivary nucleus* (p. 914). It is situated lateral to the pyramid, from which it is separated by the anterolateral sulcus and the fibres of the hypoglossal nerve. Behind, it is separated from the posterolateral sulcus by the small superficial strand of the anterior spinocerebellar tract already referred to. It is about 1·25 cm. long, and dorsilateral to its upper end there is a slight depression at the lower border of the pons to which the roots of the facial nerve are attached. The external arcuate fibres emerge from the anterior median fissure, and wind backwards across the pyramid and the olive and enter the inferior cerebellar peduncle.

The **posterior region** of the medulla oblongata (fig. 839) lies behind the posterolateral sulcus and the roots of the accessory, vagus and glossopharyngeal nerves, and, like the lateral region, is divisible into a lower and an upper portion.

The *lower part* is limited behind by the posterior median fissure, and consists of the *fasciculus gracilis* and the *fasciculus cuneatus* of the spinal cord. The fasciculus gracilis is placed along the side of the posterior median fissure, and is separated from the fasciculus cuneatus by a faint longitudinal groove and a septum. These two fasciculi are at first vertical; but at the lower part of the fourth ventricle they diverge from the median plane, and each presents an elongated swelling. The swelling on the fasciculus gracilis is named the *gracile*

tubercle, and is produced by the upper end of a subjacent nucleus of grey matter termed the *nucleus gracilis*; that on the fasciculus cuneatus is termed the *cuneate tubercle*, and is caused similarly by a grey nucleus named the *nucleus cuneatus*. The fibres of these two fasciculi end by arborising around the cells in their respective nuclei. A third elevation may be present in the lower part of the posterior region of the medulla oblongata. It lies between the fasciculus cuneatus and the roots of the accessory nerve, and is narrow below but wider above. It is produced by a nucleus which is continuous below with the substantia gelatinosa, and in which the fibres of the spinal tract of the trigeminal

FIG. 839.—The upper part of the spinal cord and the hind- and mid-brains. Exposed from behind.



nerve end; these fibres separate the nucleus from the surface of the medulla oblongata. The *obex* and the *tæniæ of the fourth ventricle* are described on p. 939.

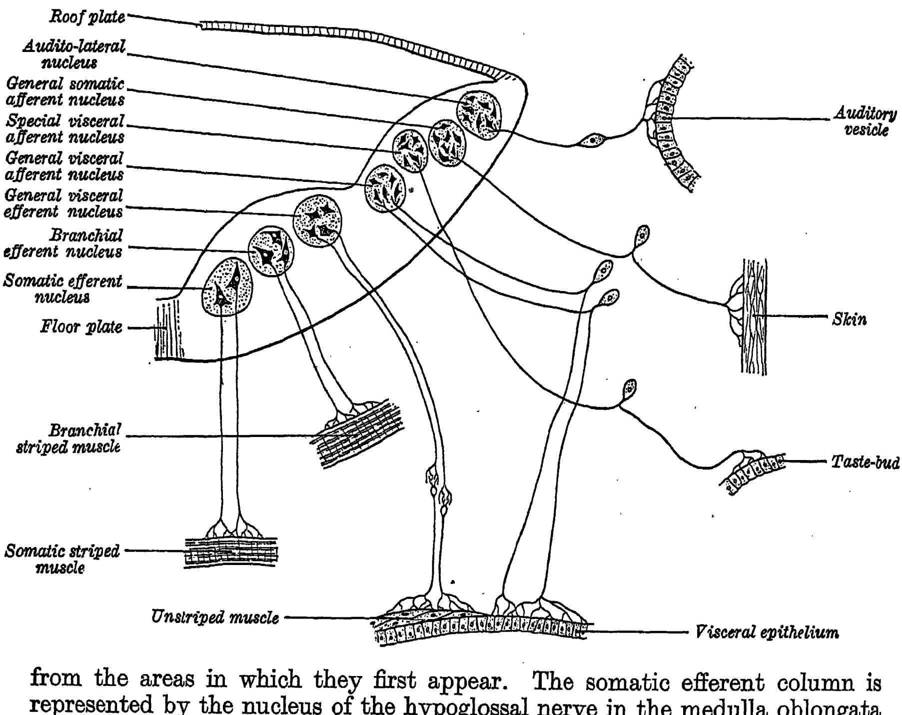
The *upper part* of the posterior region of the medulla oblongata is occupied by the *inferior cerebellar peduncle*, a thick rope-like strand situated between the lower part of the fourth ventricle and the roots of the glossopharyngeal and vagus nerves. The two inferior cerebellar peduncles leave the dorsilateral aspect of the medulla oblongata and pass to the cerebellum. As they ascend, they diverge from each other, and assist in forming the lower parts of the lateral boundaries of the fourth ventricle; higher up, they are directed backwards, each passing to the corresponding cerebellar hemisphere. Near their entrance into the cerebellum they are crossed by several strands of fibres which run to the median sulcus of the floor, or anterior wall, of the fourth ventricle and are named the *auditory striæ* (striæ medullares). The inferior

cerebellar peduncle is not, although it appears to be, the upward continuation of the fasciculus gracilis and fasciculus cuneatus, since the fibres of these fasciculi end in the nucleus gracilis and nucleus cuneatus; its constitution is described on p. 919.

The stages in the development of the hind-brain have been described in detail in a preceding section (p. 111), but certain points in the process require special emphasis in order that the internal structure of the medulla oblongata and the pons may be appreciated adequately.

Attention has been drawn to the expansion of the roof-plate which accompanies the formation of the pontine flexure, and to the consequent alteration in the position of the alar and basal laminæ (fig. 840). In their subsequent growth these laminæ do not form continuous columns of grey matter throughout the hind-brain, as they do in the spinal cord. Instead they become broken up into nuclear masses of varying size and extent, and many of them migrate

Fig. 840.—Diagram of a transverse section through the developing hind-brain to show the relative positions of the nuclei of the different varieties of nerve components.



from the areas in which they first appear. The somatic efferent column is represented by the nucleus of the hypoglossal nerve in the medulla oblongata and by the nucleus of the abducent nerve in the pons; but these two nuclei are separated from each other by an interval in which the column is unrepresented. The branchial (special visceral) efferent column, which is found only in the upper segments of the spinal cord, is represented by the nucleus ambiguus in the medulla oblongata and by the motor nuclei of the facial and the trigeminal nerves in the pons. The nucleus ambiguus gives origin to those fibres of the glossopharyngeal and vagus nerves which are distributed to striped muscle, and to some of the fibres of the accessory nerve. These nerves are intimately associated with the visceral arches. The mandibular division of the trigeminal supplies the first, the facial the second, the glossopharyngeal the third and the vagus and accessory the remaining arches. The splanchnic efferent column is represented by the dorsal nucleus of the vagus in the medulla oblongata and by the superior and inferior salivary nuclei.

In the same way, the derivatives of the alar laminæ constitute a number of separated masses of grey matter. The general visceral afferent column is represented by a portion of the dorsal nucleus of the vagus; the general somatic afferent column by the nuclei of termination of the trigeminal nerve; the

special visceral afferent column by the nucleus of the tractus solitarius, which receives gustatory fibres from the facial, the glossopharyngeal and the vagus nerves ; and the special somatic afferent column by the nuclei of the cochlear divisions of the auditory nerve (fig. 840). As already described (p. 901), the proprioceptive fibres ascend uncrossed, and without being relayed, through the spinal cord. There are, however, in the medulla oblongata and the pons, nuclei which are concerned with this variety of sensibility. The nuclei of termination of the vestibular division of the auditory nerve, the olivary nuclei, and many other smaller nuclei represent this column.

Owing to the growth of the cerebrum, which sends down large fibre tracts through the hind-brain, and the growth of the spinal cord, which sends similar fibre tracts upwards to the cerebrum, the relative positions of the various constituents of these columns may undergo considerable alteration. In addition, it has been clearly demonstrated that during the course of development, nerve-cells or groups of nerve-cells are capable of active migration. Ariëns Kappers has pointed out that a nerve-cell tends to remain as near as possible to its source of stimulation, and that when, owing to the development

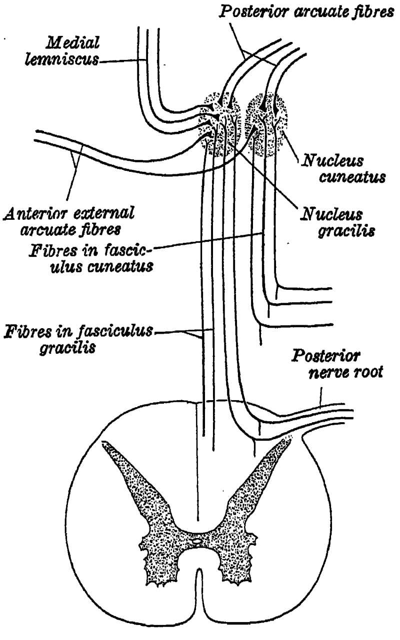
of neighbouring structures, the danger of separation arises, it will bodily migrate in the direction from which its stimuli come. The nature of the attraction exerted by the source of stimulation is unknown, and Kappers has given the phenomenon the name of Neurobiotaxis. Cells can migrate in this way only by a lengthening of their axons, which therefore map out the route taken by the cell or group of cells in its transit. The curious course of the fibres arising from the facial nucleus and the nucleus ambiguus illustrate this point clearly (p. 924).

The internal structure of the medulla oblongata.—(1) *A transverse section through the lower part of the medulla oblongata* shows many of the appearances of a transverse section through the upper end of the spinal cord. The posterior, lateral and anterior white columns can be identified easily, and they contain the same nerve tracts. The grey matter shows two very striking alterations. The anterior horn is separated from the grey matter surrounding the central canal by the pyramidal fibres, which are coursing backwards and laterally to reach the lateral white column. In the upper part of the medulla oblongata the pyramidal fibres occupy its ventrimedial portion, but in the lower part the majority of them run backwards and laterally, crossing the median plane and decussating in front of the central grey matter. The decussation of the great motor tracts [*decussation of the pyramids*] constitutes the most striking feature in sections of the medulla oblongata at this level. The actual proportion of the fibres which take part is subject to variation, but, as a rule, 75 per cent.

of them do so and continue down the spinal cord in the lateral white column as the lateral, or crossed, cerebrospinal (pyramidal) tract. The remaining fibres retain their ventrimedial position and descend in the anterior white column of the spinal cord as the anterior, or direct, cerebrospinal tract. As a result of this decussation the anterior intersegmental tract of the spinal cord is thrust backwards towards the central grey matter, which also takes up a more dorsal position so that the central canal inclines backwards as it ascends. The continuity between the anterior grey column and the central grey matter, maintained throughout the whole length of the spinal cord, is severed. At higher levels the detached anterior column rapidly diminishes in size and merges into the grey matter of the formatio reticularis (p. 914), but at this level it contains the upper end of the nucleus which gives origin to the spinal part of the accessory nerve.

The outline of the posterior horn of the grey matter can still be made out, but it, too, has undergone some modification. A narrow, strip-like portion of grey matter appears in the heart of the fasciculus gracilis, continuous ventrally with the base of the posterior horn. This constitutes the lower end of the *nucleus gracilis*, which extends upwards as far as the lower limit of the fourth ventricle and forms an elevation on the posterior surface of the medulla oblongata already described as the gracile tubercle on p. 908. A second projection from the base of the posterior horn invades the ventral part of the fasciculus cuneatus, and constitutes the *nucleus cuneatus*.

FIG. 843.—A scheme showing the connexions of the fasciculus gracilis and the fasciculus cuneatus.



The *substantia gelatinosa* is a prominent feature, capping the apex of the posterior horn of the grey matter. In this situation it constitutes the *nucleus of the spinal tract of the trigeminal nerve*, and the fibres of the tract itself are interposed between the nucleus and the surface of the medulla oblongata. It will be considered in detail in a subsequent section (p. 924).

(2) *A transverse section made through the upper part of, or just above, the decussation of the pyramids* shows an accentuation of the differences already noted and the appearance of certain new elements.

The nucleus gracilis has increased in breadth and the fibres of its corresponding fasciculus are grouped together on its dorsal, medial and lateral surfaces ; and the nucleus cuneatus has undergone a similar change. Both still retain their continuity with the central grey matter. The fibres of the fasciculus gracilis and cuneatus have ascended uncrossed through the spinal cord, and they terminate in their respective nuclei at different levels by arborising with the dendrites of their contained nerve-cells. New fibres arise in the nuclei and constitute the second neurone on the pathway of discriminative and proprioceptive sensibilities. These *internal arcuate fibres* emerge from the ventral aspects of the nuclei and, curving forwards and laterally at first round the central grey matter, they bend medially to reach the median plane, where they decussate with the corresponding fibres of the opposite side (fig. 844). Thereafter, they turn upwards and ascend close to the median raphe, constituting the *medial lemniscus*. This great *sensory decussation* occurs in the area dorsal to the pyramids and in front of the central grey matter, which is in this way thrust still further backwards towards the dorsal surface of the medulla oblongata. As the internal arcuate fibres sweep forwards they interrupt the

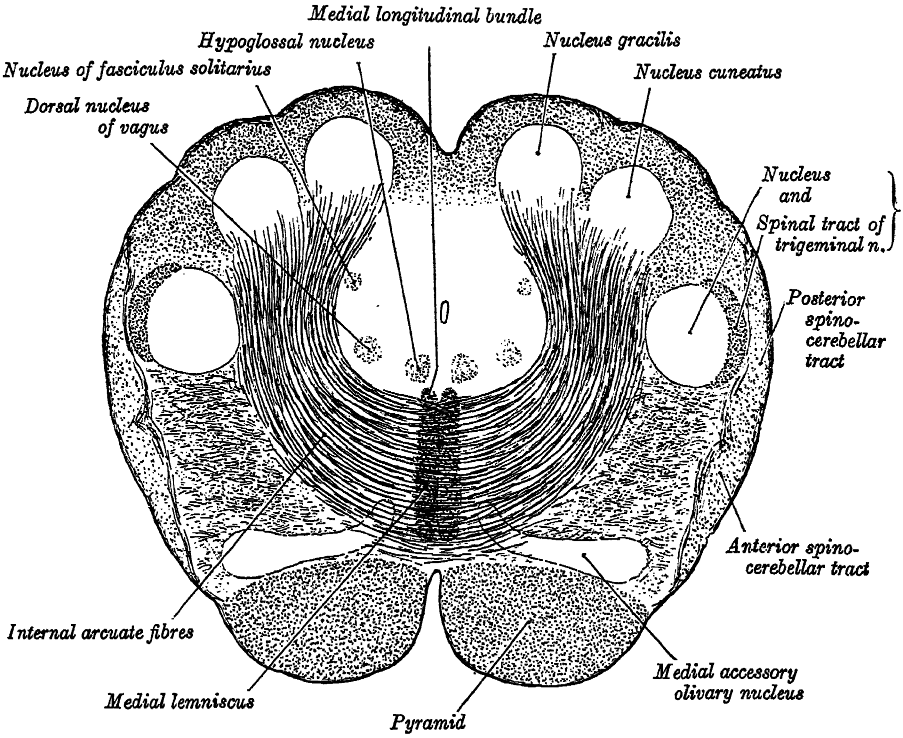
grey matter which connects the substantia gelatinosa with the central grey matter.

In addition, the nucleus gracilis and the nucleus cuneatus give origin to the *anterior* and *posterior external arcuate fibres* (pp. 917 and 919).

The *nucleus of the spinal tract of the trigeminal nerve* is now severed from the central grey matter by the internal arcuate fibres, and it is separated from the lateral surface of the medulla oblongata only by the fibres whose terminal nucleus it constitutes.

Two additional collections of grey matter are found at this level. One lies dorsal to the lateral part of the pyramid, while the other is placed to its medial side and not far from the median plane. These are portions of the *medial accessory olivary nucleus* and will be considered together with the olivary nucleus.

FIG. 844.—A transverse section through the sensory decussation. (Semidiagrammatic. After Villiger.)



The central grey matter, now occupying a position near the dorsal surface of the medulla oblongata, contains three important nuclei. A prominent group of large motor nerve-cells is situated ventrimedially, in the position of the somatic efferent column. This is the *nucleus of the hypoglossal nerve*. It extends upwards into the open part of the medulla oblongata where it lies under the medial part of the trigonum hypoglossi in the floor of the fourth ventricle. Dorsilateral to the hypoglossal nucleus, in the position of the splanchnic efferent column, there is a second group of cells, which constitutes the *dorsal nucleus of the vagus*. It contains cells of two different types. The larger cells give rise to the fine fibres which innervate unstriped muscle, while the smaller spindle-shaped cells probably represent the splanchnic afferent column (fig. 840). The dorsal nucleus of the vagus, at a higher level, lies to the lateral side of the hypoglossal nucleus in the floor of the fourth ventricle and corresponds in position to the trigonum vagi.

A third group of cells lies dorsilateral to the dorsal nucleus of the vagus, at this level. It is the *nucleus of the tractus solitarius*, and it is intimately related to a group of descending fibres which constitute the *tractus solitarius* itself. As

the nucleus is traced upwards it comes to lie a little more deeply in the substance of the medulla oblongata, on the ventrilateral aspect of the dorsal nucleus, with which it is practically coextensive. The tractus solitarius contains afferent fibres from the facial, glossopharyngeal and vagus nerves, which enter the nucleus in that order from above downwards, conveying to it gustatory sensibility from the mucous membrane of the tongue.

In addition, numerous scattered islets of grey matter are found in the centre of the ventrilateral portion of the medulla oblongata. They occupy an area which is freely intersected by nerve fibres running in all directions and which is therefore termed the *formatio reticularis*.

The white matter has undergone an important rearrangement. The *pyramidal tracts* constitute two large bundles placed on the ventral part of the section, one on each side of the anterior median fissure. Dorsally they are related to the accessory olivary nuclei and the sensory decussation.

The fibres of the *medial lemniscus*, after emerging from the sensory decussation, turn upwards abruptly and form a flattened tract, closely applied to the median raphe. In this position they ascend to the pons, increasing in bulk as additional fibres join them from the upper levels of the decussation. Ventrally they are related to the medial part of the pyramidal tract, and dorsally they are separated from the nucleus of the hypoglossal nerve by the medial longitudinal bundle and the tectospinal tract. On its lateral side lies the grey matter of the formatio reticularis intersected by the internal arcuate fibres. In the upper part of the medulla oblongata and as it enters the pons the tract undergoes an alteration in position and it comes to lie in a coronal plane in the ventral part of the tegmental region (fig. 850). In the mid-brain it occupies a similar position, dorsal to the substantia nigra, but it gradually inclines laterally. In this situation some of its fibres terminate in the substantia nigra and others in the superior quadrigeminal bodies. The majority of the fibres ascend on the lateral aspect of the red nucleus and enter the ventrilateral surface of the thalamus, where the fibres of the second neurone in the pathway of discriminative and proprioceptive sensibilities terminate by arborising round the dendrites of the cells of the ventral portion of the lateral thalamic nucleus. There the fibres of the third neurone begin, and they pass upwards to the cortex of the postcentral gyrus.

The *medial longitudinal bundle* forms a small compact tract of nerve-fibres, situated close to the median plane and ventral to the hypoglossal nucleus. Below, it is continuous with the anterior intersegmental tract of the spinal cord, but it has been thrust dorsally by the pyramidal and the sensory decussations. It is continued upwards through the pons and the mid-brain in the same position relative to the central grey matter and the median plane, and therefore comes into intimate relationship throughout its course with the somatic efferent column of the grey matter. The constituent fibres of the tract run relatively short courses within it, for they are derived from a variety of sources, which are detailed on p. 949. The tract affords a pathway for communications passing between the nuclei of the cranial nerves.

The spinocerebellar, spinothalamic, spinotectal, olivospinal, vestibulospinal and rubrospinal tracts are all found in the anterolateral area, limited dorsally by the nucleus of the spinal tract of the trigeminal nerve and ventrally by the pyramid.

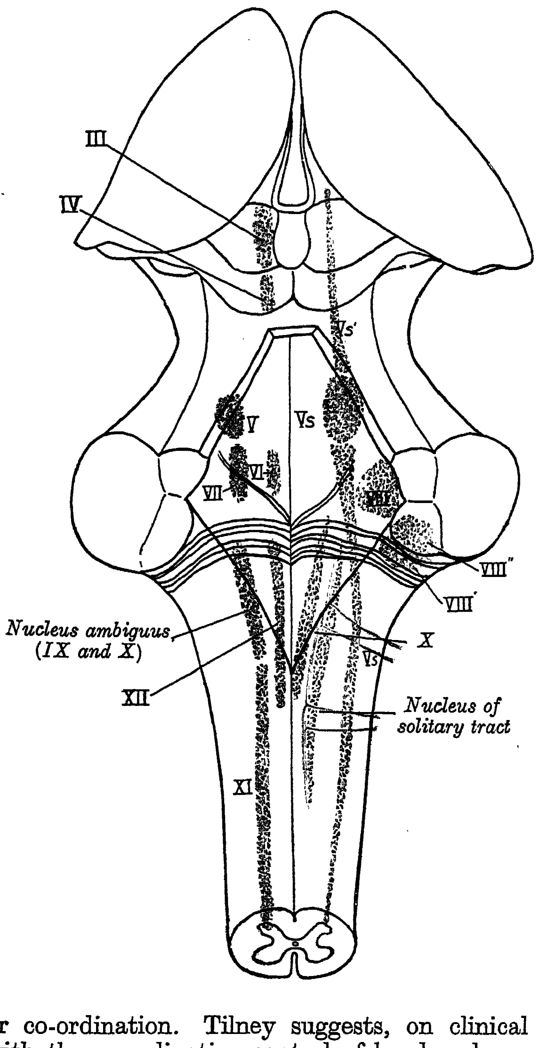
(3) *A transverse section through the medulla oblongata made on a level with the inferior limit of the fourth ventricle*, shows the appearance of a number of new elements, together with most of those already described at a lower level.

The grey matter shows a distinct increase in amount owing to the presence of the large olivary nucleus, the nucleus arcuatus and nuclei associated with the glossopharyngeal, vagus and accessory nerves.

The **olivary nucleus** (inferior olivary nucleus) is a large hollow mass of grey matter, with irregularly crenated walls and a longitudinal hilum, which is situated on its medial side. Situated dorsal to the pyramid, the nucleus underlies the surface elevation of the olive and extends upwards almost to the pons. Derived from the rhombic lip of the alar lamina (p. 112), its cells migrate ventrally and medially into the basal lamina. The site of origin of its cells indicates a probable connexion with the vestibular apparatus and the cerebellum, and that such a connexion does exist is demonstrated by the large

number of fibres which arise from the small cells of the nucleus and constitute the *olivocerebellar tract.* These fibres emerge from the hilum or through its medial wall, and run medially, intersecting the fibres of the medial lemniscus. They cross the median plane, and, sweeping dorsally, traverse the olivary nucleus of the opposite side, intersect the spinothalamic and rubropsinal tracts and nucleus of the spinal tract of the trigeminal nerve and enter the inferior cerebellar peduncle by which they are conveyed to the cerebellum. Despite the size of the nucleus and the ease with which its cerebellar connexions can be demonstrated, it has hitherto been found impossible to determine with certainty the afferent paths which lead to it. Several such pathways have, however, been described by Helweg, Flechsig, Bechterew and others. It appears probable that fibres reach the nucleus from the spinal cord, but whether they ascend in a separate spino-olivary tract or whether they are derived from the medial lemniscus and spinothalamic tracts, as Ramon y Cajal has suggested, is not clear. A group of fibres can be traced downwards through the mid-brain and pons, many of which are believed to end in the lateral aspect of the olivary nucleus, but, although they have been termed the thalamo-olivary fasciculus, their source of origin has not been demonstrated satisfactorily; some authorities ascribe them to the red nucleus and the globus pallidus of the lentiform nucleus. This bundle of fibres is sometimes described as the *central tegmental fasciculus,** and many of its constituents are continued downwards into the anterior intersegmental tract of the spinal cord.

FIG. 845.—The nuclei of the cranial nerves schematically represented. Dorsal aspect. Motor nuclei in *red*; sensory in *blue*. (The olfactory and optic centres are not shown.)



On account of its intimate and free communication with the cerebellum it is clear that the olivary nucleus plays some intermediate part in muscular co-ordination. Tilney suggests, on clinical grounds, that it is associated with the co-ordinative control of head and eye movements.

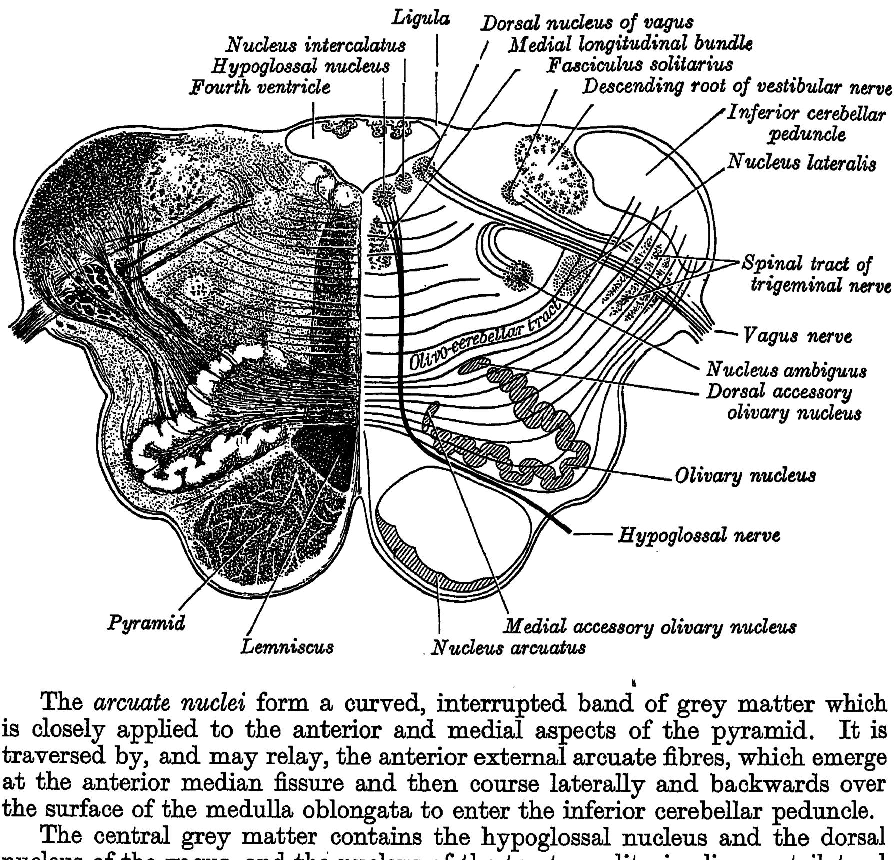
The *medial accessory olivary nucleus* is a curved lamina of grey matter which is found at this level. The concavity of the curve is directed laterally and the nucleus is interposed between the medial lemniscus and the pyramid, on the one hand, and the medial and ventral aspects of the olivary nucleus on the other.

The *dorsal accessory olivary nucleus* is a second lamina of grey matter, placed dorsal to the medial part of the olivary nucleus.

* For a detailed account, see *Modern Problems in Neurology,* by S. A. K. Wilson. Wood & Co., New York, 1929.

Both the olivary and the accessory nuclei are intimately associated with the cerebellum. Phylogenetically, the accessory nuclei are older than the olivary nucleus, and they send their fibres to the palæocerebellum (p. 928). The olivary nucleus is a later acquisition and, in the course of evolution, it has enlarged in a tailward direction. The destination of its fibres in the human brain is in harmony with its phylogenetic history, for those which arise from its upper end and the lips of the upper part of the hilum pass to the palæocerebellum, whereas those from the larger, caudal portion proceed to neocerebellum (p. 929). Gordon Holmes and Stewart have been able to demonstrate that different parts of the olivary nucleus are each represented in a definite part of the cerebellar cortex. The interdependence of the two has been emphasised recently by Brouwer, who has shown that neocerebellar atrophy is associated with a corresponding atrophy of all but the upper and medial part of the olivary nucleus.

FIG. 846.—A transverse section through the medulla oblongata below the middle of the olive.



The *arcuate nuclei* form a curved, interrupted band of grey matter which is closely applied to the anterior and medial aspects of the pyramid. It is traversed by, and may relay, the anterior external arcuate fibres, which emerge at the anterior median fissure and then course laterally and backwards over the surface of the medulla oblongata to enter the inferior cerebellar peduncle.

The central grey matter contains the hypoglossal nucleus and the dorsal nucleus of the vagus, and the nucleus of the tractus solitarius lies ventrilateral to the last-named.

A small isolated group of large motor nerve-cells, termed the *nucleus ambiguus*, is placed deeply in the formatio reticularis. It extends upwards as far as the upper limit of the dorsal nucleus of the vagus. The fibres which emerge from its upper end join the glossopharyngeal nerve, and those which emerge at a lower level join the fila of the vagus nerve. Inferiorly it is continuous with a nucleus which gives origin to fibres of the cranial root of the accessory nerve. This nucleus represents the branchial (special visceral) efferent column in the medulla oblongata, and the fibres which arise from its cells are all distributed to striped muscle of branchial origin (p. 100). The manner in which these fibres behave on leaving the nucleus indicate that it has migrated from its normal position in relation to the central grey matter,

presumably under the influence of neurobiotaxis, for they pass dorsally and medially for a short distance before they curve laterally to join the emerging fila of the vagus and glossopharyngeal nerves (fig. 846).

The nucleus gracilis and the nucleus cuneatus, now diminishing in size and irregular in outline, occupy the dorsilateral portion of the section, and ventral to them the nucleus of the spinal tract of the trigeminal nerve, which is here intersected by the fibres of the olivocerebellar tract and the emerging fila of the vagus, can be recognised without difficulty.

The white matter of the medulla oblongata shows little change at this level. The pyramid, the medial lemniscus, the tectospinal tract and the medial longitudinal bundle occupy the same relative positions as they did at a lower level. The fibres of the olivocerebellar tract, sweeping across the median plane and turning dorsally to join the inferior cerebellar peduncle, have already been described in connexion with the olivary nucleus (p. 915). The *anterior external arcuate fibres*, which arise from the nucleus gracilis and cuneatus of the opposite side, emerge from the anterior median fissure and course over the surface of the medulla oblongata. They pass through the nucleus arcuatus and may be relayed there. Then they run obliquely backwards and upwards over the surface of the olive and the spinal tract of the trigeminal nerve, where they come into relationship with the posterior spinocerebellar tract, with which they ascend to enter the inferior cerebellar peduncle.

The emerging fila of the hypoglossal nerve leave the ventral aspect of its nucleus and run forwards through the formatio reticularis. Passing lateral to the medial lemniscus and medial to the olivary nucleus, they curve laterally to emerge from the anterolateral sulcus. A relatively small lesion in the ventral part of the medulla oblongata at this level will therefore involve both the pyramidal tract and the hypoglossal nerve, causing a peculiar crossed paralysis. The muscles of the tongue are paralysed on the same side as the lesion, but it is the limbs of the opposite side of the body that are affected, for the lesion is situated above the level of the pyramidal decussation.

More dorsally, the formatio reticularis is traversed by the fila of the vagus, travelling between the posterolateral sulcus and the dorsal nucleus, the nucleus ambiguus and the nucleus of the tractus solitarius.

It should be observed that the *spinal lemniscus*, which is formed about this level by the union of the anterior and lateral spinothalamic tracts, is closely related to the nucleus ambiguus as it ascends through the upper part of the medulla oblongata. A small lesion in the ventral part of the formatio reticularis may cause paralysis of the vocal fold and of the soft palate of the same side, but a loss of sensibility to pain and temperature on the opposite side of the body.

(4) *A transverse section through the uppermost part of the medulla oblongata* shows less striking changes. The *olivary nucleus* occupies the same relative position, but the accessory olivary nuclei are being broken up and tend to disappear.

Additional elements are present in the central grey matter. The *medial nucleus of the vestibular nerve* lies on the lateral side of the dorsal vagal nucleus, under the vestibular area of the floor of the fourth ventricle. It is the largest of the four nuclear masses in which the fibres of the vestibular nerve terminate, and it extends upwards into the pons, separated from the floor of the fourth ventricle by the auditory striæ. In this nucleus fibres from the vestibular nerve are relayed to the cerebellum and to the medial longitudinal bundle.

The *inferior nucleus of the vestibular nerve* lies on the lateral side of the medial nucleus, intervening between it and the inferior cerebellar peduncle. It extends to a lower level than the medial nucleus, but it does not extend so high into the pons. It receives the descending branches of the incoming fibres of the vestibular nerve.

The dorsal nucleus of the vagus is separated from the upper end of the hypoglossal nucleus by a collection of cells which is termed the *nucleus intercalatus*. This small nucleus occupies the lateral part of the trigonum hypoglossi. A second small nucleus lies ventral to the hypoglossal nucleus and dorsilateral to the medial longitudinal bundle. It is believed to function as a respiratory centre.

Fig. 847.—The nuclei of origin of the cranial motor nerves schematically represented. Lateral aspect.

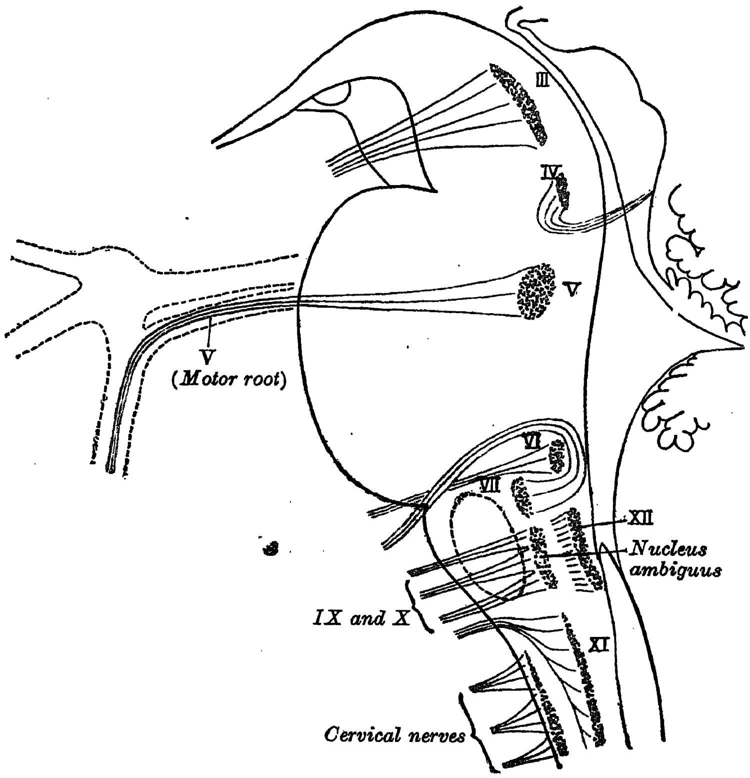


Fig. 848.—The primary terminal nuclei of the afferent (sensory) cranial nerves schematically represented. Lateral aspect. (The olfactory and optic centres are omitted.)

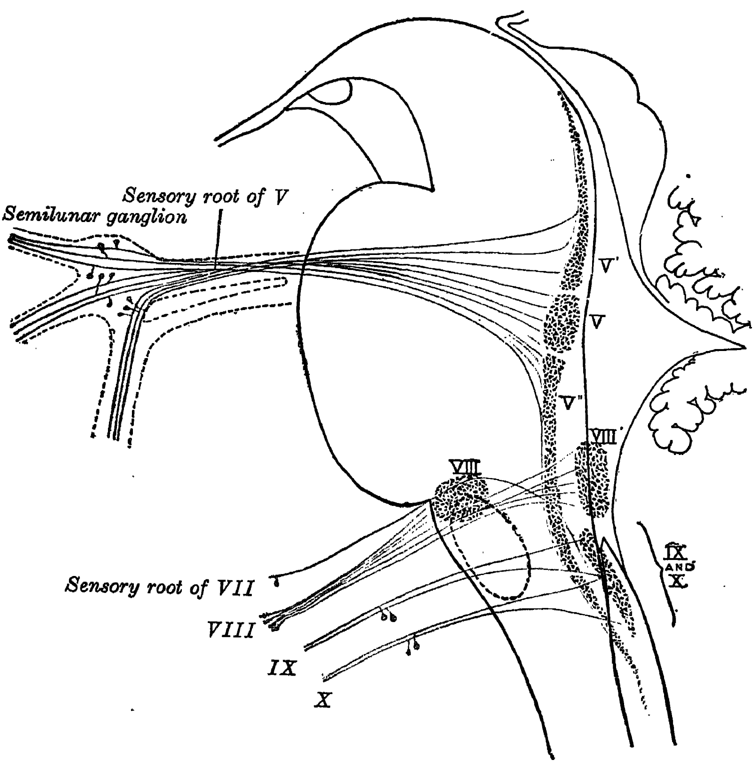
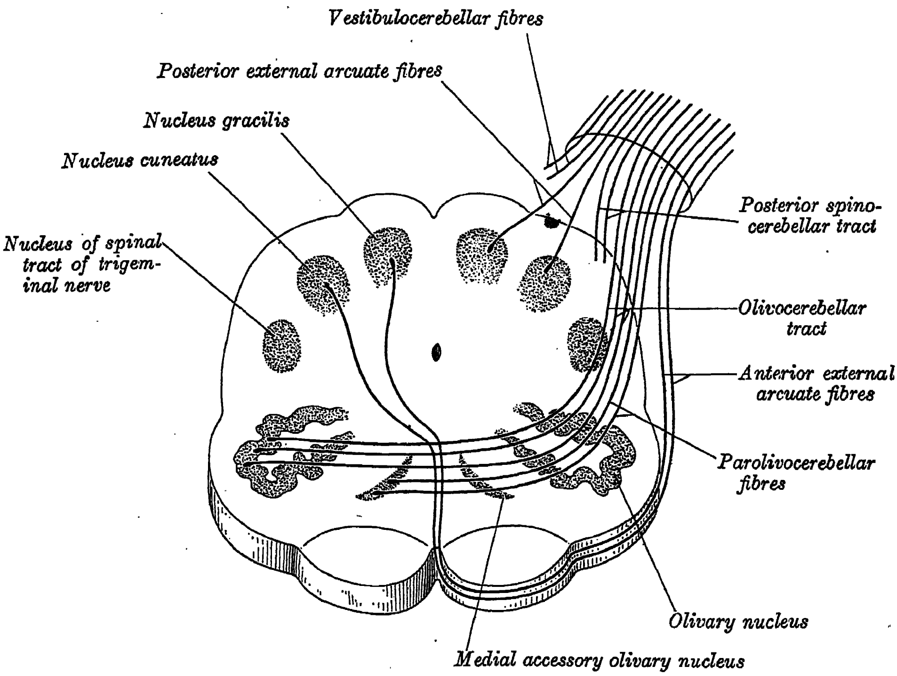


The nucleus of the tractus solitarius, the substantia gelatinosa and the nucleus ambiguus show little alteration in position. Near the upper end of the nucleus ambiguus a small collection of cells in the formatio reticularis constitutes the *inferior salivary nucleus*. The fibres which arise in this nucleus join the fila of the glossopharyngeal nerve and ultimately reach the parotid gland (p. 1068).

The arrangement of the white substance at this level shows no conspicuous alteration. The *inferior cerebellar peduncle* has increased in size and forms a well-marked elevation on the dorsilateral aspect of the medulla oblongata. Fibres from the olivary nucleus [olivocerebellar tract] and from the nucleus gracilis and the nucleus cuneatus of the opposite side [anterior external arcuate fibres] and the posterior spinocerebellar tract of the same side, have already been traced into it, and in addition it receives the *posterior external arcuate*

FIG. 849.—A scheme showing the constitution of the inferior cerebellar peduncle.



fibres which join it from the nucleus gracilis and the nucleus cuneatus of the same side (figs. 849 and 857).

The disposition of the medial lemniscus alters as it is traced upwards. Its ventral part widens and insinuates itself between the dorsal aspect of the pyramid and the narrowing upper end of the olivary nucleus. At the same time its dorsal part recedes from the tectospinal tract and the medial longitudinal bundle, with which it is in close relation at lower levels in the medulla oblongata.

THE PONS

The **pons**, or fore part of the hind-brain, is situated in front of the cerebellum. From its upper part the cerebral peduncles emerge, one on each side of the median plane. Behind and below, the pons is continuous with the medulla oblongata, but is separated from it in front and laterally by a transverse furrow in which the abducent, facial, and auditory nerves appear.

The *ventral* or *anterior surface* of the pons (fig. 836) is prominent, being markedly convex from side to side, less so from above downwards. It consists of transverse fibres arched like a bridge across the median plane, and gathered on each side into a compact mass which forms the middle cerebellar peduncle.

It rests upon the dorsum sellæ of the sphenoid bone and on the upper portion of the basilar part of the occipital bone, and is limited above and below by well-defined borders. In the median plane the anterior surface of the pons is marked by the shallow *sulcus basilaris* for the lodgement of the basilar artery; this sulcus is bounded on each side by an eminence caused by the descent of the cerebrospinal fibres through the substance of the pons. Lateral to these eminences, near the upper border of the pons, the trigeminal nerves make their exit, each consisting of a smaller, medial, motor root, and a larger, lateral, sensory root; vertical lines, drawn immediately lateral to the attachments of the trigeminal nerves, may be taken as the boundaries between the ventral surface of the pons and the middle cerebellar peduncles.

The *dorsal* or *posterior surface* of the pons, triangular in shape, is hidden by the cerebellum, and bounded laterally by the superior cerebellar peduncles; it forms the upper part of the floor of the fourth ventricle, with which it will be described (p. 940).

The surface distinctions between the medulla oblongata and the pons, which are present in all mammals but are accentuated in the anthropoid apes and man, are not discernible in lower vertebrates. Transverse sections through the pons in man show that it is readily subdivisible into a ventral and a dorsal portion. The ventral portion, which is termed the *basilar part*, contains bundles of longitudinal fibre, a great number of transverse fibres, and scattered collections of grey matter which constitute the *nuclei pontis*. The dorsal portion retains all the characteristic features of the medulla oblongata and is the true upward continuation of that structure. It contains representatives of the somatic efferent column, the branchial efferent column, the somatic afferent column and the auditolateral column. In addition, it is traversed by the medial lemniscus, the medial longitudinal bundle, the spinal lemniscus, the anterior spinocerebellar tract, the rubrospinal tract, etc., in fact, all the tracts which are passing from lower to higher or from higher to lower levels, with the single exception of the pyramidal tract.

The significance of the basilar part of the pons becomes clear when it is remembered that owing to the increased possibilities of movement in the mammalia, the mammalian cerebellum attains a vastly greater importance than it possesses in the nervous system of lower vertebrates. The complex movements of the mammalia demand perfect synergic control for their proper execution, and it is assured by the connexions which develop between the cerebral cortex and the neocerebellum, through the medium of the nuclei pontis. In man, large fibre tracts connect all the areas of the cerebral cortex with the nuclei pontis, where they are relayed to the cerebellum.

The basilar part of the pons is an expression of the importance of the effector apparatus as an index of evolutionary progress. The intimate relationship between visual and auditory impressions on the one hand and the movements involved in speech and writing on the other demand a rich connexion between the visual, auditory and motor areas of the cortex with the cerebellum. There is no need to multiply examples to illustrate that in the complexity of his movements man is far ahead of his nearest relations in the animal kingdom, and that, therefore, in man the basilar part of the pons attains its highest development.

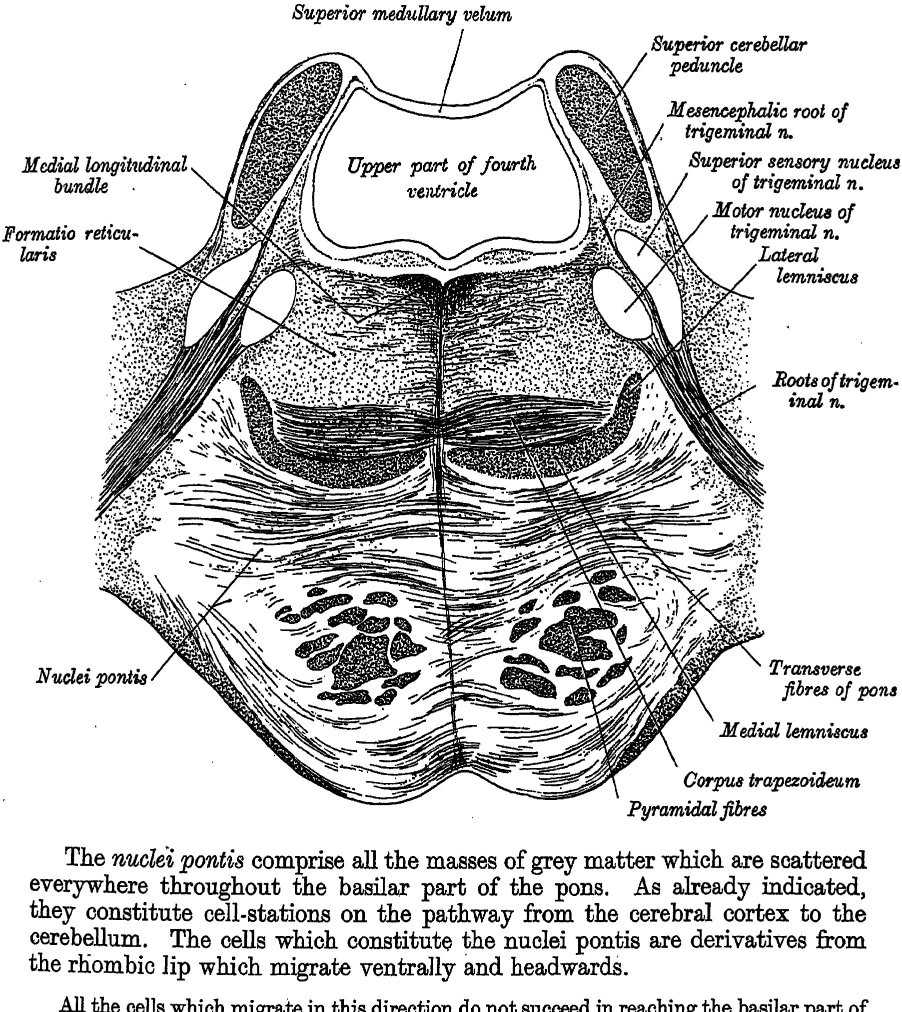
In the lowliest mammals, such as Echidna, the basilar part is present only in the region of the pons which lies above the attachment of the trigeminal nerve. Its enlargement in higher mammals is effected by its extension in a caudal direction. As a direct result of this extension, the sixth, seventh and eighth cranial nerves take their surface origin along its lower border.

Internal structure of the pons.—The *basilar part* presents a similar arrangement of its grey and white matter at all levels.

The *longitudinal bundles* comprise the cerebropontine and the important cerebrospinal (motor) fibres, which are continued downwards from the base of the cerebral peduncle. As they enter the upper limit of the basilar part of the pons, they form a compact collection of fibres, but they rapidly become broken up into numerous smaller bundles, separated from one another by the *nuclei pontis* and the transverse fibres of the pons. The *cerebrospinal fibres* descend

through the whole length of the pons and enter the pyramid of the medulla oblongata, where they form a compact tract (p. 914). In their course through the pons they give off fibres which run backwards, downwards and medially and cross the median plane to reach the motor nuclei of the fifth, sixth and seventh cranial nerves of the opposite side. The *cerebropontine fibres*, which are derived from the cerebral cortex, especially of the frontal, temporal and occipital regions, terminate at different levels in the nuclei pontis and are relayed as ponticerebellar fibres to the opposite cerebellar hemisphere (fig. 857). These latter form the transverse fibres of the pons and constitute nearly the whole of the middle cerebellar peduncle.

FIG. 850.—A coronal section through the upper part of the pons. (Semidiagrammatic. After Villiger.)



The *nuclei pontis* comprise all the masses of grey matter which are scattered everywhere throughout the basilar part of the pons. As already indicated, they constitute cell-stations on the pathway from the cerebral cortex to the cerebellum. The cells which constitute the nuclei pontis are derivatives from the rhombic lip which migrate ventrally and headwards.

All the cells which migrate in this direction do not succeed in reaching the basilar part of the pons. Some of them remain, forming an oblique ridge across the dorsilateral aspect of the inferior cerebellar peduncle, and constitute the *nucleus of the circumolivary bundle* (corpus pontobulbare). The fibres to which this discrete part of the nuclei pontis gives origin run vertically upwards on the surface between the emerging seventh nerve on the medial side, and its sensory root and the eighth nerve on the lateral side. The afferent fibres to the nucleus traverse the whole length of the pons with the cerebrospinal fibres and leave them only in the medulla oblongata. They course obliquely backwards and upwards over the surface of the olive, to reach their destination, forming the *fasciculus circumolivaris pyramidis* (fig. 856).

The *dorsal part* of the pons shows many differences in structure, in its lower and upper parts.

The areas not occupied by the central grey matter, the named nuclei and the principal fibre tracts constitute the formatio reticularis of the pons. It consists of scattered islets of grey matter, traversed by white fibres which are passing in all directions.

(A) The lower part of the tegmentum contains the somatic motor nucleus of the sixth cranial nerve, the branchial motor nucleus of the seventh cranial nerve, the auditolateral nuclei of the vestibular and cochlear divisions of the eighth nerve, and certain isolated collections of grey matter which will be referred to below.

The *medial nucleus* and the *inferior nucleus* of the vestibular nerve are continued upwards for a short distance into the tegmentum of the pons. The *lateral vestibular nucleus* is placed on the ventrilateral aspect of the medial nucleus, between it and the inferior cerebellar peduncle. This nucleus is characterised by the large size of its constituent cells, which is strongly suggestive of their motor character. Some of the fibres of the vestibular nerve are relayed in the lateral nucleus and emerge from its medial side. They turn downwards and descend through the pons and medulla oblongata to enter the anterior white column of the spinal cord, where they constitute the *vestibulospinal tract.* They end, uncrossed, by arborising round the dendrites of the large motor cells of the anterior grey column, and they clearly constitute the outgoing pathway for vestibulospinal reflexes.

The *superior vestibular nucleus* extends to a higher level in the pons than the other nuclei of the vestibular nerve. It is continuous with the upper end of the lateral nucleus and occupies the superolateral portion of the vestibular area. The fibres of the vestibular nerve which are relayed in this nucleus may pass to the cerebellum or to the medial longitudinal bundle, of which they form an important constituent.

The *ventral cochlear nucleus* is placed on the ventrilateral aspect of the inferior cerebellar peduncle (restiform body), as it passes upwards and laterally through the lower part of the pons. It receives afferent fibres from the cochlear nerve, and its outgoing fibres pass medially through the substance of the tegmentum and decussate with corresponding fibres of the opposite side. In this situation they constitute the *corpus trapezoideum* and they subsequently enter the lateral lemniscus. Small islets of grey matter are found amongst the fibres of the corpus trapezoideum, from which they receive fibres and collaterals. They send their efferent fibres into the lateral lemniscus and into the dorsal nucleus of the corpus trapezoideum (superior olive) (p. 923). These scattered collections of nerve-cells together form the *ventral nucleus of the corpus trapezoideum.*

The *dorsal cochlear nucleus,* which receives the remainder of the fibres of the cochlear nerve, lies on the dorsal aspect of the inferior cerebellar peduncle (restiform body) and forms the auditory tubercle (p. 941). The fibres to which its cells give origin course medially, lying immediately under the floor of the fourth ventricle and constituting the *auditory striæ* (striæ medullares).* On reaching the median sulcus they bend ventrally and cross the median plane, decussating obliquely with the corresponding fibres of the opposite side. Continuing in a ventrilateral direction they join the fibres of the corpus trapezoideum, and turn upwards with them to form the *lateral lemniscus* (p. 924). Some of the fibres from the dorsal cochlear nucleus take no part in the formation of the auditory striæ but run obliquely through the substance of the tegmentum to reach the lateral lemniscus of the opposite side.

The pathways followed by the second neurone fibres of the vestibular and cochlear nerves are not so sharply differentiated as might be supposed from the description given above. It would appear from the work of Winkler † and others that the vestibular nuclei (especially the lateral nucleus) contribute many fibres to the auditory striæ, the corpus trapezoideum and the lateral lemniscus, and that similar reflex movements may be induced both by vestibular and by cochlear stimulation (see also p. 949).

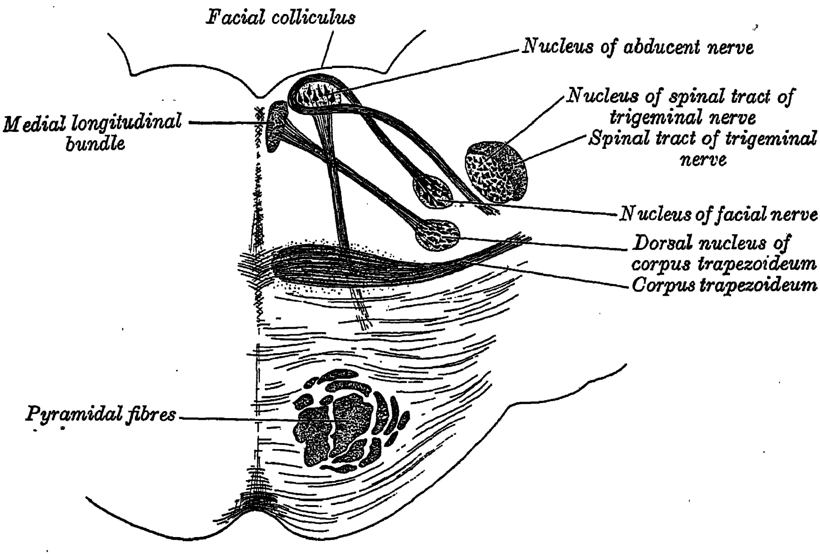
* It would appear that the striæ auditoriæ are formed by the external arcuate fibres and by fibres from the peduncle of the flocculus, as well as by fibres from the dorsal cochlear nucleus.

† Winkler, C., "The Central Course of the Nervus Octavus and its Influence on Motility." 1918. *Opera omnia*, vol. iv.

The *dorsal nucleus of the corpus trapezoideum* (superior olive) is a small nucleus which is closely related to the corpus trapezoideum in the ventrilateral part of the formatio reticularis. It receives collaterals from many of the second neurone fibres of the eighth nerve, and others of these fibres terminate in its substance. From its dorsal aspect a bundle of new fibres emerges and constitutes its *peduncle*. They pass to the medial longitudinal bundle (fig. 851), and so, probably, reach the motor nuclei of other cranial nerves and the inferior corpus quadrigeminum.

The *nucleus of the abducent nerve* lies in the central grey matter a short distance from the median plane. It is the representative at this level of the somatic efferent column, and it lies in line with the nuclei of the third and fourth cranial nerves, above, and the hypoglossal nerve, below. It is in close relation with the medial longitudinal bundle, which is placed to its ventrimedial side. In this way fibres from the vestibular and cochlear nuclei and the nuclei of other

FIG. 851.—Section through the left half of the pons, showing the course taken by the fibres of the facial nerve after leaving their nucleus of origin. Diagrammatic.



cranial nerves, especially the third nerve, have easy access to the sixth nucleus. It also bears an intimate relationship to the emerging fibres of the facial nerve (see below). The outgoing fibres of the sixth nerve pass ventrally and downwards through the formatio reticularis, intersecting the corpus trapezoideum and the medial lemniscus and traversing the basilar part of the pons to reach the surface at its lower border.

The *facial nucleus* lies in the ventrilateral part of the formatio reticularis of the pons, immediately dorsal to the dorsal nucleus of the corpus trapezoideum. Dorsal to it, and somewhat to its lateral side, lies the *spinal tract of the trigeminal nerve* and its associated nucleus. The facial nucleus receives fibres from the pyramidal tract of the opposite side and also a smaller number from the pyramidal tract of the same side. Its large motor cells give origin to the fibres of the facial nerve. These fibres do not pass directly from their origin to the surface of the pons, but pursue a very remarkable course. At first they incline dorsally and medially towards the floor of the fourth ventricle, where they come into relationship with the abducent nucleus (fig. 851). They then course upwards on the medial side of this nucleus, coming into close relationship with the medial longitudinal bundle, by means of which the seventh nerve may be brought into communication with the other cranial nerves. Finally, the fibres of the facial nerve curve forwards over the upper end of the sixth nucleus and pass forwards, laterally and downwards through the reticular formation.

In their course to the surface they pass between their own nucleus on the medial side and the nucleus of the spinal tract of the trigeminal nerve on the lateral side.

The unusual behaviour of the emerging fibres of the seventh nerve provides striking evidence in favour of the theory of neurobiotaxis (p. 911). In the 10 mm. human embryo the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the branchial (special visceral) efferent column, and at this stage it is placed at a higher level than the abducent nucleus. As growth proceeds, the facial nucleus migrates at first caudally, dorsal to the sixth nucleus, and then ventrally to reach its adult position. As it migrates the axons to which its cells give rise elongate, and their subsequent course maps out the pathway along which the facial nucleus has travelled.

It must be remembered that the facial nucleus not only receives fibres from the pyramidal tracts for volitional control, but it also receives fibres from its own sensory root (through the nucleus of the tractus solitarius) and from the nucleus of the spinal tract of the trigeminal nerve. These latter sources of stimulation complete local reflex arcs, in every way similar to the segmental reflex arcs in the spinal cord. It is in an endeavour to retain its proximity to the nucleus of the tractus solitarius and to the nucleus of the spinal tract of the trigeminal nerve that the facial nucleus migrates from its original position in the basal lamina.

The *nucleus of the spinal tract of the trigeminal nerve* is continued up through the lower part of the pons, the fibres of the tract being closely applied to the lateral aspect of the nucleus. It is placed ventral to the lateral vestibular nucleus and is intersected by the fibres of the vestibular nerve which are destined for that nucleus. The inferior cerebellar peduncle (restiform body) lies to its lateral side below, but passes dorsally as it ascends to the cerebellum, and the spinal tract of the trigeminal nerve and its nucleus are subsequently related to the middle cerebellar peduncle.

In addition to most of the important tracts already studied at a lower level the white matter of the lower part of the tegmental region of the pons has the corpus trapezoideum, the lateral lemniscus and the emerging fibres of the sixth and seventh cranial nerves which are new elements not present in the upper part of the medulla oblongata.

The *medial lemniscus* occupies the ventral part of the tegmentum. Its outline, on transverse section, is a flattened oval, extending laterally from the median raphe. The vertically running fibres of the medial lemniscus are intersected by the horizontal fibres of the corpus trapezoideum. Laterally they are related to the *spinal lemniscus* and to the *trigeminal lemniscus*. The fibres of the latter are derived from the cells of the nucleus of the spinal tract of the trigeminal nerve of the opposite side, and they convey painful and thermal impressions from the skin of the face, the mucous membrane of the tongue, mouth, nose, etc.

The *corpus trapezoideum* is formed by the fibres which arise in the ventral cochlear nucleus. They run horizontally in the ventral part of the tegmentum, and, having intersected the vertical fibres of the medial lemniscus, they cross the median raphe, decussating with the corresponding fibres of the opposite side. Before they reach the emerging fibres of the seventh nerve the fibres of the corpus trapezoideum turn upwards to form the *lateral lemniscus*. In addition to the fibres from the ventral cochlear nucleus, the corpus trapezoideum is joined by the fibres which arise in the dorsal cochlear nucleus of the opposite side (p. 922).

The course of the outgoing fibres from the nuclei of the sixth and seventh cranial nerves has already been examined.

The *medial longitudinal bundle* lies close to the median plane, immediately ventral to the central grey matter. It is closely related to the nucleus of the abducent nerve and to the emerging fibres of the facial nerve, as they ascend on the medial side of that nucleus. The proximity of the fasciculus suggests that it may receive fibres from and transmit fibres to both structures (p. 949). As it lies in the lower part of the pons, the medial longitudinal bundle receives fibres from the medial and superior vestibular nuclei, the dorsal nucleus of the corpus trapezoideum (superior olive) (p. 923), and probably also from the

auditory striæ, with which it comes into close relation. These contributions from the eighth nerve form the greater part of the fasciculus (p. 949).

(B) The tegmental region of the upper part of the pons contains new elements in connexion with the trigeminal nerve, but otherwise shows no very noticeable alteration.

The somatic efferent column of the grey matter is unrepresented, but the branchial efferent column is represented by the important *motor nucleus of the trigeminal nerve*. It is separated from the lateral part of the floor of the fourth ventricle by a thin layer of central grey matter and by a part of the formatio reticularis pontis. The general splanchnic efferent and afferent columns are not represented in the pons, and so the trigeminal motor nucleus has its sensory nucleus—which represents the somatic afferent column—situated close to its lateral side. It receives fibres from the pyramidal tract of the opposite side and from the rubrospinal tract of the same side.

The *superior sensory nucleus of the trigeminal nerve* lies on the lateral side of its motor nucleus, intervening between it and the middle cerebellar peduncle. It receives the short ascending branches of the incoming sensory fibres of the trigeminal nerve and is continuous below with the nucleus of the spinal tract, which receives their long descending branches.

The sensory root of the trigeminal nerve, unlike the sensory roots of the other cranial nerves, contains fibres of both cutaneous and deep sensibility. Clinical evidence suggests that the fibres which terminate in the nucleus of the spinal tract convey crude painful and thermal (vital) sensibility, while the superior sensory nucleus receives the fibres conveying proprioceptive and discriminative (gnostic) sensibility. This view receives additional support from the phylogenetic history of the superior sensory nucleus. It is absent in fishes, although they possess a well-defined nucleus of the spinal tract. It is present, but of small size relatively, in amphibia and reptiles, and it is constantly present in the mammalia. It therefore shows a close parallel to the nucleus gracilis and the nucleus cuneatus.

In addition, clinical evidence tends to show that painful stimuli from the area innervated by the ophthalmic nerve enter the lowest part of the nucleus of the spinal tract; those from the maxillary nerve terminate in its middle part; and those from the mandibular nerve, in its upper part.

The *nucleus of the lateral lemniscus* is a small collection of cells placed on the medial aspect of the tract in the upper part of the pons. It receives collaterals and fibres from the lateral lemniscus, and some of its efferent fibres enter the medial longitudinal bundle.

The white matter of the tegmentum at this level is marked by the absence of the corpus trapezoideum, which is now replaced by the lateral lemniscus, and the invasion of its dorsilateral part by the superior cerebellar peduncles.

The *medial lemniscus* occupies a position in the ventral part of the tegmentum, but it has moved laterally a short distance from the median raphe. Laterally it is related to the *spinal lemniscus*, the *trigeminal lemniscus*, and to the *lateral lemniscus* and its nucleus. As the lateral lemniscus ascends, it passes dorsally and lies close to the surface. It will be seen subsequently to send its fibres into the inferior corpus quadrigeminum and the medial geniculate body. The *medial longitudinal bundle* retains its paramedian position.

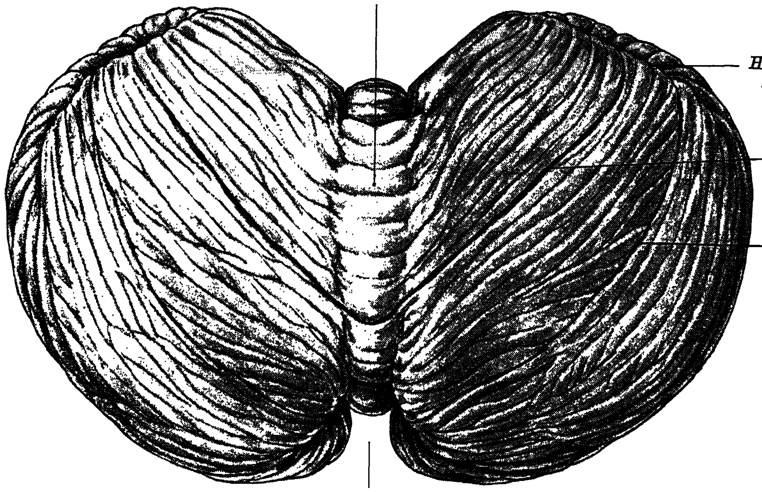
The *superior cerebellar peduncle* is formed by a large collection of fibres which take origin in the dentate nucleus of the cerebellum (p. 937), and pass upwards and forwards to enter the lateral part of the roof of the fourth ventricle. As it ascends in this position it inclines forwards and medially and enters the dorsilateral part of the tegmentum. The *anterior spinocerebellar tract* is intimately associated with the foregoing. It has already been traced up through the medulla oblongata, where it lies dorsal to the olivary nucleus and only separated from the surface by the anterior external arcuate fibres. In the lower part of the pons it inclines dorsally between the sensory nucleus of the trigeminal nerve and the middle cerebellar peduncle until it reaches the lateral aspect of the superior peduncle. Its fibres then curve downwards and backwards to enter the cerebellum.

THE CEREBELLUM

The **cerebellum**, the largest part of the hind-brain, lies behind the pons and medulla oblongata, and its median portion is separated from these structures by the cavity of the fourth ventricle. It lies in the inferior fossæ of the occipital bone and is covered by the tentorium cerebelli (p. 1024). It is somewhat ovoid in form, but constricted in its median part, and flattened from above downwards, its greatest diameter being from side to side. Its surface is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows, which vary in depth at different parts and separate its constituent folia. Its average weight in the male is about 150 gms. In the adult the proportion between the cerebellum and cerebrum is about 1 to 8, in the infant about 1 to 20.

General form.—The cerebellum consists of a narrow median strip, termed the *vermis*, and two *cerebellar hemispheres*. On the *superior surface*, however, there is no attempt at subdivision in the sagittal or parasagittal planes, so that the superior vermis, which is raised into a slight median ridge, is directly continuous with the hemisphere on each side. Anteriorly the superior vermis

FIG. 852.—The cerebellum. Superior aspect. (Sharpey-Schafer.)



projects upwards beyond the free margin of the tentorium cerebelli, and from there it slopes downwards and backwards, related above to the straight sinus. The upper surface of each hemisphere is in contact with the tentorium cerebelli, and slopes downwards and laterally from the superior vermis. It is bounded, in front, by an anterolateral margin, which corresponds to the attachment of the tentorium cerebelli to the posterior border of the petrous part of the temporal bone, and behind, by a curved posterior margin, which abuts against the transverse sinus as it lies in the attached margin of the tentorium cerebelli.

On the *inferior surface* the cerebellar hemispheres are separated from each other by a deep hollow, which is termed the *vallecula*. The inferior surface of the hemisphere is irregularly convex and lies in contact with the posterior surface of the petrous part of the temporal bone, the sigmoid sinus, the mastoid part of the temporal bone and the lower part of the squamous portion of the occipital bone. The *inferior vermis* projects into the floor of the vallecula and is limited on each side by the *sulcus valleculæ*.

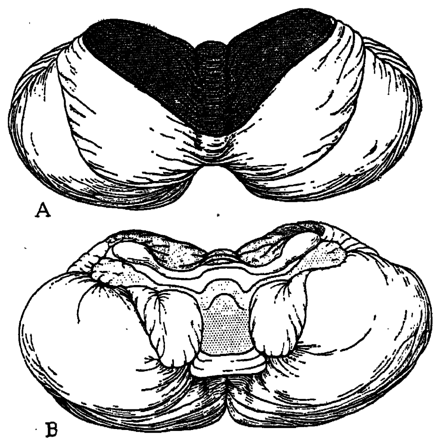
Anteriorly the cerebellum presents a wide, shallow notch, which lodges the pons and the upper part of the medulla oblongata, but these portions of the brain-stem are separated from it by the fourth ventricle. In the floor of the anterior cerebellar notch the peduncles pass into the white centre of the cerebellum.

Posteriorly the hemispheres are separated from each other by the posterior cerebellar notch, which is a deep and narrow interval, lodging the falx cerebelli of the dura mater.

SUBDIVISIONS OF THE CEREBELLUM

The nomenclature of the subdivisions of the cerebellum has undergone drastic revision in recent years and, owing to the researches of Bolk, Elliot Smith, Ingvar, Riley, Abbie and others, it is now possible to subdivide the cerebellum into areas which have the merit of possessing both an embryological and a morphological significance. Two lobes can be recognised, each consisting of a median and right and left lateral parts. They are separated by a deep fissure, termed the fissura prima, which crosses the whole width of the superior surface of the cerebellum and presents the outline of a widely open V (fig. 852). The portion of the cerebellum which lies in front of the fissura prima constitutes the anterosuperior (morphologically anterior) lobe. The portion which lies behind the fissura prima constitutes the postero-inferior (morphologically posterior) lobe; it includes not only the posterior part of the superior surface, but the whole of the inferior surface as well.

FIG. 853.—The lobes of the cerebellum.



A. Superior surface. B. Inferior surface. The anterosuperior lobe is shown in blue, and the postero-inferior lobe is uncoloured.

Superior surface.—The *anterosuperior lobe* forms rather less than one half of this surface. It is bounded in front by the anterior cerebellar notch and behind by the fissura prima, and includes a large part of the superior vermis. The remainder of this surface forms a part of the postero-inferior lobe. On each side the fissura prima reaches the anterolateral margin of the hemisphere, where it meets the middle cerebellar peduncle and cuts into the horizontal fissure. It is not continued round the anterolateral margin on to the inferior surface.

The part of the *superior vermis* which is included in the anterosuperior lobe is intersected by two short, but deep, transverse fissures, and is subdivided into three portions, termed the lingula, the central lobule and the lobulus culminis, in that order from before backwards. The *lingula* consists of a single lamella, which presents four or five poorly marked folia on its posterior aspect, while its anterior aspect is devoid of grey matter and is directly continuous with the white matter of the superior medullary velum (fig. 863). The *central lobule*, which is separated from the lingula by the *postlingual fissure*, is visible only on the anterior surface of the cerebellum; on each side it is continuous with the adjoining parts of the hemisphere, which are named the *alæ*. The *lobulus culminis* forms the whole of the median part of the anterosuperior lobe visible on the superior surface of the cerebellum. It is separated from the central lobule by the *postcentral fissure* and is limited behind by the fissura prima. On each side it is continuous with the adjoining parts of the hemisphere, which are termed the *anterior lunate lobules*.

The posterior part of the superior surface of the cerebellum is formed by the *postero-inferior lobe*. It includes a small portion of the superior vermis, which is divided into a *lobulus clivi* and a *lobulus folii*; the former adjoins the fissura prima. The large part of the superior surface of the hemisphere which belongs to this lobe is subdivided into two parts by a curved fissure, termed the *postlunate fissure*; it separates the *posterior lunate lobule* in front from the *superior surface of the ansiform lobule* behind.

The **inferior surface** of the cerebellum belongs entirely to the postero-inferior lobe: it includes the whole of the inferior vermis and the inferior aspect of each hemisphere. The *inferior vermis* is subdivided into four small portions, named, from before backwards, the nodule, the uvula, the pyramid and the lobulus tuberis. The *nodule*, which is intimately related to the fourth ventricle (*vide*

infra), is separated from the *uvula* by a short but deep transverse fissure, termed the *postnodular fissure*. A similar fissure, termed the *fissura secunda*, intervenes between the uvula and the *pyramid*, which is separated from the *lobulus tuberis* by the *postpyramidal fissure*.*

The inferior surface of the hemisphere is marked by a deep fissure, termed the *retrotonsillar fissure*, which passes laterally from the sulcus valleculæ opposite the fissura secunda and then curves forwards to gain the anterior aspect of the hemisphere. Together with the sulcus valleculæ it forms the boundaries of a circumscribed portion of the cerebellum, termed the *tonsil*, which is connected to the uvula across the floor of the sulcus valleculæ by a strip of cortex, termed the *furrowed band*. Superiorly the tonsil lies in intimate relation with the inferior surface of the inferior medullary velum. The large remaining part of the inferior surface of the hemisphere forms the *inferior surface of the ansiform lobule*, and the portion of it which lies lateral to the tonsil is connected to the lateral aspect of the pyramid across the floor of the sulcus valleculæ. The ansiform lobule is intersected by a deep fissure, named the *horizontal fissure*, which separates its inferior from its superior surface. In a general way this fissure follows the posterior and anterolateral borders of the hemisphere and its lips are separated in front by the middle cerebellar peduncle; it may appear on the superior surface of the cerebellum near the posterior cerebellar notch.

A small, partially detached portion of the cerebellum, termed the *flocculus*, lies immediately below the auditory nerve as it enters the brain-stem, and is crossed anteriorly by the fila of the glossopharyngeal and vagus nerves as they pass laterally to reach the jugular foramen. It is somewhat oval in outline, with a crenated margin, and from its medial end a narrow band of white fibres emerges, which constitutes the *peduncle* of the flocculus; it is covered anteriorly by the lateral recess of the fourth ventricle and the part of the choroid plexus which projects from the aperture of the recess (fig. 836).

The superior aspect of the nodule is directed towards the fourth ventricle. Anteriorly it is covered with grey matter and crossed by two or three shallow fissures. In this situation it is separated from the ventricular cavity by a double layer of pia mater and its contained choroid plexus, and the ventricular ependyma (fig. 863). Posteriorly the grey matter is deficient, and the white matter lies on the free surface, covered with a layer of neuroglia and the ventricular ependyma (fig. 863). The lateral aspect of the nodule is free anteriorly and is covered with grey matter; posteriorly, it presents a narrow strip, where its white core would be exposed, were it not directly continuous with the nervous layer of the inferior medullary velum.

The peduncle of the flocculus contains both afferent and efferent fibres. At the lateral angle of the floor of the fourth ventricle it divides into a dorsal and a ventral part. Through the dorsal part the flocculus establishes connexions with the cerebellar nuclei and the pyramid, and some fibres traverse the inferior medullary velum to reach the nodule and the uvula. The ventral part passes medially and turns upwards close to the lateral border of the pontine part of the floor of the fourth ventricle. Many of these fibres are afferent from the vestibular nuclei, but others are efferent and ascend to a higher level.†

Certain portions of the cerebellum are phylogenetically much older than the rest and constitute the *palæocerebellum*. They comprise the lingula in the antero-superior lobe, and the flocculi, the nodule and the uvula in the postero-inferior lobe. The appearance of higher motor centres in the neopallium (p. 973) called for increased cerebellar activity, and the demand was met by enlargement of certain portions of the vermis (lobulus culminis, lobulus clivi, lobulus folii and lobulus tuberis ‡) and by lateral extensions which formed the hemispheres. These therefore are more recent acquisitions and have become greatly expanded

* On morphological grounds this fissure is frequently termed the *prepyramidal fissure*.

† For a detailed description consult a paper by T. B. Johnston in the *Journal of Anatomy*, vol. lxviii., July, 1934.

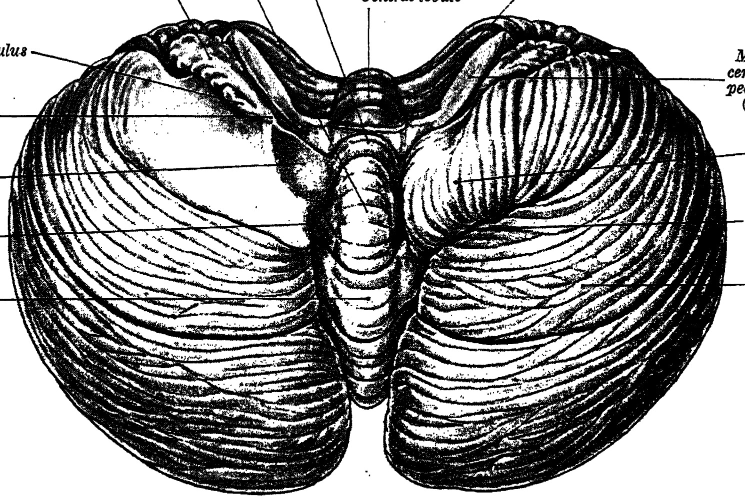
‡ According to Abbie the lobulus culminis receives, through the medium of the lower transverse fibres of the pons, numerous connexions from the temporal, parietal and occipital cortex, whereas the lobuli clivi, folii et tuberis receive similar connexions from the frontal cortex through the upper transverse fibres of the pons. For a detailed account, see *Phil. Trans. Series B. vol.* 115, *No. B.* 795, "The Projection of the Forebrain on the Pons and Cerebellum," by A. A. Abbie.

and elaborated in the mammalia and especially in the anthropoid apes and man. They are linked up freely with the cerebral cortex and constitute the *neo-cerebellum*, which has kept pace in its evolution with the growth of the basilar part of the pons and the growth of the olivary nucleus.

The superior (anterior) medullary velum is a thin lamina of white substance, which stretches between the superior cerebellar peduncles (brachia conjunctiva), and with them forms the roof of the upper part of the fourth ventricle; its deep surface is covered with the ventricular ependyma. The velum is narrow above, where it extends into the interval between the inferior corpora quadrigemina, and broader below, where it is continuous with the white substance of the superior vermis. The folia of the lingula are prolonged on to the dorsal surface of its lower half, and a median ridge, termed the *frenulum veli*, descends upon its upper part from between the inferior corpora quadrigemina. The trochlear nerves emerge at the sides of the frenulum (fig. 864).

The inferior (posterior) medullary vela form two thin, somewhat crescentic, sheets, placed one on each side of the nodule. Each consists of a thin layer of

FIG. 854.—The cerebellum. Inferior aspect. (Sharpey-Schafer.)



The tonsil and the adjoining part of the ansiform lobule of the right side have been removed.

white matter and neuroglia, covered on its upper aspect with the ventricular ependyma, and on its lower aspect with pia mater. Its superior surface forms the lower wall of the lateral dorsal recess of the fourth ventricle (p. 938); its inferior surface is related to the superior aspect of the tonsil. Its convex peripheral margin is continuous with the white core of the cerebellum and with the sides of the pyramid, uvula and nodule; its anterior (sometimes inferior) border is free (fig. 863) and from it the ventricular ependyma is prolonged downwards in close apposition with the pia mater to form the thin part of the roof of the ventricle and to reach the tæniæ. At its anterolateral corner the velum is continuous with the dorsal part of the peduncle of the flocculus, from which most, if not all, of its nerve fibres are derived.

Development of the Cerebellum

Early in the third month the cerebellum is represented by a mass which stretches across the roof of the upper part of the hind-brain vesicle and presents the appearance of a dumb-bell (fig. 145). Its narrow median part is destined to form the vermis, and its enlarged extremities develop into the hemispheres. As growth proceeds a number of transverse grooves appear on the dorsal aspect of the cerebellar rudiment, and give rise to the numerous fissures which characterise the surface of the cerebellum (fig. 854).

The first of these grooves demarcates the most caudal portion of the hemisphere, and is termed the *parafloccular fissure*. The parts which lie caudal to the fissure form the flocculus and the paraflocculus,* which is only a vestigial structure in the human brain. At first these structures constitute the most caudal part of the hemisphere, but, owing to the growth of the adjoining areas, they come to occupy the anterior part of the inferior surface in the adult. About the same period a small groove delimits the most caudal part of the vermis, which forms the nodule. This *postnodular fissure* is in line with the parafloccular fissure, and throughout life the nodule remains connected to the flocculus by the inferior medullary velum. Both these parts of the cerebellum are formed in close proximity to the line of attachment of the epithelial roof, i.e. to the rhombic lip (p. 112).

At the end of the third month a transverse furrow appears on the cephalic slope of the cerebellar rudiment, and deepens to form the *fissura prima*, which cuts into the vermis and both hemispheres, separating off the most headward portion of the rudiment to form the anterosuperior lobe of human anatomy (morphologically anterior lobe).

About the same period two short transverse grooves appear on the inferior vermis behind the postnodular fissure. The first of these is the *fissura secunda*, which demarcates the uvula, and the second is the *postpyramidal fissure*, which demarcates the pyramid (fig. 855). The whole cerebellum grows in a dorsal direction, and the caudal, or inferior, aspects of the hemispheres undergo much greater enlargement than the inferior vermis, which therefore becomes buried at the bottom of a deep hollow —the *vallecula*. While these changes are taking place numerous additional fissures develop, but they have little morphological significance. The most extensive of them forms the *horizontal fissure*.

THE INTERNAL STRUCTURE OF THE CEREBELLUM

The cerebellum exhibits a profound difference in structure from the spinal cord, the medulla oblongata and the pons, for the grey and white matter of which it is comprised are arranged in a precisely opposite manner. The grey matter is found covering the whole surface of the cerebellum and dipping in to line the various fissures which cross its surface. It is true that certain aggregations of grey matter are found in its interior, but that does not in any way alter the importance of the peripheral distribution of the grey matter as a whole, and the central arrangement of the white matter. In this way the cerebellum resembles the cerebrum, and it is this modification of the disposition of the grey matter which has rendered possible the enormous degree of expansion which these two parts of the nervous system have undergone during the process of evolution.

The **white matter** forms a central core, which is much thicker in the lateral parts than it is in the median area, where it forms a flattened strip connecting the enlarged lateral portions to each other. From its surfaces a series of nearly parallel plates or laminæ project towards the surface, and these give off secondary laminæ, usually more or less at right angles to the primary laminæ. In turn the secondary laminæ may give off still shorter laminæ, all of which are covered with grey matter. When a section is made through the cerebellum parallel to the median plane it divides the primary laminæ at right angles, and the cut surface presents a characteristic branched appearance which is termed the *arbor vitæ* (fig. 860).

The white matter of the cerebellum consists of (1) *fibriæ propriæ* and (2) *projection fibres*.

(1) The *fibræ propriæ* do not leave the cerebellum, but connect different cortical areas with one another. They may cross the median plane, and in that

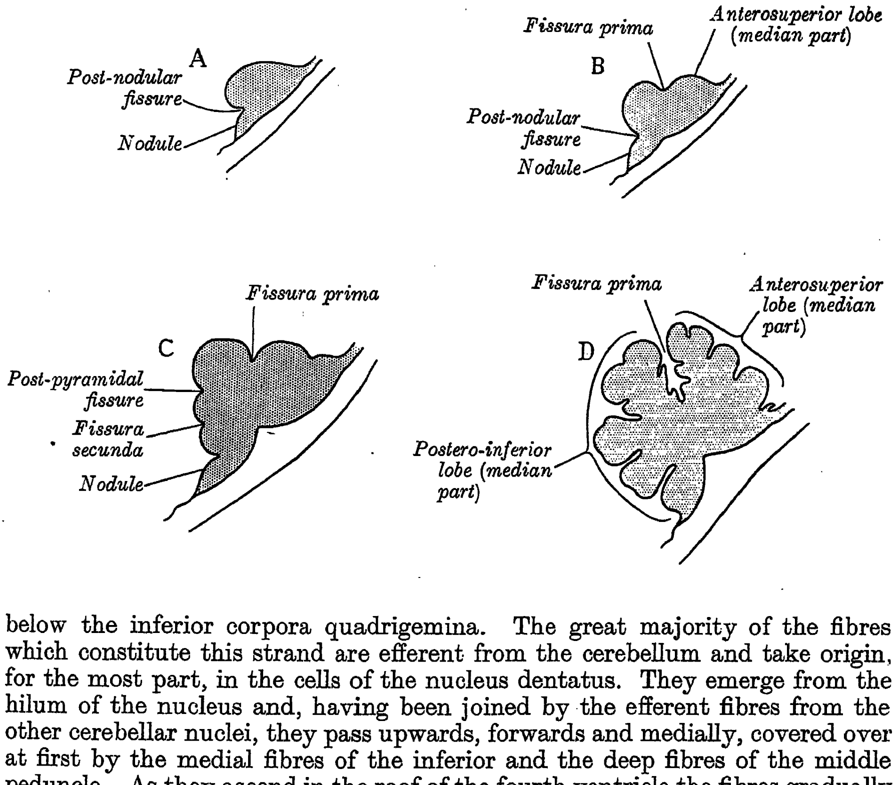
* In man the paraflocculus is represented by one or two small folia, placed on the inferior aspect of the middle cerebellar peduncle, close to the posterior margin of the flocculus, from which it is separated by a distinct fissure (fig. 854).

event they are termed *commissural fibres*, or they may be homolateral *association fibres*. The latter may pass between adjoining laminæ or they may extend from one area to another through the central white core.

(2) The **itinerant (projection) fibres** connect the cerebellum with other parts of the brain and the spinal cord. They are grouped together into three large bundles or *peduncles* on each side and these issue from the anterior cerebellar notch. The superior peduncles connect the cerebellum to the mid-brain, the middle peduncles connect it to the pons, and the inferior peduncles connect it to the medulla oblongata.

The **superior cerebellar peduncles** (brachia conjunctiva) emerge from the upper part of the anterior cerebellar notch and are hidden from view by the anterosuperior lobe of the cerebellum. When that structure is pulled aside they can be seen connected by the superior (anterior) medullary velum, and ascending in the lateral part of the roof of the fourth ventricle to disappear just

FIG. 855.—Median sagittal sections through the developing cerebellum, showing four different stages.



below the inferior corpora quadrigemina. The great majority of the fibres which constitute this strand are efferent from the cerebellum and take origin, for the most part, in the cells of the nucleus dentatus. They emerge from the hilum of the nucleus and, having been joined by the efferent fibres from the other cerebellar nuclei, they pass upwards, forwards and medially, covered over at first by the medial fibres of the inferior and the deep fibres of the middle peduncle. As they ascend in the roof of the fourth ventricle the fibres gradually incline forwards, and sink into the tegmental region of the mid-brain under cover of the lateral lemniscus. They then sweep medially to decussate with the corresponding fibres of the opposite side. After the decussation the fibres divide into ascending and descending branches. Most of the ascending branches end in the red nucleus, but some are continued upwards into the subthalamic region, where most of them end in the arcuate portion of the lateral nucleus of the thalamus. Others are said to proceed to the nuclei of the oculomotor and trochlear nerves. The descending branches can be traced downwards through the pons into the medulla oblongata and, according to Cajal, they are continued into the anterior and lateral white columns of the spinal cord. The red nucleus, through the rubrospinal tract, acts as the main distributing centre for efferent cerebellar impulses.

In addition to these efferent fibres the superior cerebellar peduncle contains the afferent fibres of the anterior spinocerebellar tract and a group of fibres

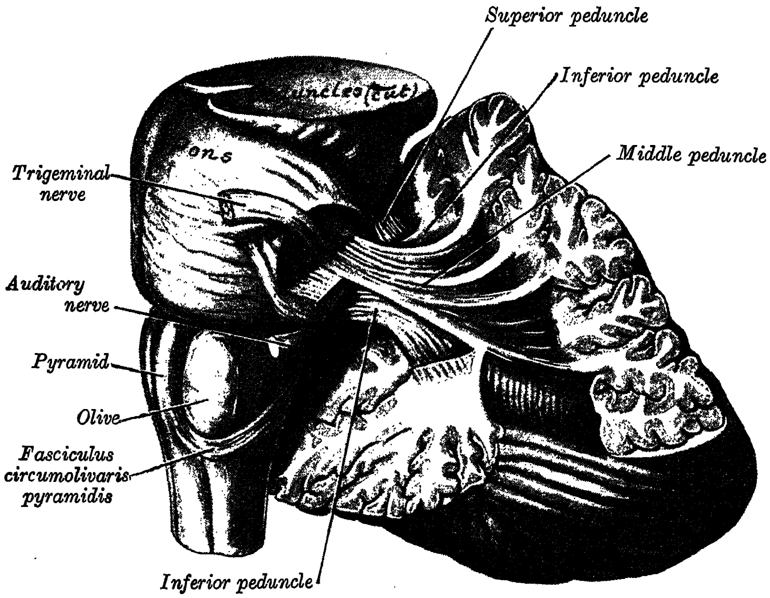
which take origin in the tectum of the mid-brain and constitute a tectocerebellar pathway for the passage of visual impulses to the cerebellum. These two afferent tracts utilise the peduncle as a convenient mode of access to the cerebellum.

The fibres of the anterior spinocerebellar tract ascend from the spinal cord (pp. 900 and 925), and terminate in the cortex of the superior vermis on both sides of the median plane.

The **middle cerebellar peduncles** (brachia pontis) (fig. 856) are largely composed of centripetal fibres, which arise from the cells of the nuclei pontis of the opposite side and end in the cortex of the cerebellar hemispheres (neocerebellum); they are said to contain also some efferent fibres to the nuclei pontis, and others to the spinal cord.

The fibres of each middle peduncle are arranged in three fasciculi, superior, inferior, and deep. The *superior* fasciculus is derived from the upper transverse fibres of the pons; it is directed backwards and laterally superficial to the other two fasciculi, and is distributed mainly to the lobules on the inferior surface of the cerebellar hemisphere, and to the parts

Fig. 856.—A dissection showing the projection fibres of the cerebellum. (E. B. Jamieson.)



of the superior surface adjoining the posterior and lateral margins. The *inferior* fasciculus is formed by the lowest transverse fibres of the pons; * it passes under cover of the superior fasciculus and is continued downwards and backwards more or less parallel with it, to be distributed to the folia on the under surface close to the vermis. The *deep* fasciculus comprises most of the deep transverse fibres of the pons. It is at first covered by the superior and inferior fasciculi, but crossing obliquely it appears on the medial side of the superior, from which it receives a bundle; its fibres spread out and pass to the upper anterior cerebellar folia. The fibres of this fasciculus cover those of the inferior peduncle.

The **inferior cerebellar peduncle** (restiform body) forms a second large tract of afferent fibres to the cerebellum. It draws its constituent fibres from a variety of sources, and they come together on the dorsilateral aspect of the upper part of the medulla oblongata. At the anterior cerebellar notch the tract bends backwards abruptly and insinuates itself between the superior and the middle peduncles. Each inferior peduncle contains the following fasciculi: (1) the posterior spinocerebellar tract, which ascends uncrossed from the spinal cord, and terminates in the cortex of the vermis on both sides of the median

* See footnote ‡, p. 928.

plane * ; (2) the olivocerebellar tract from the olivary nucleus of the opposite side, which terminates for the most part in the cortex of the hemispheres ; (3) the parolivocerebellar fibres from the accessory olivary nuclei of the opposite side, which terminate in the cortex of the palæocerebellum. (4) The anterior external arcuate fibres from the nucleus gracilis and nucleus cuneatus of the opposite side ; (5) the posterior external arcuate fibres from the corresponding nuclei of the same side. Both these groups end in the cortex of the cerebellum, but

FIG. 857.—The connexions of the cerebellum. Diagrammatic.

their precise connexions have not been satisfactorily demonstrated. (6) Vestibular fibres, derived partly from the vestibular nuclei but largely from the vestibular division of the auditory nerve, occupy the medial part of the inferior cerebellar peduncle and terminate in the cerebellar cortex, including the flocculus ; (7) cerebello-vestibular fibres, which constitute an efferent pathway from the roof nuclei to the superior and lateral vestibular nuclei.

Grey matter.—The grey matter of the cerebellum is found in two situations : (1) on the surface, forming the cortex ; (2) as independent masses in the interior.

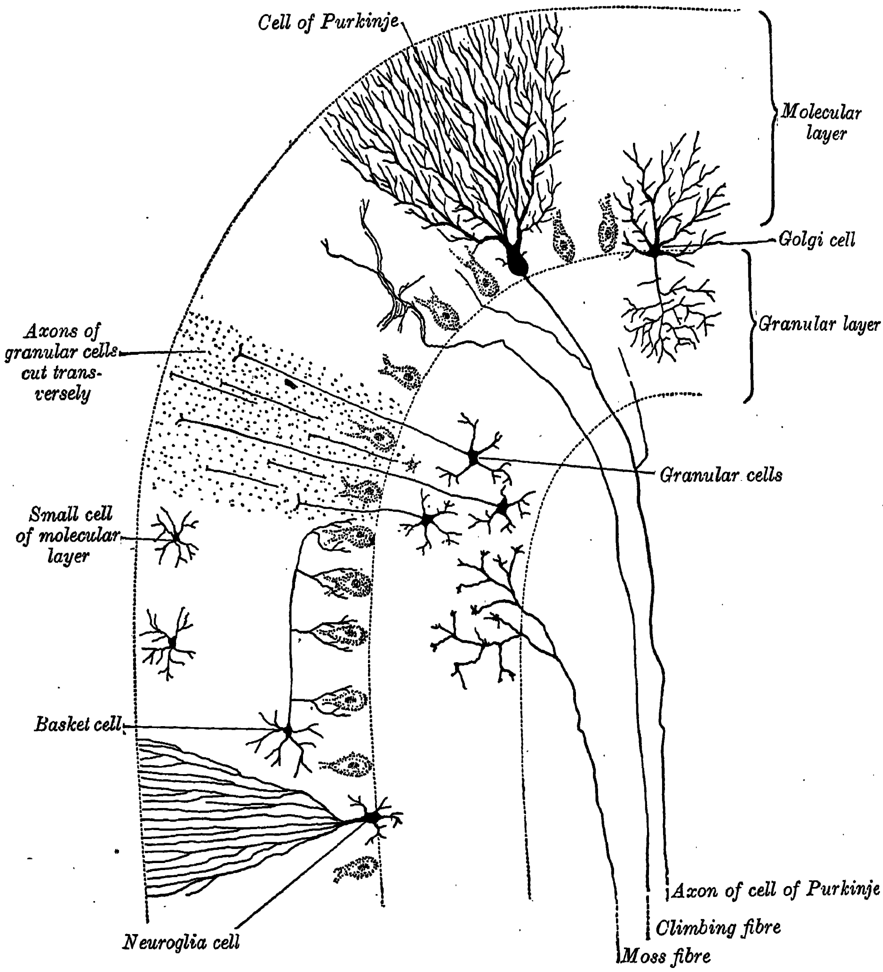
(1) The **grey matter of the cortex** presents a characteristic foliated appearance, due to the series of laminæ which project from the central white matter ;

* The fibres of the posterior spinocerebellar tract terminate in the vermis, but very few can be traced into the lobuli clivi, tuberis et folii. This distribution was demonstrated by Salisbury, McNulty and Horsley, and has recently been confirmed by Ingvar.

these in their turn give off secondary laminæ, which are covered by grey matter. Externally the cortex is covered with pia mater ; internally it rests on the white matter.

Throughout its whole extent the cerebellar cortex shows complete uniformity of structure. Local differences, which are so pronounced in the cerebral cortex, do not occur in the cerebellum, so that it is impossible to distinguish between sections taken from different areas. Not only is this the case in man, but it holds good throughout the vertebrate kingdom.

FIG. 858.—A transverse section through a cerebellar folium. Diagrammatic. (After Ramón y Cajal and Kölliker.)

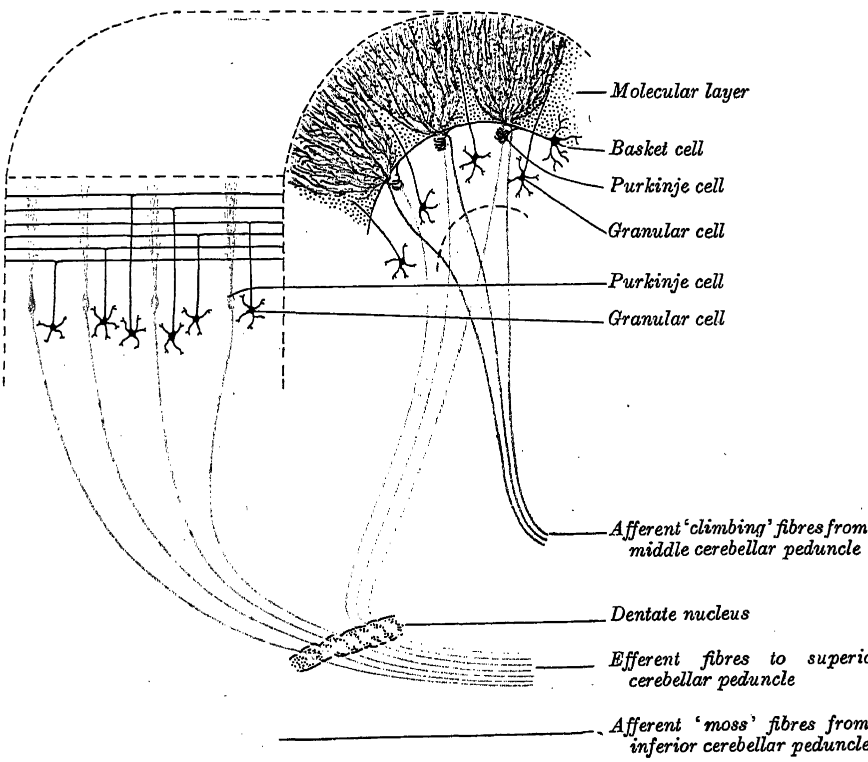


The cerebellar cortex consists of three layers, viz. an outer, molecular layer, an inner, granular layer and an intermediate, ganglionic layer formed by the large Purkinje cells.

The *molecular layer* comprises a large number of non-medullated nerve-fibres and two layers of nerve-cells. The nerve-fibres are derived from several sources. (*a*) The axons of the cells in the granular layer pass into the molecular layer where they divide at right angles, the individual branches passing right and left in the long axis of the folium. As these branches traverse the folium they come into contact association with the dendrites of a large number of Purkinje cells, and they are described as forming cruciate axodendritic synaptic connexions. (*b*) Fibres enter the molecular layer from the white matter of the cerebellum. They come into intimate relation with the dendrites of Purkinje's cells, breaking up into end filaments which follow the dendrites in their arbor-

isations (fig. 859). They are termed 'climbing fibres,' and Cajal regards them as the afferent fibres from the vestibular (in the palæocerebellum) and pontine nuclei (in the neocerebellum). (c) The dendrites and the collaterals of the axons of the cells of Purkinje, which will be referred to below. (d) The dendrites and fibres of the nerve-cells which lie within the molecular layer. In addition to these there are other fibres which have a vertical direction and are the processes of large neuroglia cells situated in the granular layer. They pass outwards to the periphery of the grey matter, where they expand into little conical enlargements, which form a sort of limiting membrane beneath the pia mater, analogous to the membrana limitans interna of the retina.

FIG. 859.—Schematic representation of the intracortical connexions of the cerebellar projection fibres.



In the right part of the figure a cerebellar folium is shown in transverse section; in the left part of the figure, the same folium is shown cut parallel with its long axis.
Blue: cells of Purkinje and their axons. *Red*: climbing fibres. *Orange*: 'moss' fibres.

The *cells of the molecular layer* are arranged in superficial and deep strata. The deep stratum contains large pyramidal cells, which have been termed the '*basket*' *cells*. Their dendrites and their axons extend in a sagittal direction, and the latter are clearly of great importance since they not only end by arborising around the body of a Purkinje cell, but they also give off collaterals which terminate in the same way. One basket cell may, through its axon, come into relationship with six or seven Purkinje cells (fig. 858). The superficial stratum consists of small pyramidal cells which, like the basket cells, send their dendrites and axons in a sagittal direction. Their axons terminate by establishing synaptic relationships with the dendrites of Purkinje's cells.

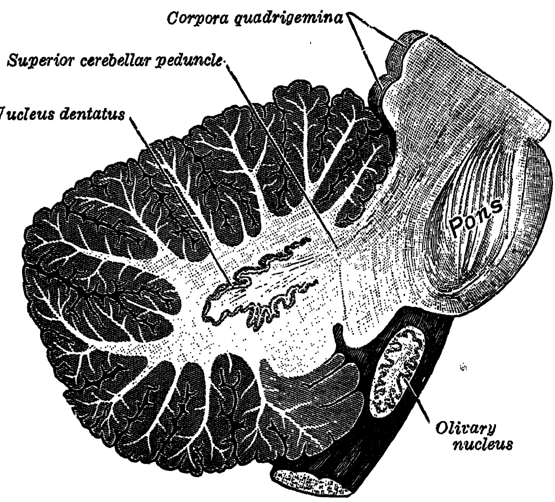
The *ganglionic layer* consists of *cells of Purkinje*, which are peculiar to the cerebellum; they form a single stratum of large, flask-shaped cells at the junction of the molecular and granular layers, their bases resting against the latter. The cells are flattened in a direction transverse to the long axis of a folium, and thus appear broad in sections carried across a folium, and fusiform in sections parallel to the long axis of a folium (fig. 859). From the neck of the flask one

or more dendrites arise and pass into the molecular layer, where they subdivide and form an extremely rich arborescence, the various subdivisions of the dendrites being covered by lateral spine-like processes. This arborescence, like the cell, is flattened at right angles to the long axis of a folium ; in other words, it resembles the branches of a fruit-tree trained against a trellis or a wall. Hence, in sections carried across a folium the arborescence is broad and expanded ; whereas in sections parallel to the long axis of a folium, the arborescence, like the cell, is seen in profile, and is limited to a narrow area (fig. 859).

From the bottom of the flask-shaped cell the axon arises ; this passes through the granular layer, and, becoming medullated, is continued as a nerve-fibre in the subjacent white matter. As it traverses the granular layer it gives off fine collaterals, some of which run into the molecular layer. The axons of the cells of Purkinje terminate in the deep nuclei of the cerebellum.

The *granular layer* (fig. 859) contains numerous small nerve-cells together with many nerve-fibres. The *granular cells*, which are the most abundant of

FIG. 860.—A sagittal section through the right cerebellar hemisphere. The right olive has also been cut sagittally.



the elements of the cerebellar cortex, are small and round, with relatively large nuclei. Each cell is provided with four or five dendrites, which radiate out from it and end close to the cell body in fine terminal tufts. The axons of the granular cells have already been described in the molecular layer.

Many fibres enter the granular layer from the white substance of the cerebellum. Some merely pass through it on their way to the molecular layer (climbing fibres), but others end in the granular layer by dividing into numerous branches, on which peculiar moss-like appendages can be seen. They are termed *moss fibres*, and they end by forming synaptic connexions with the dendrites of the granular layer. According to Cajal these fibres are derived from the inferior cerebellar peduncle and especially from the spinocerebellar and olivocerebellar tracts.

Apart from the homogeneity of the cortex, the most striking feature of the minute anatomy of the cerebellum is the provision which is made for the simultaneous discharge of the impulses transmitted by the basket and granular cells into a large number of Purkinje cells. As each 'moss' fibre discharges into several granular cells; the number of Purkinje cells which can be stimulated by one 'moss' fibre is considerably magnified. It will be remembered that the Purkinje cells constitute the first neurone on the efferent pathway from the cerebellum, and this arrangement therefore provides a mechanism whereby an afferent impulse is able to bring about a widely distributed response.

(2) **The independent centres of grey matter** are imbedded in the white matter of the cerebellum and are four in number on each side : one is of large size,

and is known as the nucleus dentatus; the other three, much smaller, are situated near the middle of the cerebellum, and are known as the nucleus emboliformis, nucleus globosus, and nucleus fastigii. These nuclei receive the axons of the cells of Purkinje, and they therefore constitute cell stations on the efferent pathways from the cerebellar cortex.

The *nucleus dentatus* (fig. 860) is situated a little to the medial side of the centre of the stem of the white matter of the hemisphere. It consists of an irregularly folded grey lamina, containing a white centre and presenting, on its anteromedial aspect, an opening, termed the hilum, from which most of the fibres of the superior cerebellar peduncle (brachium conjunctivium) emerge (p. 931).

The *nucleus emboliformis* lies close to the medial side of the nucleus dentatus, and partly covering its hilum. The *nucleus globosus*, an elongated mass, lies on the medial side of the nucleus emboliformis, and is directed anteroposteriorly. The *nucleus fastigii*, somewhat larger than the other two, is situated close to the median plane in the anterior part of the superior vermis. All these nuclei lie in the upper wall of the lateral dorsal recess of the fourth ventricle (p. 938) and are separated from its cavity by a thin layer of white matter.

It may be noted that, whereas electrical stimulation of the cerebellar cortex produces no visible response, electrical stimulation of the dentate nucleus causes movements which vary in their site and character with the particular part of the nucleus stimulated, the different parts of the body being definitely associated with specific areas of the nucleus.

The Functional Significance of the Cerebellum

The cerebellum differs from the portions of the central nervous system which have been examined hitherto in showing no sign of segmentation at any stage of its development. It is entirely a suprasegmental structure, which presumbly took over functions previously carried out in the individual segments of the spinal cord.

Its outstanding feature, and one that differentiates it from all other parts of the central nervous system, is the homogeneity of the structure of its cortex. In the cerebral cortex it has been possible to map out a number of areas which show differences in structure (p. 988), and it has been demonstrated in many instances that differences in structure are associated with differences in function. Accordingly there is good ground for supposing that the influence which the cerebellum exerts on the motor apparatus can be referred to one function only. The experimental and clinical evidence, though sometimes contradictory, tends on the whole to show that the cerebellum exerts a controlling and regulating influence over muscle tone, the word 'tone' being used in its broadest sense. Luciani summed up the cardinal symptoms of cerebellar disease as 'Atonia, Asthenia and Astasia,' but it is certainly probable that the asthenia can be ascribed to loss of tone in the actively contracting muscle groups, and not unlikely that the astasia may be attributed to loss of tone in the antagonistic groups.

The cells which form the cerebellum in the embryo migrate from the rhombic lip and especially from the region of the vestibular nuclei, but this intimate relationship with the equilibratory centres does not necessarily mean more than that the muscular movements concerned in equilibratory reflexes demand corresponding adjustments of muscle tone, which are carried out by the cerebellum. The part which the cerebellum plays in muscular co-ordination and in synergic control is probably also attributable to its control and regulation of muscle tone.

Functional localisation.—Of recent years many attempts have been made to demonstrate the association of definite areas of the cerebellum with individual parts of the body. The enormous elaboration of the neocerebellum in mammals at once suggests its association with the complicated, unilateral movements of the individual limbs, while the palæocerebellum would, on the same grounds, be associated with the movements of the head, neck and trunk and the automatic associated movements of the limbs. To a certain extent this can be said to be

borne out both by experimental and by clinical evidence, but only in a very broad and general way. In lesions confined to the superior vermis falling forwards is a striking symptom, indicating a loss of tonus in the extensor muscles of the trunk and head. In lesions confined to the inferior vermis the striking feature is falling backwards, indicating a loss of tonus in the flexor muscles. Gordon Holmes, however, has found that it is impossible to localise a small cerebellar lesion by studying the muscle groups affected, for in every case, and independent of the size of the lesion, he has found alterations in more than one part of the body. Nevertheless, it would appear that certain regions do exercise a general but not exclusive dominance over certain parts of the body.

A different type of cortical localisation, the importance of which cannot yet be appreciated fully, has been worked out by Gordon Holmes and Grainger Stewart. They found that definite areas of the olivary nucleus are associated with definite areas of the cerebellar cortex of the opposite side. They showed that the accessory olives and the upper and medial portion of the olivary nucleus are associated with the vermis, while the much larger, lower part of the olivary nucleus is associated with the hemisphere, not in a general way but in a very particular manner, definite portions of the nucleus being associated with quite circumscribed areas of the cerebellar cortex. This work has been confirmed by Brouwer in his study of cases of neocerebellar atrophy. The comparative study of the olivary nucleus is in perfect harmony with these findings, for the greater part of it develops *pari passu* with the development of the ventral part of the pons and the cerebellar hemispheres. What this close relationship connotes will only be determined when the connexions of the olivary nucleus have been more fully studied and elucidated.

The Fourth Ventricle (figs. 861—864)

The **fourth ventricle**, or cavity of the hind-brain, is a somewhat lozenge-shaped space situated in front of the cerebellum, and behind the pons and upper half of the medulla oblongata. Developmentally considered, it consists of three parts: a *superior* belonging to the isthmus rhombencephali, an *intermediate*, to the metencephalon, and an *inferior*, to the myelencephalon. It is lined with ciliated epithelium, and its inferior angle is continuous with the central canal of the medulla oblongata; its superior angle is continuous with the aqueduct of the mid-brain, which opens above into the cavity of the third ventricle. From its middle part a narrow, curved pouch, named the *lateral recess*, is prolonged on each side between the inferior cerebellar peduncle and the peduncle of the flocculus, and reaches as far as the medial part of the flocculus itself. It is crossed anteriorly by the fila of the glossopharyngeal and vagus nerves. The lateral extremity of the recess is open, allowing a portion of the choroid plexus of the fourth ventricle to protrude into the subarachnoid space (fig. 836). In the median plane the cavity extends dorsally into the white core of the cerebellum, forming a *dorsal median recess* (fig. 861) above the nodule, and on each side a *lateral dorsal recess* extends backwards still further (fig. 906), lying below the cerebellar nuclei, from which it is separated by a thin layer of white matter.

The fourth ventricle possesses lateral boundaries, a roof or dorsal wall, and a floor or ventral wall (rhomboid fossa).

Lateral boundaries.—The lower part of each lateral boundary is constituted by the gracile tubercle (clava), the fasciculus cuneatus, and the inferior cerebellar peduncle (restiform body); the upper part, by the superior cerebellar peduncle.

The **roof or dorsal wall** (fig. 862).—The upper portion of the roof is simple, and is formed by the superior cerebellar peduncles (brachia conjunctiva) and the superior medullary velum. The lower portion is more complicated; it is formed by: (1) the posterior part of the upper surface of the nodule, which is devoid of grey matter, (2) the inferior medullary vela, (3) the ventricular ependyma, covered with the tela chorioidea inferior, (4) the tæniæ of the ventricle, and (5) the obex.

The *superior cerebellar peduncles* (p. 931), on emerging from the central white matter of the cerebellum, pass upwards and forwards, forming at first

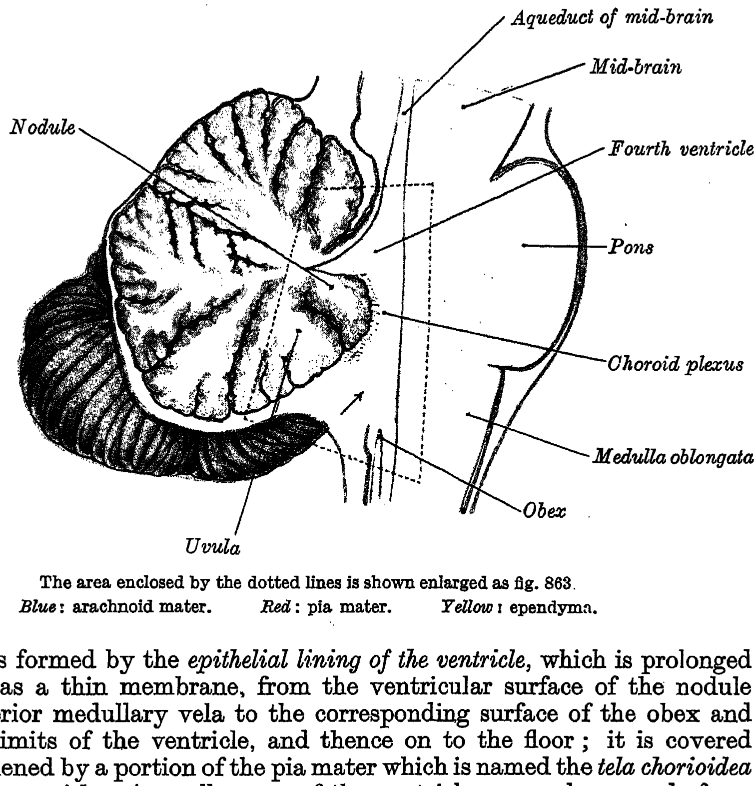
the lateral boundaries of the upper part of the ventricle ; on approaching the inferior corpora quadrigemina, they converge, and their medial portions overlap the ventricle and form part of its roof.

The *superior* (*anterior*) *medullary velum* (p. 929) fills the angular interval between the superior cerebellar peduncles, and is continuous behind with the central white matter of the cerebellum ; it is covered on its dorsal surface by the lingula of the superior vermis (fig. 863).

The nodule (p. 927) and the inferior medullary vela (p. 929) have already been described in detail.

Below the free margin of the inferior medullary velum on each side, and over the anterior part of the nodule in the median plane, the roof of the ventricle is devoid of nervous matter except in the immediate vicinity of the lower lateral boundaries of the ventricle, where two narrow white bands, termed the *tæniæ of the fourth ventricle*, appear ; these bands meet over the inferior angle of the ventricle in a thin triangular lamina, named the *obex*. The non-nervous part

FIG. 861.—Sagittal section through the brain-stem and the cerebellum close to the median plane. Diagrammatic. The arrow is in the median aperture of the fourth ventricle.



The area enclosed by the dotted lines is shown enlarged as fig. 863.
Blue: arachnoid mater. *Red*: pia mater. *Yellow*: ependyma.

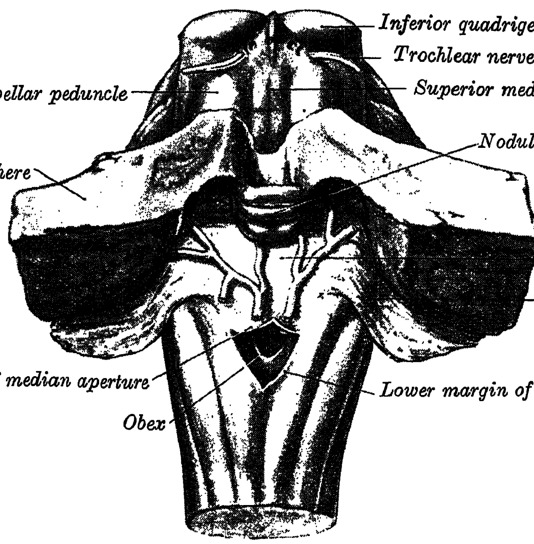
of the roof is formed by the *epithelial lining of the ventricle*, which is prolonged downwards as a thin membrane, from the ventricular surface of the nodule and the inferior medullary vela to the corresponding surface of the obex and the lateral limits of the ventricle, and thence on to the floor ; it is covered and strengthened by a portion of the pia mater which is named the *tela chorioidea of the fourth ventricle*. A small recess of the ventricle passes downwards for a short distance behind the obex (fig. 861), which is thus separated from the pia mater ascending from the posterior aspect of the medulla oblongata.

The *obex* is a thin, triangular, grey lamina, which covers the lower angle of the ventricle and is attached by its lateral margins to the gracile tubercle. It is covered with ependyma on both its anterior and posterior surfaces. The *tela chorioidea of the fourth ventricle* is the name applied to the fold of pia mater which is carried upwards between the cerebellum and the medulla oblongata. It consists of two layers, which are continuous with each other above, and are more or less adherent throughout. The posterior layer covers the antero-inferior surface of the cerebellum, while the anterior is applied to the structures which form the lower part of the roof of the ventricle, and is continuous inferiorly with the pia mater on the inferior cerebellar peduncles and the lower part of the medulla.

The openings in the roof.—In the roof of the fourth ventricle there are three openings, a median and two lateral. The *median aperture* is a large opening, situated below the nodule (fig. 862); it varies considerably in its extent and its irregular upper border is drawn backwards towards the inferior vermis in a somewhat funnel-shaped manner (fig. 863). The *lateral apertures* are placed at the ends of the lateral recesses and they are partly occupied by portions of the choroid plexus, which protrude into the subarachnoid space (fig. 836). Through these openings the ventricular cavity communicates with the subarachnoid space, and the cerebrospinal fluid can circulate from the one cavity to the other. Occasionally one of the lateral recesses may fail to open into the subarachnoid space, but the median aperture is constantly present.

The choroid plexuses.—Two highly vascular fringe-like processes of the tela chorioidea contain the choroid plexuses of the fourth ventricle; they invaginate the lower part of the roof of the ventricle and are everywhere covered by the epithelial lining of the cavity. Each consists of a vertical and a horizontal

Fig. 862.—The roof and the lateral recesses of the fourth ventricle exposed from behind.



portion: the former lies close to the median plane, and the latter passes into the lateral recess and projects through the lateral aperture still covered by ependyma. The vertical parts of the plexuses are distinct from each other, but the horizontal portions are joined in the median plane; and hence the entire structure presents the form of the letter T, the vertical limb of which, however, is double. Numerous small tufts of the plexus are associated with the drawn-back upper wall of the median aperture and project into the subarachnoid space (fig. 863), like the tufts which protrude from the foramina of the lateral recesses.

The floor of the fourth ventricle (rhomboid fossa) (fig. 864).—The anterior wall or floor of the fourth ventricle is rhomboidal in shape; it is formed by the posterior surfaces of the pons and medulla oblongata. It is covered by a layer of grey matter continuous with that surrounding the central canal of the medulla oblongata and spinal cord; superficial to this there is a thin lamina of neuroglia covered with a layer of ciliated epithelium, which constitutes the *ependyma* of the ventricle. The floor consists of three parts, superior, intermediate and inferior. The *superior* part is triangular in shape and limited laterally by the superior cerebellar peduncles; its apex, directed upwards, is continuous with the aqueduct of the mid-brain; its base is represented by an imaginary line at the level of the upper ends of two small depressions, named the superior foveæ. The *intermediate* part extends from this level to that of the horizontal portions of the tæniæ of the ventricle and is prolonged into the lateral

recesses. The *inferior* part is triangular, and its downwardly directed apex is continuous with the wall of the central canal of the closed part of the medulla oblongata.

The floor of the fourth ventricle is divided into symmetrical halves by a *median sulcus*, which reaches from its upper to its lower angle and is deeper below than above. On each side of this sulcus there is an elevation, termed the *medial eminence*, bounded laterally by a sulcus which represents the *sulcus limitans* and separates the basal from the alar lamina. In the superior part of the floor the medial eminence has a width equal to that of the corresponding half of the floor, but opposite the superior fovea it forms an elongated swelling, named the *facial colliculus*, which overlies the nucleus of the abducent nerve, and is in part produced by the ascending portion of the root of the facial nerve. In the inferior part of the fossa the medial eminence assumes the form of a triangular

FIG. 863.—The relationship of the nodule to the fourth ventricle.

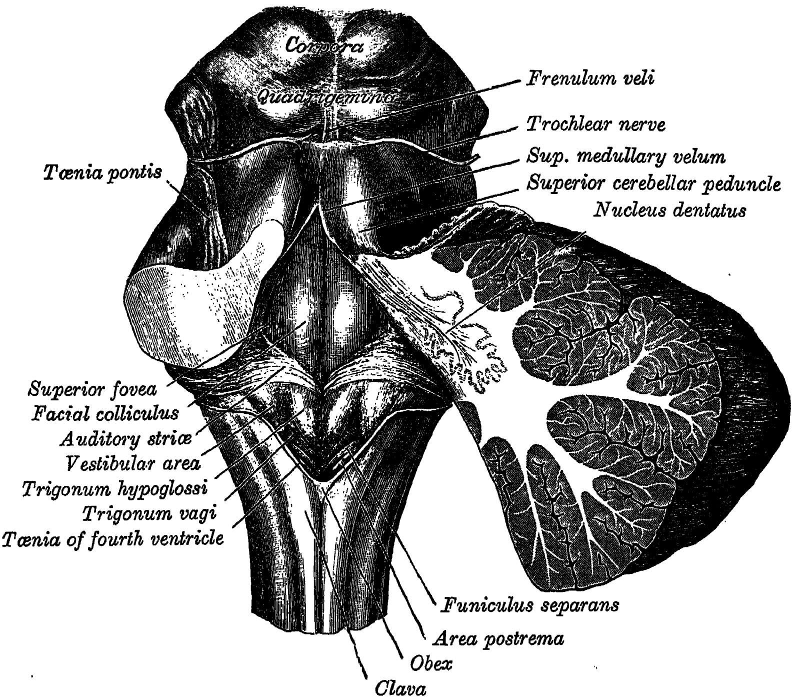
The arrow is placed in the median aperture of the fourth ventricle.

area, termed the *hypoglossal triangle* or *trigonum hypoglossi*. When examined under water with a lens the hypoglossal triangle is seen to consist of a medial and a lateral area separated by a series of oblique furrows; the medial area corresponds with the upper part of the nucleus of the hypoglossal nerve, the lateral with a small nucleus, termed the *nucleus intercalatus*.

The *sulcus limitans* forms the lateral boundary of the medial eminence. Its superior part corresponds with the lateral limit of the floor and presents a bluish-grey area, named the *locus cæruleus*, which owes its colour to a patch of deeply pigmented nerve-cells, termed the *substantia ferruginea*. At the level of the colliculus facialis the sulcus limitans widens into a flattened depression, termed the *superior fovea*, and in the inferior part of the floor appears as a distinct dimple termed the *inferior fovea*. Lateral to the foveæ there is a rounded elevation named the *vestibular area* (area acustica), which extends into the lateral recess where it forms the *auditory tubercle* (p. 922). Winding round the inferior cerebellar peduncle and crossing the vestibular area and the medial eminence are a number of white strands, most of which are derived from the dorsal nucleus of the cochlear nerve. They are termed the *auditory striæ* (striæ

medullares), and disappear into the median sulcus (p. 941). Below the inferior fovea, and between the hypoglossal triangle and the lower part of the vestibular area a triangular dark field, named the *vagal triangle* or trigonum vagi, overlies the dorsal nucleus of the vagus nerve (p. 913). The lower part of the vagal triangle is crossed by a narrow translucent ridge, often named the *funiculus*

FIG. 864.—The floor of the fourth ventricle.



separans, and between this funiculus and the gracile tubercle (clava) is a small tongue-shaped area, which is often termed the *area postrema*. On section it is seen that the funiculus separans is formed by a strip of thickened ependyma, and the area postrema by loose, highly vascular, neuroglial tissue containing nerve-cells of moderate size.

THE MESENCEPHALON OR MID-BRAIN

The **mesencephalon** or **mid-brain** is derived from the second of the three primary cerebral vesicles. In the course of its development in man and in its phylogenetic history it retains a much simpler form than either the fore-brain or the hind-brain. In lower vertebrates the leading feature of the mid-brain is the development in its roof-plate or *tectum* of the higher visual, and, later, the higher auditory centres. In the mammalia, however, these centres shift forwards to the neopallium, and the importance of the tectum is correspondingly diminished.

The sulcus limitans develops, as in the hind-brain and the spinal cord, differentiating the basal and the alar laminæ. Representatives of the somatic efferent column are present in the form of the nuclei of the third and fourth cranial nerves, and the somatic afferent column is represented by the mesencephalic nucleus of the trigeminal nerve. In these respects, therefore, the mid-brain shows indications of a primitive metamerism and resembles the medulla oblongata and the tegmental portion of the pons.

With the development of the neopallium of the cerebrum the mid-brain becomes invaded by great tracts of fibres of cortical origin. Some of these

form the great new motor-pathway from the cortex, while others are destined to be relayed in the nuclei pontis and constitute cerebro-cerebellar connexions (p. 921). These fibre tracts group themselves on the ventral aspect of the mid-brain on each side of the median plane and cause a characteristic alteration in its appearance.

Position and surface form.—The mid-brain passes upwards and forwards through the gap in the tentorium cerebelli and connects the pons and cerebellum (rhombencephalon) with the subthalamic region (diencephalon) and the cerebral hemispheres (telencephalon). It is the shortest segment of the brain-stem, being not more than 2 cm. in length. On each side it is related to the hippocampal gyrus, which hides its lateral aspect from view when the inferior, or basal, aspect of the brain is examined.

The mid-brain consists of *ventral* and *dorsal portions*, separated from one another in its interior by the aqueduct of the mid-brain (cerebral aqueduct), which represents the lumen of the primitive neural tube. The ventral portion consists of the two *cerebral peduncles*, which are separated from each other in front by a deep notch but are continuous with each other behind, across the median plane.

The dorsal portion, or *tectum*, comprises the *corpora quadrigemina*, which consist of four rounded elevations symmetrically arranged in superior and inferior pairs.

The **cerebral peduncles** emerge from the upper surface of the pons, one on each side of the median plane, and, diverging as they pass upwards and forwards, disappear into the substance of the cerebral hemispheres. Curving round each peduncle, close to the upper surface of the pons, a thin white band, named the *tænia pontis*, is frequently seen ; it enters the cerebellum between the middle and the superior cerebellar peduncles. The depressed area between the diverging cerebral peduncles forms the posterior part of the *interpeduncular fossa* (p. 971), and consists of a layer of greyish substance, termed the *posterior perforated substance* (p. 963).

The ventral surface of each peduncle is crossed anteriorly, from the medial to the lateral side, by the superior cerebellar and posterior cerebral arteries, while, close to the point of disappearance of the peduncle into the cerebral hemisphere, the optic tract winds backwards around it. The medial surface of the peduncle is marked by a longitudinal furrow, termed the *medial sulcus*, from which the roots of the oculomotor nerve emerge (fig. 866). In its upper part it forms the lateral boundary of the interpeduncular fossa. The lateral surface of the peduncle is in relation with the gyrus hippocampi of the cerebral hemisphere and is crossed from behind forwards by the trochlear nerve (fig. 838). This surface is marked by a longitudinal furrow, termed the *lateral sulcus* ; the fibres of the lateral lemniscus come to the surface in this sulcus, and pass backwards and upwards. Some of them disappear under the inferior quadrigeminal body ; the remainder enter the inferior brachium.

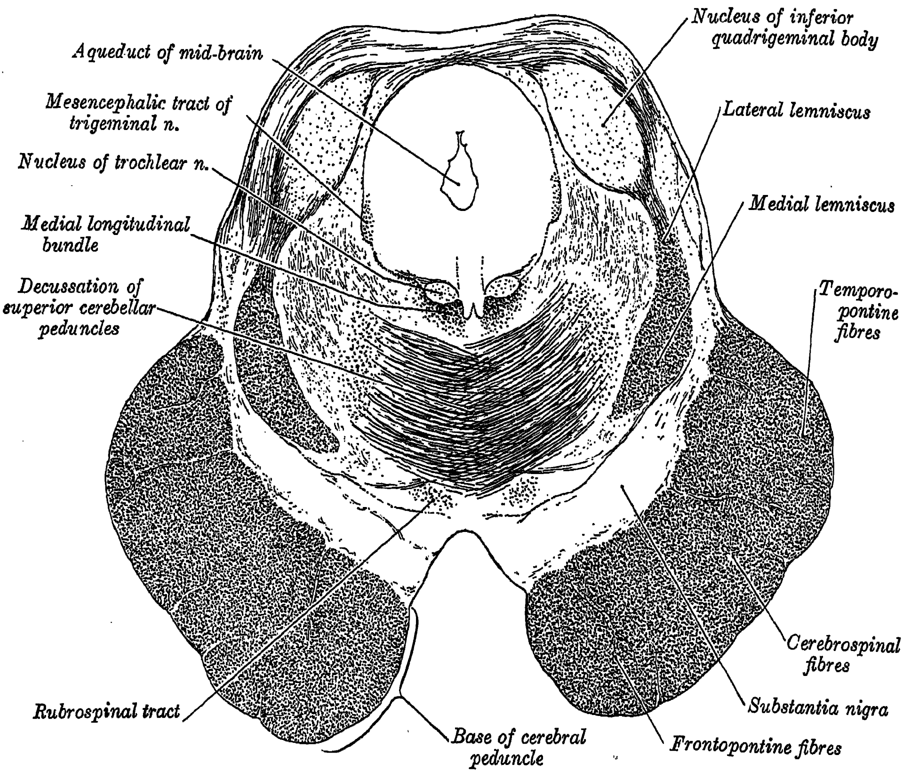
Structure of the cerebral peduncles (figs. 865, 866).—On transverse section, each peduncle is seen to consist of a dorsal and a ventral part, separated by a deeply pigmented lamina of grey matter, termed the *substantia nigra*. The dorsal part is named the *tegmentum* ; the ventral, the *base*. The basal parts of the peduncles are separated from each other, but the tegmenta are continuous with one another across the median raphe. Laterally, the tegmenta are free ; dorsally, they blend with the corpora quadrigemina.

The base is semilunar on transverse section, and consists almost entirely of longitudinal bundles of efferent fibres which arise from the cells of the cerebral cortex and are grouped into two principal sets, viz. cerebrospinal and cerebropontine (fig. 865). The *cerebrospinal* fibres are derived from the cells of the motor area of the cerebral cortex, and occupy the middle three-fifths of the base ; they descend through the pons and medulla oblongata, where some of them end in the nuclei of the motor cranial nerves of the opposite side, but most of them are continued into the pyramids of the medulla oblongata. The cerebropontine fibres arise in the cerebral cortex and terminate in the nuclei pontis, where they are relayed to the opposite cerebellar hemisphere. They are subdivided into two groups : (*a*) *frontopontine* and (*b*) *temporopontine*. (*a*) The frontopontine fibres arise in the frontal lobe, traverse the anterior limb

of the internal capsule, and occupy the medial one-fifth of the base of the cerebral peduncle. (*b*) The temporopontine fibres arise in the temporal lobe, traverse the posterior limb of the internal capsule and occupy the lateral one-fifth of the base of the cerebral peduncle; they originate in the temporal lobe and end in the nuclei of the pons.*

The **substantia nigra** is a layer of grey matter containing numerous, deeply pigmented, multipolar nerve-cells. It is semilunar on transverse section, its concavity being directed towards the tegmentum; from its convex surface, processes extend between the fibres of the base of the peduncle. Thicker medially than laterally, it reaches from the medial to the lateral sulcus, and extends from the upper surface of the pons to the subthalamic region; its medial part is traversed by the fibres of the oculomotor nerve as these stream

FIG. 865.—A transverse section through the mid-brain at the level of the inferior quadrigeminal bodies. (Semidiagrammatic. After Villiger.)



forwards to reach the oculomotor sulcus. The fibre connexions and the functions of the substantia nigra are still obscure. It has been stated that it receives afferent fibres from the inferior frontal gyrus (Monakow), the medial and lateral lemnisci, the superior quadrigeminal bodies and the fasciculus retroflexus (p. 963), and that it sends efferent fibres into the tegmentum to reach the globus pallidus of the lentiform nucleus, the red nucleus and the superior quadrigeminal bodies. It is relatively small in lower mammals, and contains no pigment. It has been suggested recently that the substantia nigra constitutes a co-ordinating centre for proprioceptive impulses.

* A band of fibres, named the *tractus peduncularis transversus*, is sometimes seen emerging from the optic tract on the lateral aspect of the cerebral peduncle; it passes round the ventral surface of the peduncle about midway between the pons and the optic tract, and disappears by entering the interpeduncular fossa behind and lateral to the corpus mamillare, where it terminates in a small nucleus. This band is a constant structure in many mammals, but is only present in about thirty per cent. of human brains. Since it undergoes atrophy after enucleation of the eyeballs, it may be considered as being associated with the visual pathway.

The tegmentum of the mid-brain presents appearances which differ according to the level of the section examined. Below it is directly continuous with the tegmentum of the upper part of the pons and contains the same fibre tracts.

A. In its *lower part*, i.e. on a level with the inferior quadrigeminal bodies, the grey matter is restricted to the immediate environs of the aqueduct of the mid-brain and to the scattered collections in the reticular formation (fig. 865).

The *nucleus of the trochlear (fourth cranial) nerve* lies in the ventral part of the central grey matter, close to the median plane. It occupies a position homologous with that occupied by the abducent and hypoglossal nerves at lower levels in the brain-stem, and it constitutes the representative of the somatic efferent column. Closely related throughout its extent to the medial longitudinal bundle, which lies on its ventral aspect, the nucleus extends through the lower half of the mid-brain, and its upper limit lies just below the lower limit of the oculomotor nucleus. Its *outgoing fibres* pass laterally and backwards round the central grey matter. Inclining downwards, they decussate with each other immediately below the inferior quadrigeminal bodies and emerge from the dorsal aspect of the superior medullary velum (fig. 864).

The unusual course of the outgoing fibres, their decussation and their emergence on the dorsal aspect of the brain-stem, are very difficult to explain. The fact that in the embryo the trochlear nucleus is at first separated from the oculomotor nucleus by a distinct gap and later migrates headwards into the mid-brain until it reaches the caudal end of the oculomotor nucleus, indicates that the region of the isthmus rhombencephali is unstable. Frazer has recently suggested that the isthmus is partly ‘ telescoped ’ into the mid-brain, and that during this process the basal lamina extends laterally over the inner surface of the alar lamina, carrying the point of emergence of the trochlear nerve with it. The same author suggests, on the analogy of the anterior nerve-roots of the spinal nerves, which possess a large homolateral and a small contralateral component, that the trochlear nerve possesses a large contralateral and a small homolateral component.*

The *mesencephalic nucleus of the trigeminal nerve* lies in the lateral part of the central grey matter. It is the representative of the somatic afferent column and retains its primitive position in the alar lamina. Fibres of the mandibular division run upwards on its lateral aspect and terminate within it (p. 1043). They are believed to convey proprioceptive fibres from the muscles of mastication.†

Apart from these two nuclei the central grey matter at this level contains large numbers of scattered nerve-cells, the significance of which is unknown. Irregular collections of grey matter occur in the reticular formation, especially in the region immediately above the pons.

The *white matter* at this level of the mid-brain contains all the tracts which have already been examined in the tegmentum of the pons, and it is characterised by the great decussation of the fibres of the superior cerebellar peduncles.

The *superior cerebellar peduncle*, which has already been described (p. 931), enters the dorsilateral part of the tegmentum and passes forwards and medially round the central grey matter to reach the median raphe, where it decussates with its fellow of the opposite side. Having crossed the median plane, the

* See footnote on p. 114.
In all vertebrates the trochlear nerves behave in the same peculiar way. Nevertheless it would appear to be certain that in some unknown ancestral form the trochlear nerves, like the oculomotor, abducent and hypoglossal nerves, emerged from the ventrilateral aspect of the brain-stem. It has been suggested that the trochlear nerve originally supplied the muscles of the pineal eye, and this would offer an explanation for the course of the fibres in a dorsal direction. The position of the nerve within the mid-brain medial to the mesencephalic nucleus of the trigeminal nerve may possibly be associated with the history of the nucleus, which is generally regarded as a derivative of the neural crest, secondarily included in the substance of the brain-stem. If, prior to the inclusion of the nucleus, the trochlear nerve passed dorsally across the side of the brain-stem to reach the muscles of the pineal eye, it too would necessarily be included in the process. The decussation of the trochlear nerves presents a further difficulty, but it might possibly be ascribed to changes affecting the disposition of the muscles of the primitive pineal eye. It must be admitted, however, that these explanations are in the highest degree speculative.

† In connexion with the function of this nucleus see also papers by E. P. Stibbe, *Journal of Anatomy*, vol. lxiv. 1929, and vol. lxv. 1903, and H. H. Woollard, *Journal of Anatomy*, vol. lxv. 1931.

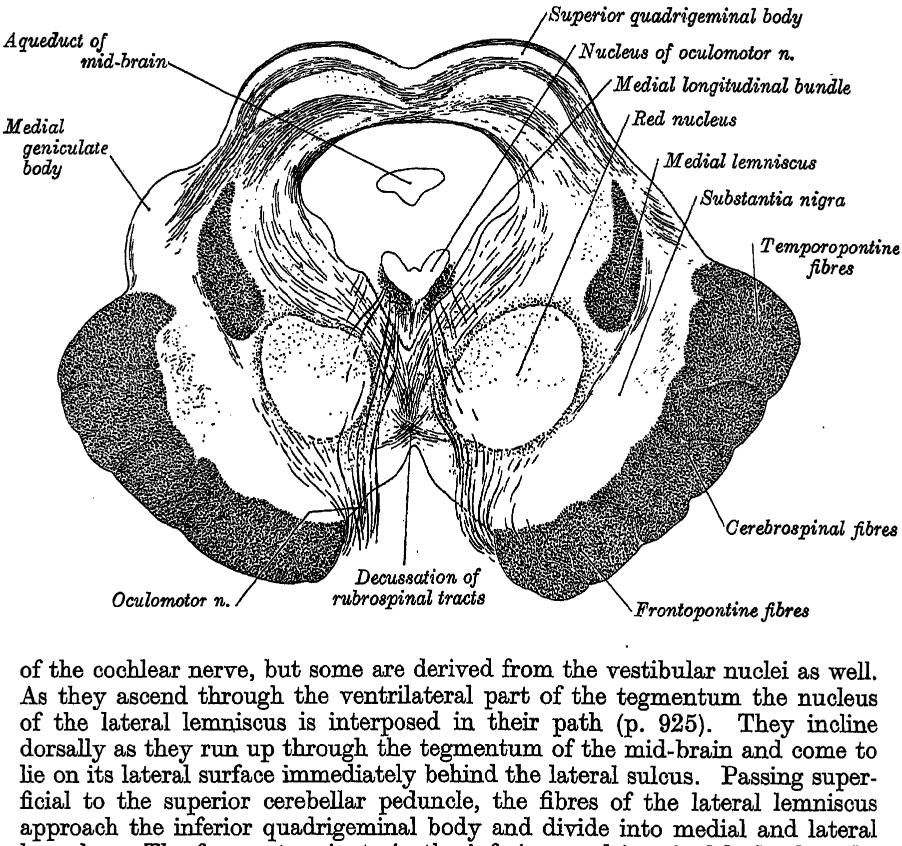
fibres divide into ascending and descending branches, and the former terminate for the most part in the red nucleus, which they encapsulate, but some are continued upwards and have been variously described as ending in the nucleus subthalamicus, the medial and the lateral nuclei of the thalamus.

The *medial longitudinal fasciculus* retains its intimate relationship to the somatic efferent column, and therefore lies dorsal to the decussating fibres of the superior cerebellar peduncles.

The *medial lemniscus* forms a curved band lying dorsal to the lateral part of the substantia nigra, in which some of its fibres terminate. Laterally the tract is closely related to the lateral lemniscus, which is ascending with a backward inclination to reach the inferior quadrigeminal body.

The *lateral lemniscus* is formed in the tegmentum of the pons by the fibres issuing from the corpus trapezoideum and by the fibres of the auditory striæ. These arise, for the most part, in the ventral and dorsal nuclei, respectively,

Fig. 866.—A transverse section through the mid-brain at the level of the superior quadrigeminal bodies. (Semidiagrammatic. After Villiger.)



of the cochlear nerve, but some are derived from the vestibular nuclei as well. As they ascend through the ventrilateral part of the tegmentum the nucleus of the lateral lemniscus is interposed in their path (p. 925). They incline dorsally as they run up through the tegmentum of the mid-brain and come to lie on its lateral surface immediately behind the lateral sulcus. Passing superficial to the superior cerebellar peduncle, the fibres of the lateral lemniscus approach the inferior quadrigeminal body and divide into medial and lateral branches. The former terminate in the inferior quadrigeminal body, but the latter are continued into the inferior brachium by which they are conducted to the medial geniculate body.

The fibres of the *spinal* and *trigeminal lemnisci* are indistinguishable from the fibres of the lateral portion of the medial lemniscus, with which they ascend to the thalamus.

B. In its *upper part* the tegmentum presents the same general plan, but it is strikingly modified by the appearance of a large nucleus, which extends upwards into the subthalamic region and is termed the red nucleus.

The *central grey matter* surrounds the aqueduct and contains in its ventrimedial portion the *nucleus of the oculomotor nerve,* which represents the somatic efferent column. This nucleus is closely related on its ventrilateral aspect to

the medial longitudinal bundle, and inferiorly it extends to the upper end of the trochlear nucleus (fig. 865).

The cell-groups are arranged in such a definite manner that it is possible to subdivide the nucleus into a number of constituent parts, viz. (*a*) The dorsilateral nucleus ; (*b*) the ventrimedial nucleus ; (*c*) the central nucleus ; (*d*) the Edinger-Westphal nucleus ; and (*e*) the caudal central nucleus (fig. 937). The dorsilateral nucleus does not extend so far inferiorly as the ventrimedial, which is in direct line with the trochlear nucleus. The central nucleus stretches across the median plane and is common to both oculomotor nerves. These three nuclei contain typical large pyramidal motor cells, and endeavours have been made to determine a localisation of function in them. The available evidence suggests that the dorsilateral nucleus is associated with upward movements of the eye, and the ventrimedial with downward movements. The close relationship of the latter to the trochlear nucleus, which is also concerned with downward movements, is in keeping with this scheme of localisation. The central nucleus, according to Brouwer and other workers, is concerned with movements of convergence (see also p. 1040). The Edinger-Westphal nucleus differs from these three nuclei in the smaller size of its constituent cells. It is situated more dorsally in the central grey matter and extends headwards beyond the other nuclei but does not reach so far inferiorly. This nucleus has been regarded for many years as the site of origin of those fibres of the third nerve which innervate the ciliary muscle and, according to some authorities, the sphincter iridis. Although present in most mammals, it is not constant, and according to Latumeten, it gives no direct fibres to the ciliary ganglion.

The *nucleus of Darkschewitsch* is a large-celled nucleus which lies dorsilateral to the upper end of the oculomotor nucleus in the central grey matter. It sends efferent fibres into the medial longitudinal bundle and also into the posterior commissure, but its functional significance is unknown.

The **red nucleus** is a large, ovoid mass of grey matter which occupies most of the medial part of the tegmentum of the upper half of the mid-brain, and extends upwards into the subthalamic region. Ventrally it is related to the substantia nigra, from which it is only separated by some of its surrounding fibres. Laterally it is related to the medial lemniscus ; dorsally it is separated from the central grey matter by the formatio reticularis, here very much reduced in area, and the medial longitudinal bundle. On its medial side, its surrounding fibres and the outgoing oculomotor nerve separate the nucleus from the median raphe and the ventral and dorsal tegmental decussation.

It is not homogeneous in structure, and the cells of the upper two-thirds, which are small in size, bear no resemblance to the large cells which are found in its lower third.

Afferent fibres reach the red nucleus from the superior cerebellar peduncle, and the globus pallidus of the lentiform nucleus (striatorubral fibres), and, possibly, direct from the cerebral cortex. The origin of the cortical fibres has been variously ascribed to the frontal, temporal and parietal lobes.

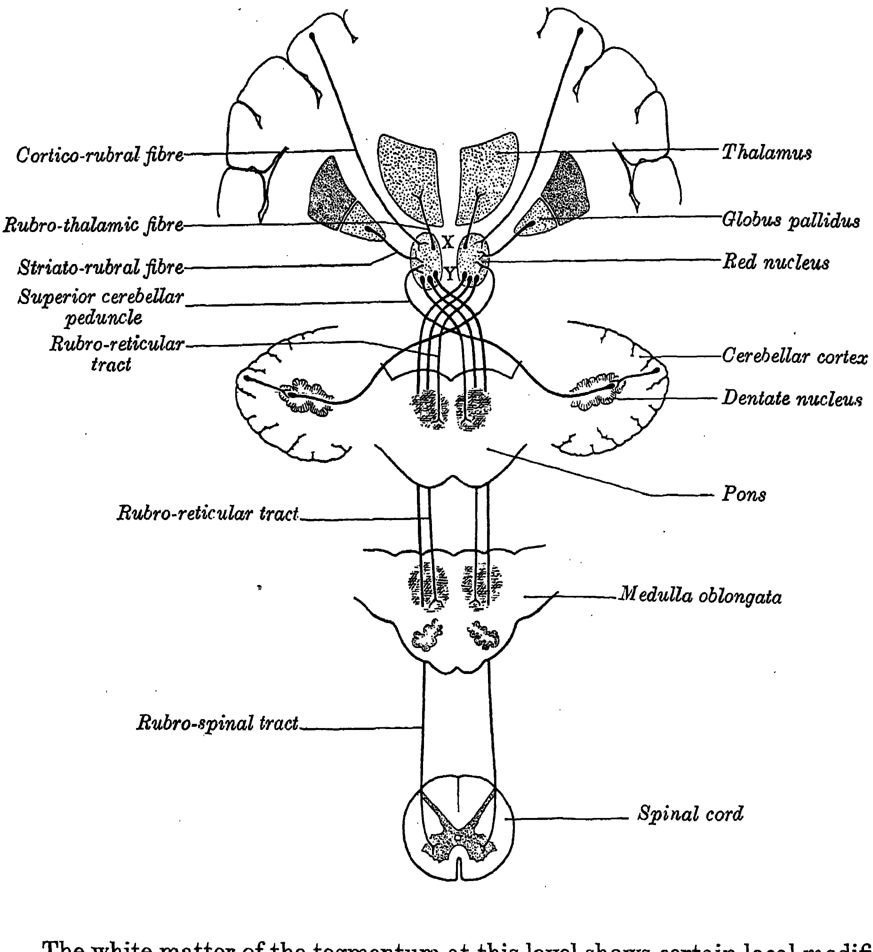
The efferent fibres from the red nucleus connect it with (1) the anterior column of the grey matter of the spinal cord (rubrospinal tract), (2) the nuclei of the reticular formation of the pons and the medulla oblongata (rubroreticular tract) and (3) the thalamus.

The red nucleus constitutes an important cell-station on the principal efferent pathway from the cerebellum to the spinal cord. At the same time it is also interposed on the pathway from the corpus striatum to the spinal cord. It is clear from both these connexions that the red nucleus plays an important part in the nervous mechanism of movements. It is connected to the anterior column of the grey matter of the spinal cord by the rubrospinal tract, but it is not at all certain that this is the principal pathway involved, for although the rubrospinal tract is a large bundle in many lower mammals, it is relatively small in man. It is possible that the rubroreticular tract, which is relatively large in man, may transmit impulses from the cerebellum and also, perhaps, from the corpus striatum, through a series of relay stations in the reticular formation in the hind-brain to the spinal cord. Rademaker, as the result of a long series of experiments, believes that the red nucleus acts as a centre for the distribution

of muscle tonus and that an intact red nucleus is an essential part of the arc concerned in the labyrinth-righting and body-righting reflexes.

Although it is clear that the large-celled lower portion of the red nucleus is derived from the basal lamina of the mid-brain, it would appear that the small-celled upper portion is a derivative of the diencephalon. This part of the nucleus becomes developed and elaborated *pari passu* with the expansion of the cerebellar hemispheres and the frontal lobes of the cerebrum, with which, according to Monakow, the red nucleus is freely connected.

FIG. 867.—A scheme to show the connexions of the red nucleus.



The white matter of the tegmentum at this level shows certain local modifications, chiefly in the region of the median raphe.

The *rubrospinal tract* takes origin at this level from the large cells in the lower part of the red nucleus. The fibres at once pass to the median raphe and there decussate in its ventral portion with the corresponding fibres of the opposite side, forming the *decussation of the rubrospinal tracts* (ventral tegmental decussation). They then pass downwards in front of the decussation of the superior cerebellar peduncles and descend in the formatio reticularis of the pons and medulla oblongata. Finally they enter the spinal cord, lying on the ventrilateral aspect of the lateral cerebrospinal tract, and terminate by arborising round the cells in the anterior column of the grey matter. Despite the fact that the rubrospinal tract is a relatively small bundle in man, it is generally regarded as the principal pathway connecting the corpus striatum and the cerebellum with the spinal cord.

The *tectospinal* and the *tectobulbar tracts* also take origin at this level. Their fibres arise in the grey matter of the superior quadrigeminal bodies and sweep

forwards round the central grey matter to decussate with one another in the median raphe ventral to the oculomotor nucleus and the medial longitudinal bundle. Emerging from the decussation the tectospinal tract descends on the ventral aspect of the medial longitudinal bundle as far as the decussation of the medial lemniscus in the medulla oblongata. Thereafter it diverges ventrilaterally and in the spinal cord it lies in the lateral column in front of the rubrospinal tract.* The tectobulbar tract, which may be divided into a dorsal, crossed tract and a ventral, uncrossed tract, descends through the reticular formation of the mid-brain and the pons and terminates by sending its fibres into the oculomotor, trochlear, abducent and accessory nuclei. It serves as a pathway for reflex movements of the eyes in response to visual stimuli.

The *medial longitudinal bundle* lies on the ventrilateral aspect of the oculomotor nucleus. At this level its fibres are more spread out than they are at lower levels in the brain-stem, but the intimate relationship to the somatic efferent nuclei is retained.

The bundle extends upwards to the *interstitial nucleus*—a small collection of cells situated in the lateral wall of the third ventricle immediately above the upper end of the aqueduct of the mid-brain—which contributes fibres to it. As has already been seen, the medial longitudinal bundle retains its position relative to the central grey matter throughout the whole extent of the mid-brain, pons and the upper part of the medulla oblongata. It is displaced forwards by the successive decussations of the medial lemnisci and the pyramidal tracts, and becomes continuous with the anterior intersegmental fasciculus of the spinal cord.

The intimate relationship which it bears successively to the nuclei of the third, fourth and sixth cranial nerves, to the emerging fibres of the seventh, the auditory striæ of the eighth and the nucleus of the twelfth nerve renders it a very convenient pathway for the passage of fibres from one nucleus to another in the brain-stem. The harmonious co-operation obviously existing between the facial nerves and the hypoglossal nerves in the movements of the lips and tongue in speech is frequently attributed to connexions between their nuclei conveyed by the medial longitudinal bundle, and a similar explanation is given for the co-operation of the oculomotor, trochlear and abducent nerves in the movements of the eyes. It is, however, very doubtful whether it is the medial longitudinal bundle which provides the pathway for these connexions. Edinger, Winkler and others have shown that the most substantial contributions to the bundle are made by the vestibular nuclei, and their work strongly suggests that its chief function is to ensure the co-ordinate movements of the eyes and head in response to stimulation of the eighth nerve. Fibres from the vestibular nuclei (superior, lateral and medial), both of the same and of the opposite side, join the bundle, where they ascend, descend or divide into ascending and descending branches. These vestibular fibres send collaterals to, or they may end in, the nuclei of the third, fourth and sixth cranial nerves and the spinal nucleus of the eleventh nerve. In addition, fibres join the bundle from the dorsal nucleus of the corpus trapezoideum and the nucleus of the lateral lemniscus. It is probable, therefore, that the cochlear as well as the vestibular nerve is capable of influencing the movements of the eyes and head through the bundle. The continuity of the bundle with the anterior intersegmental tract offers a pathway to those nuclei of the spinal cord which innervate the rotator muscles of the head and neck other than the sternomastoid.

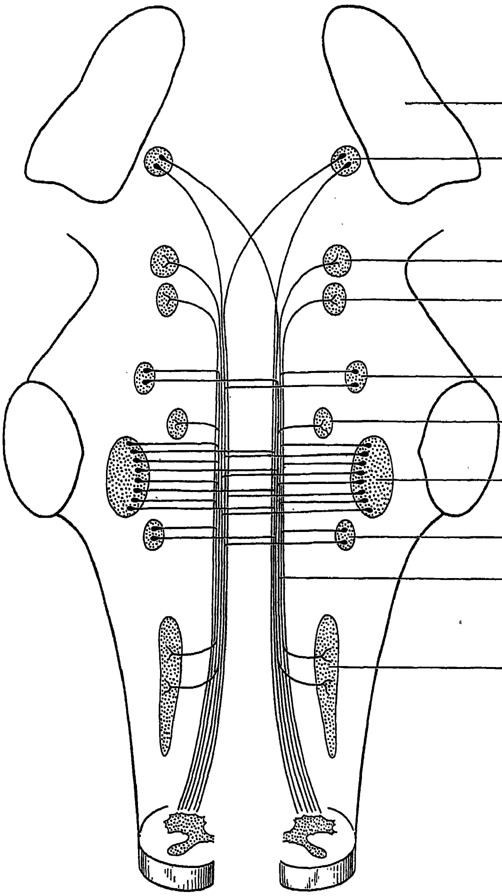
The *inferior brachium* forms a rounded strand on the lateral aspect of the upper part of the mid-brain. Its fibres are derived from the lateral lemniscus and they are ascending to reach the medial geniculate body. In their course they separate the dorsilateral fibres of the medial lemniscus from the surface.

The **corpora quadrigemina** (fig. 864) are four rounded eminences which form the dorsal part of the mesencephalon. They are situated above and in front of the superior medullary velum, and below and behind the third ventricle and posterior commissure. They lie below the splenium of the corpus callosum, and are partly overlapped on each side by the pulvinar of the thalamus. The corpora quadrigemina are arranged in pairs (superior and inferior), and are separated from one another by a cruciform sulcus. The longitudinal part

* See footnotes * on pp. 899 and 900.

of this sulcus expands superiorly to form a slight depression in which the *pineal body* (p. 961) lies. From the inferior end of the longitudinal sulcus a white ridge, termed the *frenulum veli*, is prolonged downwards to the superior medullary velum; at the sides of this ridge the trochlear nerves emerge, and pass forwards on the lateral aspects of the cerebral peduncles to reach the base of the brain. The *superior corpora quadrigemina* are larger and darker in colour than the inferior, and constitute centres for visual reflexes (p. 968). The *inferior corpora quadrigemina*, though smaller, are somewhat more prominent than the superior and are associated with the auditory pathway (p. 951).

FIG. 868.—A scheme of the connexions of the medial longitudinal bundle.

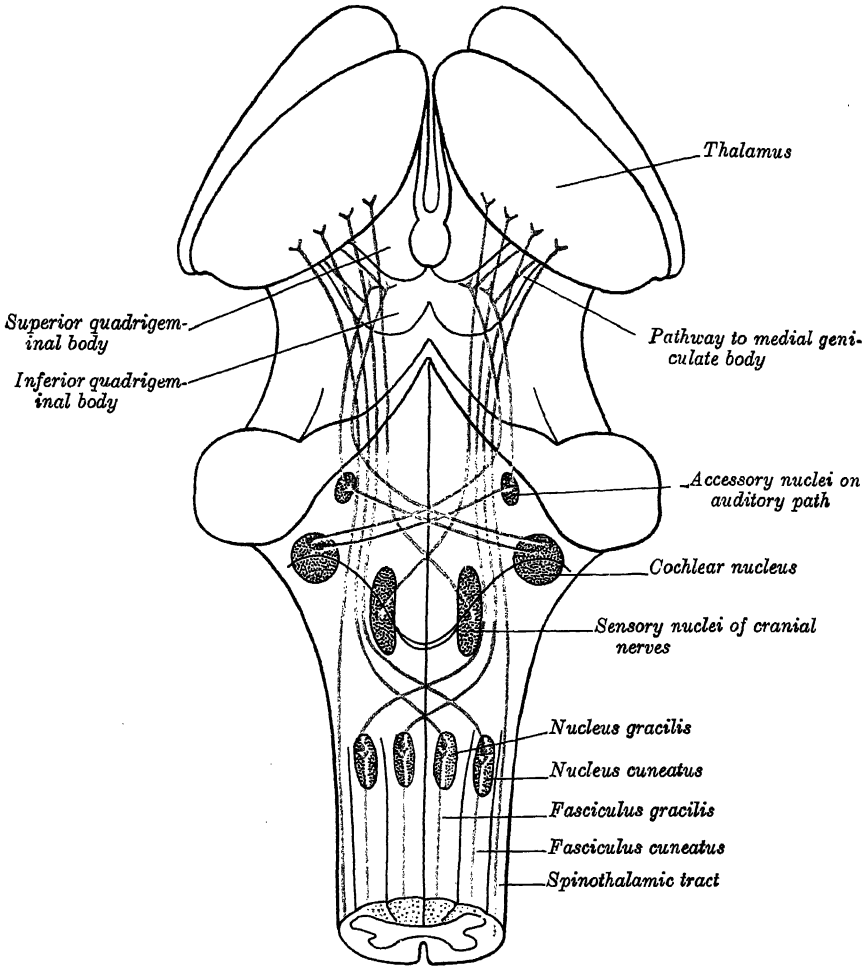


From the lateral aspect of each quadrigeminal body a white band, termed the *brachium*, is prolonged upwards and forwards. The *superior brachium* extends laterally from the superior quadrigeminal body, and, passing between the pulvinar and medial geniculate body, is partly continued into an eminence called the lateral geniculate body, and partly into the optic tract. It conducts visual fibres from the optic radiation to the superior quadrigeminal body. The *inferior brachium* passes forwards and upwards from the inferior quadrigeminal body; it conveys fibres from the lateral lemniscus and, possibly, also from the inferior quadrigeminal body to the medial geniculate body and, in addition, fibres from the inferior quadrigeminal body to the thalamus.

Structure of the corpora quadrigemina.—The *inferior quadrigeminal body* consists of a compact nucleus of grey matter which contains large and small multipolar nerve-cells, and is more or less completely surrounded by fibres derived from the lateral lemniscus; most of these fibres end in the grey nucleus of the same side, but some cross to that of the opposite side. These, however,

do not account for all the fibres of the lateral lemniscus, for the majority are continued through the inferior brachium to the medial geniculate body, where they are relayed to the auditory cortex (p. 995). The inferior quadrigeminal body also receives afferent fibres from the temporal cortex, and, of its efferent fibres, some pass into the inferior brachium and are destined for the thalamus and, possibly, the medial geniculate body, while others descend into the tegmentum to reach the motor nuclei of the cranial nerves.

FIG. 869.—A scheme showing the course of the fibres of the lemnisci; lateral lemniscus in *red*, medial and spinal lemnisci in *blue*.



The inferior quadrigeminal body reaches its highest development in mammals, and it is only found in those animals which possess a well-developed cochlea. It is to be regarded as a centre for auditory and, possibly, some vestibular reflexes (p. 922) rather than as a relay station on the path to the cerebral cortex. In this connexion it should be observed that many of the fibres of the lateral lemniscus divide into medial and lateral branches which are distributed to the inferior quadrigeminal body and the medial geniculate body, respectively.

The *superior quadrigeminal body* is covered by a thin stratum of white fibres, which constitute the *stratum zonale*. Beneath this the *stratum cinereum* forms a cap-like layer of grey matter, thicker in the centre than at the circumference, and consisting of numerous small multipolar nerve-cells imbedded in a fine network of nerve-fibres. Still deeper is the *stratum opticum*, containing

large multipolar nerve-cells separated by numerous fine nerve-fibres. Finally, there is the *stratum lemnisci*, consisting of fibres, many of which are derived from the medial lemniscus ; others are commissural and derived from the cells of the stratum opticum ; many large multipolar nerve-cells are interspersed among these fibres.

Afferent fibres reach the superior quadrigeminal body from at least three sources : (1) fibres originating in the retina * and conveyed by the superior brachium ; (2) fibres arising in the visual cortex of the occipital lobe and travelling by the optic radiation to the superior brachium ; (3) fibres arising in the spinal cord and ascending in the spinotectal tract.

Efferent fibres take part in the dorsal tegmental decussation and constitute the tectobulbar and the tectospinal tracts (p. 948), which establish connexions with the motor nuclei of the cranial nerves, more particularly the third, fourth, sixth and eleventh, and the anterior column cells of the spinal cord. Others cross the median plane to reach the superior quadrigeminal body of the opposite side, while still others have been described as entering the medial longitudinal fasciculus.

In fishes, reptiles and birds the whole of the tectum is given over to the superior corpora quadrigemina, which thus constitute the corpora bigemina and are frequently termed the optic lobes. In these animals they function as one of the highest visual centres and they receive practically all the fibres from the retinæ. In mammals, however, the evolution of the visual cortex has resulted in a diminution of the importance of these centres, and most of the fibres of the optic tracts avoid them and are relayed in the lateral geniculate bodies on their way to the higher centres. The superior quadrigeminal body continues to receive some fibres from the optic tract,* and it is believed that they are an essential part of the arc of the light reflex. In addition the superior quadrigeminal body receives afferent fibres from the visual cortex, which are relayed through the tectobulbar and tectospinal tracts, so as to provide a pathway for reflex movements of the musculature of the eyes, head and neck which may be necessitated by visual impressions.

The **aqueduct of the mid-brain** (cerebral aqueduct) is a narrow canal, about 15 mm. long, situated between the corpora quadrigemina and tegmentum, and connecting the third with the fourth ventricle. Its form, as seen in transverse sections, varies at different levels, being T-shaped below, triangular above, and oval in the middle ; its central part is slightly dilated, and was named by Retzius the *ventricle of the mid-brain*. It is lined with ciliated columnar epithelium, and is surrounded by a layer of grey matter named the *central grey stratum* ; this is continuous below with the grey matter in the floor of the fourth ventricle, and above with that of the third ventricle. Dorsally the aqueduct is partly separated from the grey matter of the quadrigeminal bodies by the fibres of the lemnisci ; ventral to it are the medial longitudinal bundle, and the formatio reticularis of the tegmentum. Scattered throughout the central grey stratum are numerous nerve-cells of various sizes, interlaced by a network of fine fibres. Besides these scattered cells it contains three groups, which constitute the nucleus of the mesencephalic root of the trigeminal nerve and the nuclei of the oculomotor and trochlear nerves (pp. 945 and 946).

THE FORE-BRAIN OR PROSENCEPHALON

The **fore-brain or prosencephalon** consists of : (1) the *diencephalon*, corresponding in a large measure to the third ventricle and the structures which bound it ; and (2) the *telencephalon*, comprising the largest part of the brain, viz. the cerebral hemispheres ; these hemispheres are connected with each other across the median plane, and each contains an extensive cavity, named the lateral ventricle. The lateral ventricles communicate with each other and with the third ventricle through the interventricular foramen, and are separated

* Some authorities deny that any fibres originating in the retina terminate in the superior colliculi.

from each other over a wide area only by a median septum, termed the septum lucidum ; this contains a slit-like cavity, which does not communicate with the ventricles.

The Diencephalon

The **diencephalon** is derived from the caudal end of the fore-brain. In the human embryo and in all vertebrates it is situated in front of (headwards of) the anterior (or upper) end of the notochord, and it may therefore be regarded as an extension of the brain beyond the limits of the primitive segments of the body. It may be expected that the imprints of metamerism and branchiomerism, which have been observed in the brain-stem and spinal cord, will no longer be found in the diencephalon.

The recent work of Kingsbury and J. B. Johnston suggests that the sulcus limitans does not extend into the region of the fore-brain, which is derived in its entirety from the alar laminæ.

The lateral walls of this portion of the embryonic neural tube undergo enormous thickening and form two large nuclear masses, which are termed the *thalami*. They are the largest and most important of all the derivatives of the diencephalon. In primitive vertebrates they constitute the highest centres for the correlation of all sensory impressions but, with the evolution of the neopallium, they become relegated to a position of less importance, acting as relay stations on the sensory pathway to the cortex. Although they are no longer the dominant factor in determining behaviour they do retain a large measure of their earlier importance, for it would appear that sensory impressions can reach consciousness in the thalami themselves, when their cortical connexions have been severed.

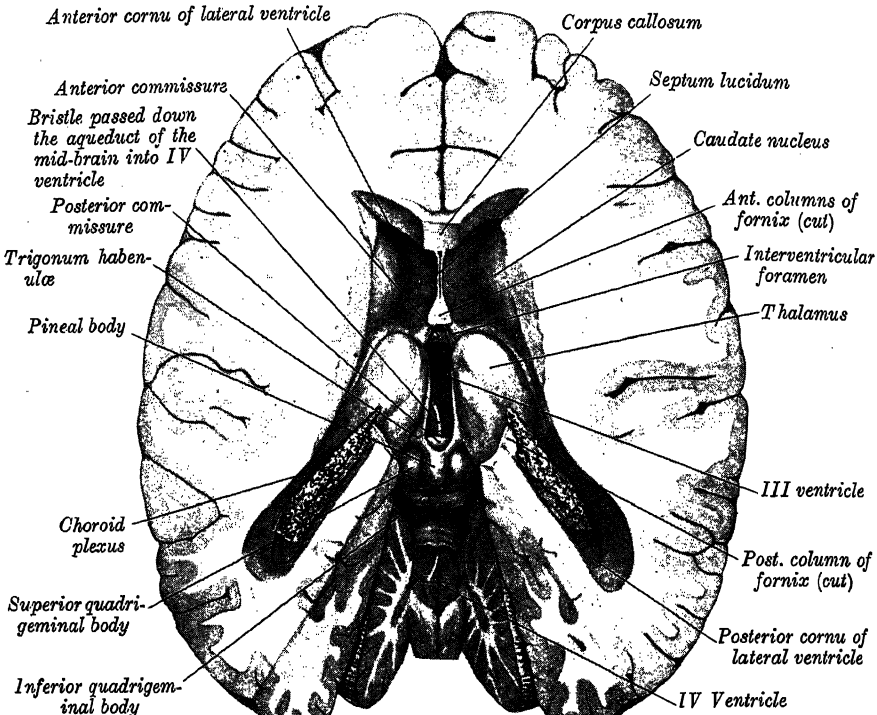
Caudal to the thalamus two elevations appear on the lateral aspect of the diencephalon, and they can at first be recognised on the inner wall as two hollowed out areas. They form the medial and lateral geniculate bodies, which together constitute the *metathalamus*. As the thalamus enlarges it extends tailwards and, growing backwards so as to overhang the mid-brain, intervenes between the geniculate bodies and the cavity of the diencephalon. The medial geniculate body has already been seen in the groove between the lateral aspect of the mid-brain and the overhanging posterior end of the thalamus, while the lateral geniculate body comes to lie in close contact with the inferior aspect of the posterolateral part of the thalamus and appears to be incorporated in it.

The roof-plate of the fore-brain retains its epithelial character throughout the greater part of its extent and forms, in the adult, the *ependymal roof of the third ventricle*. At its posterior (or caudal) end the roof and the adjoining portions of the lateral walls give rise to a number of structures which together constitute the *epithalamus*. A collection of cells in this part of the lateral wall forms the *habenular nucleus* (habenular ganglion), which sends its fibres across the median plane through the roof-plate, to constitute the *habenular commissure*. More caudally a second commissural bundle invades the roof, and is termed the *posterior commissure*. In the interval between these two commissures a hollow diverticulum grows backwards in the median plane. This is termed the *epiphysis*. In many reptiles it gives off a second process from the anterior wall of its base, which constitutes the pineal or parietal eye (p. 962). This organ has been identified in the human embryo, but it does not persist ; the epiphysis, on the other hand, which forms a hollow glandular structure in reptiles, secreting directly into the third ventricle, becomes converted into a solid organ, termed the *pineal body*.

We have seen how the thalamus, the metathalamus, the epithalamus and a large part of the roof of the third ventricle are derived from the diencephalon. The parts which have still to be considered are derived from the ventral portions of the lateral walls and from the floor. They contribute to the formation of the *hypothalamus*, forming the subthalamic region, the corpora mamillaria, the tuber cinereum, and the infundibulum. The remainder of the hypothalamus is derived from the telencephalon and includes the optic chiasma and the lamina terminalis.

The *subthalamic region* is the upward continuation of the tegmentum. It lies immediately below the thalamus in the human brain and contains certain masses of grey matter derived from the alar laminæ. The mamillary bodies form as a median thickening in the floor of the diencephalon, which is subsequently divided into two by a median groove. They form an important cell-station on the efferent pathway from the rhinencephalon (p. 987). The area in front of them constitutes the tuber cinereum. This area is very highly developed in those fishes in which the olfactory is dominated by the gustatory sense, but it undergoes marked reduction in air-breathing vertebrates.

FIG. 870.—The ventricles of the brain. Exposed from above and behind.



The splenium and most of the trunk of the corpus callosum have been removed; and the body of the fornix and most of the tela chorioidea have been excised, together with portions of the occipital lobes and the cerebellum. A bristle has been passed from the third ventricle through the aqueduct of the mid-brain into the fourth ventricle.

The *infundibular process* arises as a hollow outgrowth from the floor of the diencephalon, which subsequently loses its cavity and becomes converted into a solid mass of cells to form the posterior lobe of the hypophysis cerebri. The stalk which connects the hypophysis to the floor of the third ventricle forms the infundibulum, and it retains its hollow character in the adult. It will be remembered that the anterior lobe of the hypophysis develops as a hollow diverticulum from the roof of the primitive mouth (p. 166), and it is probable that in some ancestral vertebrates there was a bucconeural duct, such as occurs in larval ammocetes. Such a duct provided for the passage of water from the mouth to the neural tube and afforded the possibility of a water-vascular circulation for the central nervous system. In all reptiles and amphibia the infundibular process remains hollow, but in nearly all mammals it becomes a solid body and forms, as in man, the posterior lobe of the hypophysis cerebri.

The *optic chiasma* is developed in association with the optic nerves. Before the fore-brain is differentiated into the telencephalon and the diencephalon, two diverticula grow out from its inferolateral aspects to form the optic vesicles. The connexion of the vesicle with the fore-brain lengthens into an optic stalk, which retains its original hollow character for some time. Nerve fibres from

the retina grow in along the walls of the stalk, and as a result its cavity becomes obliterated and is replaced by a solid optic nerve. The optic recess of the third ventricle is all that remains of the cavity of the stalk. In all vertebrates the fibres of the optic nerves decussate, either completely or partially, in the floor of the fore-brain, and constitute the optic chiasma (p. 967).

The *lamina terminalis* is the cephalic end of the neural tube and, in view of the development of the roof and floor of this part of the telencephalon, it forms the one area where large and important commissural connexions between the cerebral hemispheres are able to develop.

Parts derived from the diencephalon.—The diencephalon comprises the thalamus, metathalamus and epithalamus (which together constitute the *thalamencephalon*), and most of the hypothalamus, but these structures include so many of the boundaries of the third ventricle of the brain that it will be convenient to describe the anterior part of the hypothalamus and the third ventricle as a whole in this section, together with the true derivatives of the diencephalon.

The thalami (figs. 871, 872) are two large ovoid masses, situated one on each side of the third ventricle and reaching for some distance behind that cavity. Each thalamus is about 4 cm. long, and has two ends and four surfaces.

The *anterior end* is narrow; it lies close to the median plane and forms the posterior boundary of the interventricular foramen.

The expanded *posterior end*, which is termed the *pulvinar*, is directed backwards and laterally and overhangs the superior quadrigeminal body and the superior brachium. The lateral geniculate body (p. 960) forms a small, oval elevation on the inferior aspect of its lateral part. Inferiorly the pulvinar is separated from the medial geniculate body (p. 959) by the superior brachium.

The *superior surface* is free, slightly convex, and covered by a layer of white matter, termed the *stratum zonale*. It is separated laterally from the ventricular surface of the caudate nucleus by a white band, termed the *stria semicircularis* (stria terminalis), and by the thalamostriate vein (vena terminalis) (p. 814). It is divided into a medial and a lateral portion by an oblique shallow furrow, which runs from behind forwards and medially from the lateral part of the posterior end to the anterior part of the medial border; this furrow corresponds with the lateral margin of the fornix. The lateral part forms a portion of the floor of the lateral ventricle. It is covered with the epithelium of that cavity, and is partly hidden by the vascular fringe of the choroid plexus of the lateral ventricle (fig. 872). The medial part of this surface is covered with the tela chorioidea of the third ventricle, by which it is separated from the body of the fornix. Between the lateral edge of the fornix and the upper surface of the thalamus the lateral margin of the tela chorioidea with its contained plexus is invaginated into the ventricle through the choroidal fissure. In front, the superior surface is separated from the medial surface by a narrow, raised ridge from which the epithelial lining of the third ventricle is reflected to the under surface of the tela chorioidea. This ridge covers a small bundle of white fibres, named the stria habenularis (p. 961). Posteriorly it turns medially to form the anterior boundary of the *trigonum habenulæ* (fig. 871), from which the upper surface of the thalamus is separated by the *sulcus habenulæ*.

The *inferior surface* rests upon and is continuous with the upward prolongation of the tegmentum (*subthalamic tegmental region*).

The *medial surface* constitutes the upper part of the lateral wall of the third ventricle; it is covered with a thin layer of grey matter, and is connected to the corresponding surface of the opposite thalamus by a flattened grey band, named the *connexus interthalamicus* (massa intermedia). This band lies close behind the interventricular foramen, and averages about 1 cm. in its anteroposterior diameter: it sometimes consists of two or even three parts, and occasionally is absent. It contains nerve-cells and nerve-fibres; a few of the latter may cross the median plane, but most of them pass towards the median plane and then curve laterally on the same side.

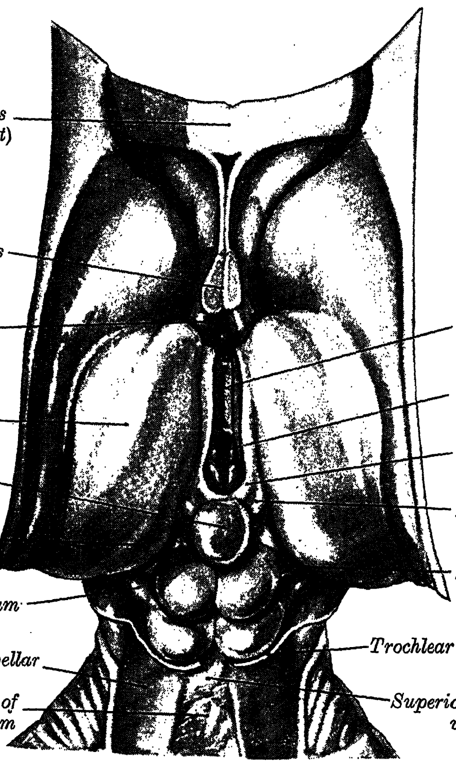
On its *lateral surface* there is a thick band of white substance consisting of itinerant fibres (projection fibres) which form the posterior limb of the internal capsule and separate the thalamus from the lentiform nucleus of the corpus striatum (fig. 872).

Structure.—The thalamus consists chiefly of grey matter, but its upper

surface is covered by a layer of white matter, named the *stratum zonale*, and its lateral surface by a similar layer, termed the *external medullary lamina*. Its grey matter is incompletely subdivided into three parts—anterior, medial, and lateral—by a vertical white layer, the *internal medullary lamina* (fig. 873).

The *anterior nucleus* comprises the anterior tubercle, and its tapered posterior end intervenes between the medial and lateral nuclei. The *medial nucleus* lies between the internal medullary lamina on the lateral side and the third ventricle on its medial side. These two nuclei are phylogenetically the oldest portion of the thalamus and together comprise the *palæothalamus*. They have, however, become modified in structure and progressively differentiated in the process of evolution, and it must not be assumed that their functions have

FIG. 871.—The thalami exposed from above by removal of the trunk and splenium of the corpus callosum, the body of the fornix, and the tela chorioidea.



The trunk and splenium of the corpus callosum, most of the septum lucidum, the body of the fornix, the tela chorioidea with its contained plexuses and the epithelial roof of the third ventricle have all been removed.

remained entirely primitive. The *lateral nucleus* lies between the internal and the external medullary laminæ. It is the largest of the three nuclei, forming the greater part of the thalamus and constituting the *neothalamus*. It includes the *pulvinar* and is traversed by numerous fibres which pass through the internal capsule to reach the cerebral cortex.

Connexions * (fig. 874).—In man the thalamus is a large cell-station interposed on the sensory path to the cortex and short-circuiting a number of different impulses to the corpus striatum. It receives *afferents* from : (1) the medial lemniscus (proprioceptive and discriminative or gnostic sensibility) ; (2) the spinal lemniscus (pain and temperature) ; (3) the trigeminal lemniscus (all varieties of sensibility from the trigeminal area) ; (4) the mamillo-thalamic tract ; (5) the hypothalamus (visceral sensibility) ; (6) the superior cerebellar peduncle of the opposite side ; (7) the rubro-thalamic tract of the same side ; and (8) all parts of the cerebral cortex.

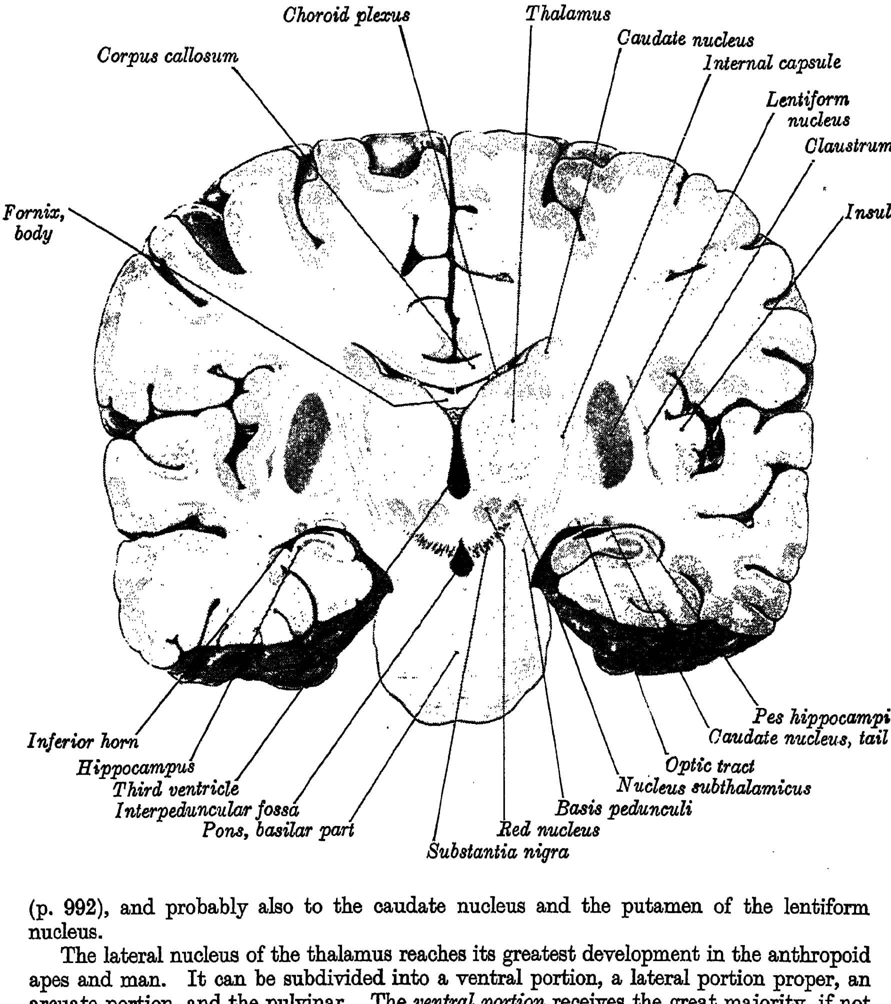
* The description in the text differs in many particulars from that given in previous editions and is based on the work of W. E. le Gros Clark, *Journal of Anatomy*, vols. lxvii., lxx. and lxxi., and *Brain*, vol. lv. etc.

Its *efferents* proceed through the internal capsule to reach: (1) all parts of the cerebral cortex, but especially the postcentral gyrus and the parietal and frontal association areas; (2) the caudate nucleus; and (3) the putamen of the lentiform nucleus.

Afferent stimuli reach the anterior nucleus through the mamillo-thalamic tract, and it therefore receives olfactory stimuli which have already been passed through the rhinencephalon. Its efferent fibres pass to the gyrus cinguli, to the medial nucleus of the thalamus and to the caudate nucleus.

The medial nucleus receives afferent fibres from the anterior nucleus and from certain of the nuclei of the hypothalmus. Its efferents pass to the frontal area of the cortex

FIG. 872.—A coronal section through the brain at the anterior part of the pons. Posterior aspect.



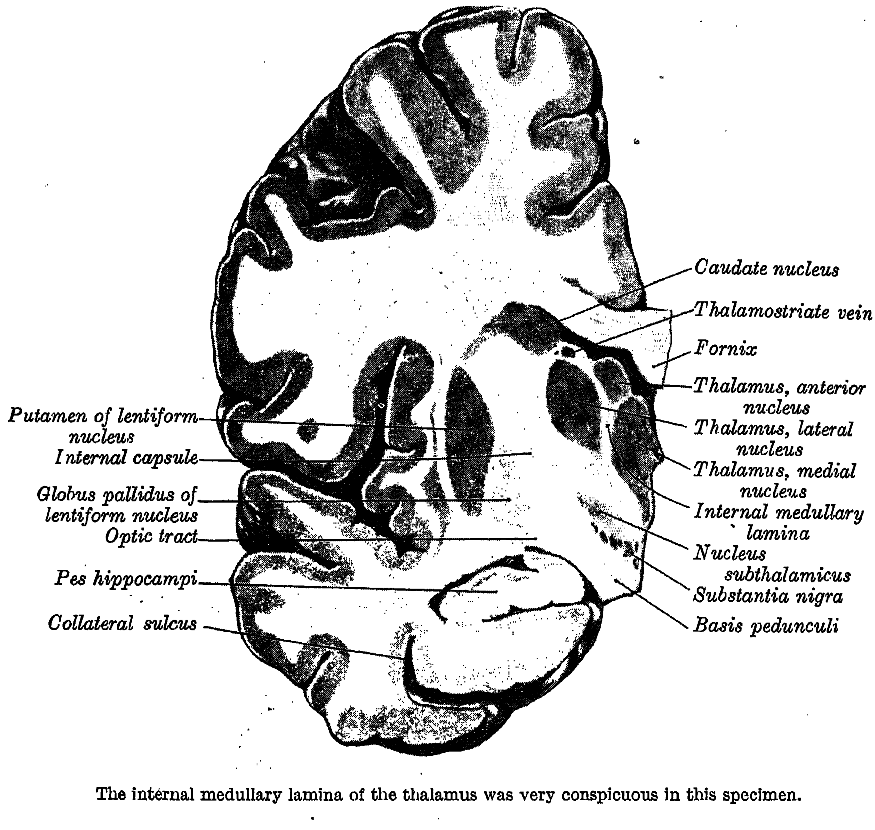
(p. 992), and probably also to the caudate nucleus and the putamen of the lentiform nucleus.

The lateral nucleus of the thalamus reaches its greatest development in the anthropoid apes and man. It can be subdivided into a ventral portion, a lateral portion proper, an arcuate portion, and the pulvinar. The *ventral portion* receives the great majority, if not all, of the fibres which ascend in the medial lemniscus (proprioceptive and discriminative or gnostic sensibility), and in the spinal and trigeminal lemnisci (pain and temperature). Its efferent fibres traverse the posterior limb of the internal capsule and terminate in the cortex of the post-central gyrus (p. 993), where these somesthetic impressions can be localised, analysed, and dealt with in the light of past experience. The connexions of the *lateral portion* are still obscure, but it is probably linked up with the medial nucleus, and the ventral portion and the pulvinar. Its efferent fibres, for the most part, proceed through the posterior limb of the internal capsule to reach the postcentral area (p. 993). Those which pass below the lentiform nucleus intervene between it and the anterior perforated substance, and constitute the *ansa peduncularis.* The *arcuate portion* lies between the ventral portion and the medial nucleus. In the macaque monkey it apparently receives afferent fibres from the tongue, mouth and lips regions through the trigeminal lemniscus,

and it projects on to the granular cortex which lies immediately below the lower limit of the motor cortex in that animal (Le Gros Clark, *Phil. Trans.*, B., 1937).

The *pulvinar* occupies the posteromedial portion of the lateral nucleus, and it was formerly believed to act as a cell-station on the visual pathway to the occipital cortex. It is now known that, after extirpation of the eyes, relatively few degenerated fibres can be traced into the pulvinar. Further, its efferent fibres proceed, for the most part, to the cortex of the lips of the lateral sulcus, over an area which extends from the audito-sensory cortical area (p. 995) to the middle part of the inferior parietal lobule. Its projection on to the last-named region is believed to be essential for that component of stereognosis which requires the association of visual with tactile memories, but it is clear that if, as seems certain, the pulvinar functions in this way it must receive afferent fibres either from the visual cortex or from the lateral geniculate body or from both. A few fibres from the

FIG. 873.—A coronal section through the right cerebral hemisphere. Anterior aspect.



The internal medullary lamina of the thalamus was very conspicuous in this specimen.

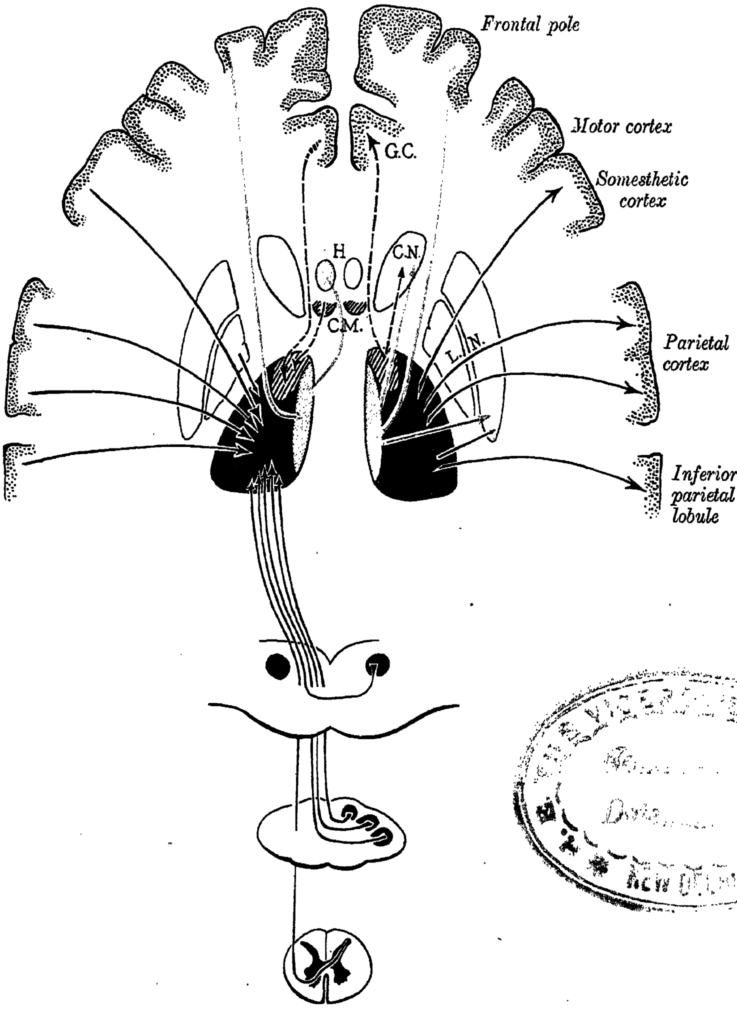
immediate vicinity of the geniculate bodies pass to the peri- and parastriate areas of the occipital cortex.

Functional significance of the thalamus.*—The thalamus is the most important of the subcortical correlation centres. Into it stream impulses from the olfactory apparatus, the visual apparatus, the somatic receptors of all kinds and the splanchnic receptors. In the thalamus these impulses are correlated with one another before they are transmitted to the cerebral cortex, but the correlation which occurs in the thalamus is something more than the simple interaction of nervous impulses, for there is good ground for supposing that the activities of the thalamus enter into and are appreciated by consciousness. It is certain that the higher forms of sensibility such as discriminative sensibility require the co-operation of the cerebral cortex, but cruder forms of sensibility, especially pain, are consciously experienced when the connexions existing between the thalamus and the cortex have been destroyed.

* For a full analysis of current views on the connexions and functions of the thalamus see "Functional Localisation in the Thalamus and Hypothalamus," W. E. le Gros Clark, *Journal of Mental Science*, March, 1936.

As already stated (p. 957), the medial nucleus of the thalamus receives afferents from the hypothalamus, which contains higher centres associated with the viscera. The cortical connexions of this nucleus bring visceral activities under the influence of the cortex and so provide a mechanism whereby the cortex is enabled to control or inhibit emotional and instinctive reactions which would otherwise result from visceral stimuli.

FIG. 874.—Scheme to show the principal connexions of the thalamus.



C.M. = Corpora mamillaria : C.N. = Caudate nucleus : G.C. = Gyrus cinguli : H. = Nuclei of hypothalamus : L.N. = Lentiform nucleus.
The lateral nucleus is shown in *black* : the medial nucleus in *blue* : and the anterior nucleus is *shaded*.

Fishes and, to a lesser extent, amphibia are dependent on the palæothalamus for the appreciation of harmful or beneficial stimuli. Co-ordinated responses arise in the thalamus and subthalamic region and result in the avoidance or the quest of such stimuli, as the case may be. In man such stimuli receive recognition in the thalamus, but the association areas of the cerebral cortex are necessary for their analysis and localisation.

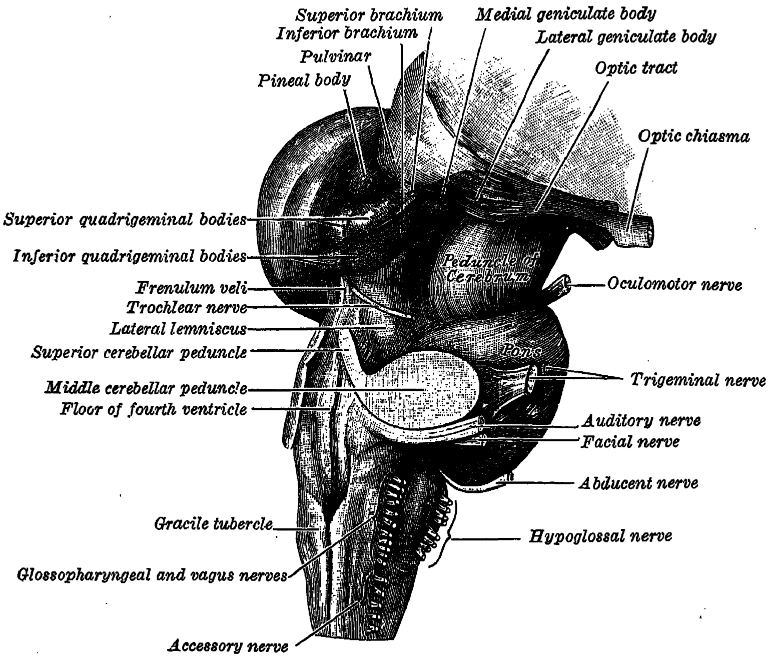
The **metathalamus** (fig. 875) comprises the geniculate bodies, which are two in number—a medial and a lateral—on each side.

The *medial geniculate body* lies under cover of the pulvinar of the thalamus, and lateral to the corpora quadrigemina. Oval in shape, with its long axis

directed forwards and laterally, it is lighter in colour and smaller in size than the lateral geniculate body. Through the inferior brachium it receives auditory fibres from the inferior corpus quadrigeminum and from the lateral lemniscus. Its cells send a relay of similar fibres to the cortex of the temporal lobe. The medial geniculate body is connected with its fellow and with the inferior corpus quadrigeminum of the opposite side by commissural fibres, which pass through the posterior part of the optic chiasma and run in the medial roots of the optic tracts.

The *lateral geniculate body* is an oval elevation on the lower surface of the lateral part of the posterior end of the thalamus, and is connected with the superior corpus quadrigeminum by the superior brachium. It receives most

FIG. 875.—The hind-brain and the mid-brain. Posterolateral aspect.



of the fibres of the optic tract, the remainder passing through the superior brachium to the superior corpus quadrigeminum, and very few, if any, terminating in the pulvinar. Its cells are large and pigmented, and are arranged in six laminæ, alternate laminæ being associated with the right and left eyes respectively.* Their axons pass through the optic (thalamo-occipital) radiation to the visual area in the occipital cortex.

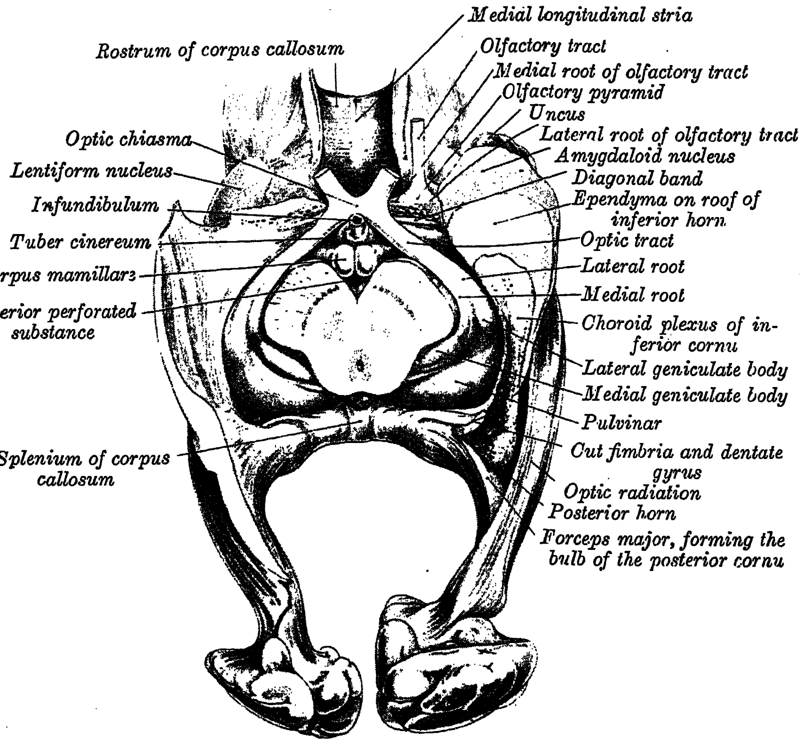
The superior corpus quadrigeminum, the pulvinar and the lateral geniculate body are termed the lower visual centres, but it must clearly be understood that *the great majority, if not all, of the fibres which are destined for the visual cortex are relayed in the lateral geniculate body.* Brouwer and Zeeman excised portions of the retina in rabbits, cats and monkeys and were unable to trace any degenerated fibres of the optic tract into the pulvinar. Further, they were able to localise the retinal fibres in definite areas of the lateral geniculate body. Fibres from the upper half of the retina are connected to its medial portion, those from the lower half of the retina to its lateral portion. Macular fibres occupy the central zone, and the area allotted to them is a large one (fig. 883). Those fibres from the nasal side of the retina which are concerned with monocular vision only are found in the ventral part of the lateral geniculate body, and occupy a narrow strip-like area (fig. 883).

The epithalamus comprises the trigonum habenulæ, the pineal body, and the posterior commissure.

* W. E. le Gros Clark and G. G. Penman, *Proc. Roy. Soc.*, B, 1934, cxiv.

The *trigonum habenulæ* is a small, depressed, triangular area, situated in front of the superior quadrigeminal body and medial to the posterior part of the thalamus, from which it is separated by the sulcus habenulæ (fig. 871). It contains a group of nerve-cells named the *habenular nucleus* (habenular ganglion). Afferent fibres are conveyed to the ganglion by the *stria habenularis* (stria medullaris thalami), which is formed at the anterior end of the thalamus by fibres which ascend from the anterior perforated substance and by fibres from the anterior column of the fornix. The stria then passes backwards on the medial surface of the thalamus (p. 955) and forms the medial boundary of the trigonum habenulæ. Some of the fibres cross in the peduncle of the pineal body and reach the habenular nucleus of the opposite side. They constitute the

FIG. 876.—A dissection of the brain from below, showing the metathalamus and the optic tracts.



On the right side of the figure the inferior horn of the ventricle is exposed. The floor has been removed but the choroid plexus is *in situ* and obscures most of the roof.

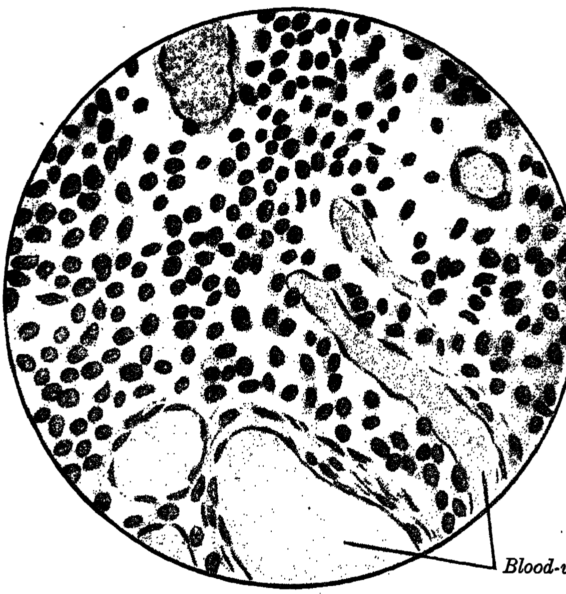
habenular commissure. Efferent fibres leave the ganglion and pass ventrally forming the *fasciculus retroflexus.* They descend medial to the red nucleus and end in the interpeduncular nucleus (interpeduncular ganglion) (p. 963), and some are described as reaching the substantia nigra of the mid-brain. The habenular nucleus and its afferent and efferent paths constitute a portion of the rhinencephalon.

The *pineal body* (figs. 871, 877) is a small, conical, reddish-grey body which lies in the depression between the superior quadrigeminal bodies. It is placed below the splenium of the corpus callosum, but is separated from it by the tela chorioidea of the third ventricle and the contained cerebral veins. It is enveloped by the lower layer of the tela, which is then reflected over the tectum (quadrigeminal lamina) (fig. 884). The pineal body measures about 8 mm. in length, and its base, directed forwards, is attached by a stalk or peduncle of white substance. The *stalk* divides anteriorly into two laminæ, a dorsal and a ventral, which are separated from each other by the pineal recess of the third ventricle. The ventral lamina is continuous with the posterior commissure and the dorsal lamina with the habenular commissure.

Structure (fig. 877).—The bulk of the parenchyma of the pineal gland consists of rounded cells, the so-called *pineal* cells, with irregular nuclei poor in chromatin. At birth a few neuroglia-cells and nerve-cells are present; the latter have scanty protoplasm and angular nuclei rich in chromatin. Connective tissue cells and fibrils appear during the first year, and gradually increase in quantity; the rate at which fibrosis takes place is very variable. Calcareous concretions are constantly present in the pineal body after the seventeenth year; spaces or cysts may also be present.*

The human pineal body is developed from the epiphysis, which grows out from the caudal end of the roof-plate of the diencephalon. In Cyclostome fishes the epiphysis gives rise to two diverticula, a parietal or parapineal and a pineal organ. Both these derivatives grow towards the dorsal surface of the head, and they become connected to the habenular region by a solid stalk containing nerve-fibres. Their vesicular extremities show a distinct resemblance to the optic vesicle. In Sphenodon, one of the most primitive reptiles, the parietal organ reaches the dorsal surface of the head and constitutes the parietal eye,

FIG. 877.—A section through the pineal body of a child aged 13 months. Stained with hæmatoxylin and eosin. ×400.



possessing a well differentiated cornea, lens and retina. The pineal organ, on the other hand, remains as a hollow, glandular structure which pours its secretion into the third ventricle. In mammals the parietal organ disappears at an early stage of embryonic life, and the pineal body is homologous with the pineal organ.

The *posterior commissure* is a small band of fibres crossing the median plane on the dorsal surface of the upper end of the aqueduct of the mid-brain, covered by the ventral lamina of the peduncle of the pineal body. Its fibres acquire their medullary sheaths early, but their connexions have not been definitely determined. Most of them have their origin in the *nucleus of Darkschewitsch* (p. 947), which lies in the ventral grey matter of the upper end of the aqueduct of the mid-brain, ventrimedial to the upper end of the oculomotor nucleus; some are probably derived from the posterior part of the thalamus and from the superior quadrigeminal body; others are believed to be continued downwards into the medial longitudinal bundle.

The **hypothalamus** (fig. 881) includes: (1) the subthalamic tegmental region; (2) the structures forming the floor of the third ventricle, viz. the posterior perforated substance, the corpora mamillaria, tuber cinereum, infundibulum, hypophysis cerebri and optic chiasma; and (3) the anterior part of the lateral wall of the third ventricle, below and in front of the thalamus.

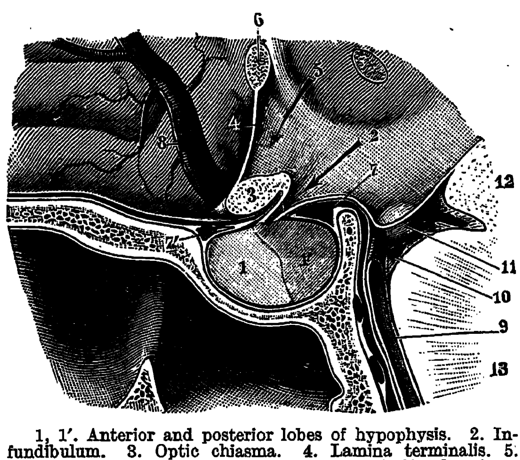
* Consult an abstract of an article by K. H. Krabbe in the *Review of Neurology and Psychiatry*, Edinburgh, 1915, xiii. 300.

(1) The *subthalamic tegmental region* consists of the forward continuation of the tegmentum beneath the posterior part of the thalamus. The red nucleus and the substantia nigra can be followed into its posterior part, where they gradually diminish, and disappear behind the corpus mamillare. The fibres of the medial lemniscus, on their way to enter the ventral surface of the thalamus, lie first lateral and then dorsal to the red nucleus. Some of the ascending branches of the fibres of the superior cerebellar peduncle pass directly into the thalamus, but the majority end in the red nucleus. A small, brownish-coloured nucleus, named the *subthalamic nucleus*, appears on the dorsal surface of the base of the cerebral peduncle. Shaped like a biconvex lens when seen in coronal sections of the brain, the nucleus lies dorsilateral to the upper end of the substantia nigra and extends backwards as far as the lateral aspect of the red nucleus. Dorsally (or above) it is related to the lateral nucleus of the thalamus, from which it is separated by a narrow area, termed the *zona incerta* (fig. 872). The fibre connexions of the subthalamic nucleus are still obscure, but it is known to receive a substantial bundle of fibres from the *ansa lenticularis*, which arise from the globus pallidus of the lentiform nucleus and enter its dorsal aspect, after intersecting the fibres of the internal capsule. In addition it receives afferents from some of the nuclei of the hypothalamus and probably represents the principal motor co-ordinating centre of that region. Clinical evidence indicates that destruction of the subthalamic nucleus is associated with uncontrollable movements, choreic in type, and exceedingly violent in character.

(2) *The structures forming the floor of the third ventricle.*—The *posterior perforated substance* is a small area of greyish substance which lies on the basal surface of the brain in the interval between the diverging cerebral peduncles. It is pierced by a number of small apertures which transmit the posteromedial central branches of the posterior cerebral arteries. In its posterior part it contains a small nucleus, named the *interpeduncular nucleus* (interpeduncular ganglion), in which the fasciculus retroflexus ends (p. 961). Superiorly the posterior perforated substance forms a small part of the floor of the third ventricle.

The *corpora mamillaria* (fig. 836) are two round white masses, each about the size of a small pea, placed side by side below the grey matter of the floor of the third ventricle in front of the posterior perforated substance. Each consists of white matter externally and of grey matter internally, the cells of the latter forming two nuclei, a *medial* of small and a *lateral* of large cells. The white matter is mainly formed by the fibres of the anterior columns of the fornix, which descend to the base of the brain and end partly in the corpora mamillaria. From the cells of the medial nucleus a bundle of fibres arises and divides into a *mamillo-thalamic tract*, which passes upwards into the anterior nucleus of the thalamus, and a *mamillo-tegmental tract*, which is directed downwards into the tegmentum. The fibres of the latter may arise as collaterals of the fibres of the mamillothalamic tract or they may arise independently. Afferent fibres run forwards to the lateral nucleus from the tegmentum and constitute the peduncle of the mamillary body.

Fig. 878.—A sagittal section through the hypophysis cerebri, in situ. Schematic. (Testut.)



1, 1'. Anterior and posterior lobes of hypophysis. 2. Infundibulum. 3. Optic chiasma. 4. Lamina terminalis. 5. Optic recess. 6. Anterior commissure. 7, 7'. Circular sinus. 8. Anterior cerebral artery. 9. Basilar artery. 10. Posterior cerebral artery. 11. Corpus mamillare. 12. Cerebral peduncle. 13. Pons.

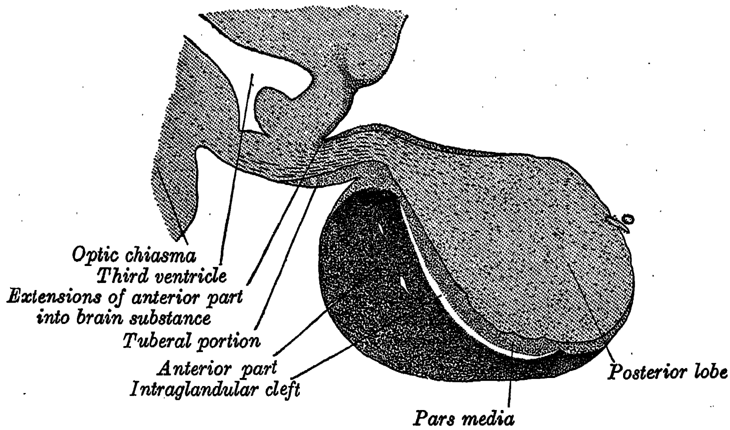
The corpora mamillaria form important cell-stations in the rhinencephalon. Olfactory impressions travelling from the hippocampus (p. 986) via the fornix

are relayed to the thalamus by the mamillothalamic tract, and can there be correlated with somesthetic and, probably, other visceral impressions. Thence the connexions of the thalamus with the corpus striatum offer a channel for the resulting co-ordinated motor response. The mamillotegmental tract affords a shorter pathway to the brain-stem for effector responses, and Kappers suggests that the snuffling of herbivorous animals when feeding is brought about by this pathway.

The *tuber cinereum* is a hollow eminence of grey matter which is situated between the corpora mamillaria behind and the optic chiasma in front. From its under surface, which is covered by the tuberal part of the hypophysis cerebri (p. 965), a hollow conical process, termed the infundibulum, projects downwards and is attached to the posterior lobe of the hypophysis. On each side the tuber cinereum is continuous with the anterior perforated substance, but it is separated from it on the basal surface of the brain by the optic tract.

The region occupied by the tuber cinereum is much more elaborated in fishes, and it owes its importance to its intimate relationship to the mouth and

FIG. 879.—A median sagittal section through the hypophysis cerebri of an adult monkey. Semidiagrammatic. (Herring.)



its consequent association with the sense of taste (Tilney). The dominance of the gustatory by the olfactory sense in air-breathing vertebrates is accompanied by a reduction in the development of this part of the hypothalamus, although several nuclei and commissural pathways have been described. It is in this region that the nervus terminalis (p. 1037) is attached, and the fact that it contains sympathetic fibres is not surprising in the light of recent work on the hypothalamus (p. 966).

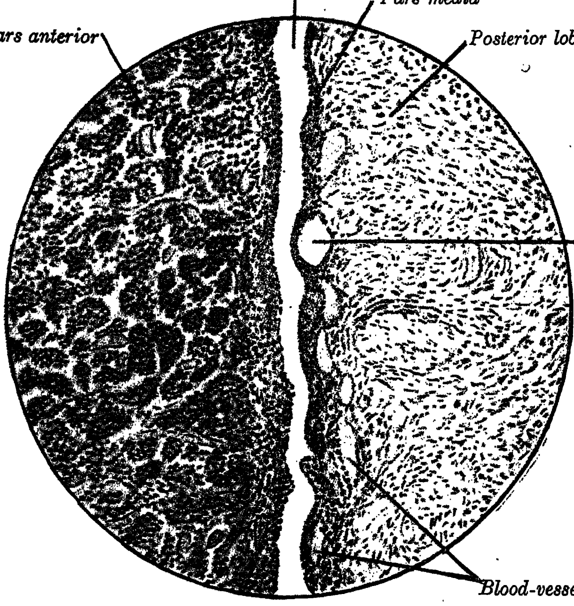
The *hypophysis cerebri* (fig. 879), is a reddish-grey, somewhat ovoid body, measuring about 12 mm. in its transverse, and 8 mm. in its anteroposterior diameter. It is attached to the end of the infundibulum, and is situated in the hypophyseal fossa of the sphenoid bone, where it is retained by a circular fold of dura mater, which is termed the *diaphragma sellæ*; this fold almost completely roofs in the fossa, leaving only a small central aperture through which the infundibulum passes, and it separates the anterior part of the upper surface of the hypophysis cerebri from the optic chiasma (fig. 878). On each side, the hypophysis cerebri is related to the cavernous sinus and the structures which it contains (p. 819). Inferiorly, it is separated from the floor of the fossa by a large, partially loculated, venous sinus, which communicates freely with the circular sinus.

The infundibulum, which is directed downwards and forwards, contains a funnel-shaped recess from the cavity of the third ventricle, and is surrounded (fig. 879) by an upward extension from the anterior lobe of the gland.

The hypophysis consists of an anterior and a posterior lobe, which differ in their development and structure (fig. 880). The *anterior lobe* is the larger,

and is somewhat kidney-shaped, the concavity being directed backwards and embracing the posterior lobe. It is developed from a diverticulum of the ectoderm of the primitive buccal cavity or stomodæum (p. 166), and consists of an anterior and a posterior part, separated from each other by a narrow cleft, which represents the remnant of the cavity of the diverticulum. The *anterior part* is extremely vascular and consists of granular epithelial cells of varying size and shape, arranged in cord-like trabeculæ or alveoli and separated by large, thin-walled blood-vessels. It is continuous above with the *tuberal portion*, which surrounds the infundibulum (fig. 879) and covers the tuber cinereum. The posterior part of the anterior lobe fuses with the anterior surface of the posterior lobe, forming the *middle part* (pars intermedia) of the hypophysis. It contains a few blood-vessels and consists of finely granular cells, between which are small masses of colloid material. The *posterior lobe*, which constitutes the *posterior part* of the hypophysis, is developed as a down-growth from the

FIG. 880.—A section of the hypophysis cerebri. × 100.



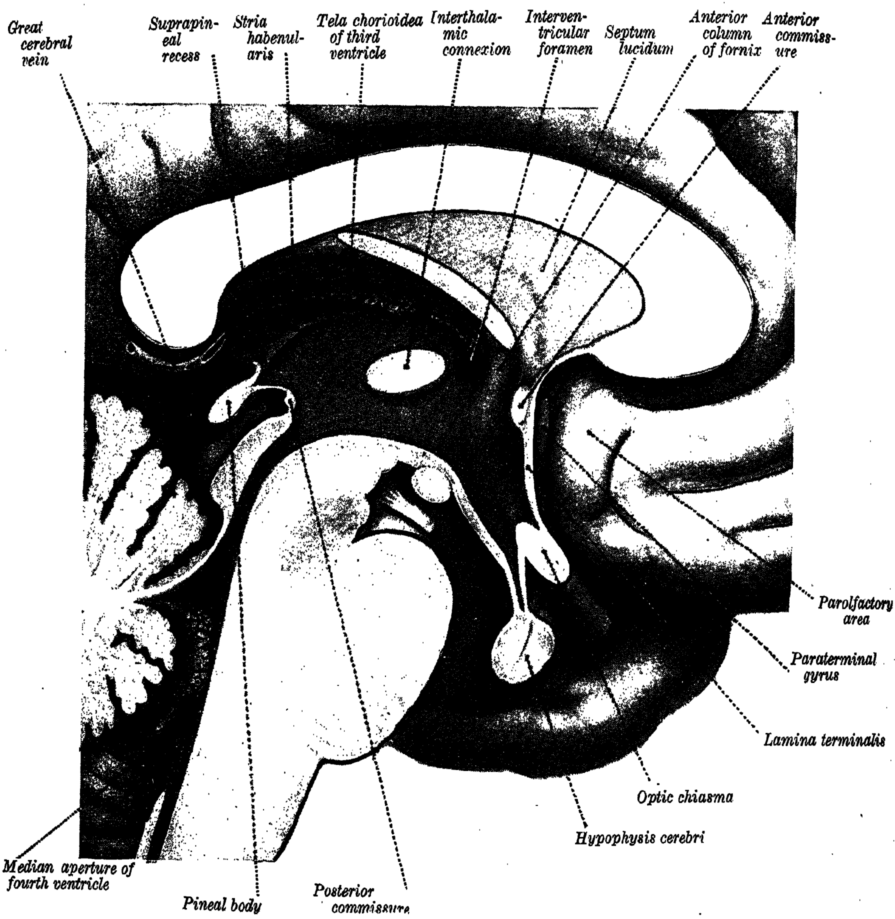
floor of the diencephalon, and during early fœtal life contains a cavity continuous with that of the third ventricle. In some animals (e.g. cat) this cavity persists throughout life. Although of nervous origin the posterior lobe contains no nerve-cells, but it receives nerve fibres from some of the nuclei of the hypothalamus. It consists of neuroglia-cells and fibres, and is invaded by cell-columns which grow into it from the middle part; imbedded in it are scattered masses of a colloid substance histologically similar to that found in the thyroid gland. In certain of the lower vertebrates (e.g. fishes) nervous structures are present, and the lobe is of large size. It draws a somewhat limited blood-supply from the internal carotid arteries.

Applied Anatomy.—Enlargement of the hypophysis cerebri and of the cavity of the sella turcica is found in the rare disease *acromegaly*, which is characterised by gradual increase of the size of the face, hands, and feet, with headache and often a peculiar type of blindness. This blindness is due to the pressure of the enlarging hypophysis on the inferior aspect of the optic chiasma (fig. 878). The pressure causes atrophy of the nerve-fibres coming from the lower nasal quadrants of the retinæ; with the result that the patient loses the upper temporal quadrants of his fields of vision while retaining his nasal fields (bitemporal quadrantic hemianopia).

The *optic chiasma* is described on p. 967.

(3) The *anterior part of the lateral wall of the third ventricle* is separated from the thalamus, above and behind, by the hypothalamic sulcus (p. 970); posteriorly it covers the terminal (lower) part of the anterior column of the fornix (fig. 881). In this part of the hypothalamus several nuclei have been identified and described and evidence which associates them with the activities of the viscera is gradually accumulating. Further the relationship between some of these nuclei and the hypophysis is very intimate, and the whole hypothalamus is now generally regarded as a complex neuroglandular mechanism

FIG. 881.—Part of a median sagittal section through the brain. Compare with fig. 884.



Red=pia mater, cut edge; Blue=ependyma.

which is concerned with the regulation and co-ordination of visceral activities. In its posterior part it contains the highest centres which have hitherto been identified in connexion with the sympathetic nervous system.

In recent years the hypothalamus has been the subject of much investigation, both anatomical and experimental, and, owing to the researches of Ransom, Cushing, Beattie and many others,* it is possible to speak with some certainty on particular aspects of its functional activity.

(1) Some, at least, of the activities of the hypophysis are controlled by hypothalamic nuclei, several of which (notably the *supra-optic nucleus*, which covers the upper surface of the optic chiasma) send efferent fibres to terminate in the posterior lobe. Experimental

* For a full list of references, consult papers by S. W. Ransom (*Bulletin of the New York Academy of Medicine*, May, 1937) and W. E. le Gros Clark (*Journal of Mental Science*, March, 1936).

section of these fibres is followed by atrophy of the posterior lobe and is associated with the condition of diabetes insipidus, which can be controlled by the administration of posterior lobe extract. From these experiments, which have been fully confirmed, it may be inferred that normally the posterior lobe secretes an antidiuretic hormone which regulates the outflow of water from the kidney.

(2) All the signs of sympathetic activity, acceleration of heart, etc., can be obtained on electrical stimulation of an area in the lateral wall of the third ventricle immediately above the mamillary body. This area contains a well-defined group of nerve cells, termed the *posterior hypothalamic nucleus*, which send their efferents upwards to the medial nucleus of the thalamus (p. 957) and caudally into the brain-stem. The precise course of these fibres in the brain-stem is uncertain. Ransom believes that they travel in the lateral part of the substance of the tegmentum, but most authorities hold that they descend close to the floor of the fourth ventricle in a bundle often termed the fasciculus longitudinalis dorsalis of Schutz.

(3) The hypothalamus is closely connected with the sleep mechanism. Destructive lesions, situated in the depths of the hypothalamic part of the lateral wall of the third ventricle in monkeys and just above and behind the mamillary body in cats, are associated with profound somnolence, and the grey matter in the last-named situation is extensively involved in the disease known as encephalitis lethargica.

(4) Evidence is rapidly accumulating to show that the temperature-regulating mechanism is placed in the hypothalamus. Lesions of the floor of the third ventricle between the infundibulum and the supra-optic nucleus are always associated with loss of temperature control, which may be complete.

(5) There is ground for believing that a parasympathetic centre is present in the hypothalamus, in front of the posterior hypothalamic nucleus and on a deeper plane, in a group of cells termed the *lateral hypothalamic nucleus*. By electrical stimulation of this nucleus, Beattie, Brow and Long produced many of the signs of parasympathetic activity, which were abolished on section of both vagus nerves.

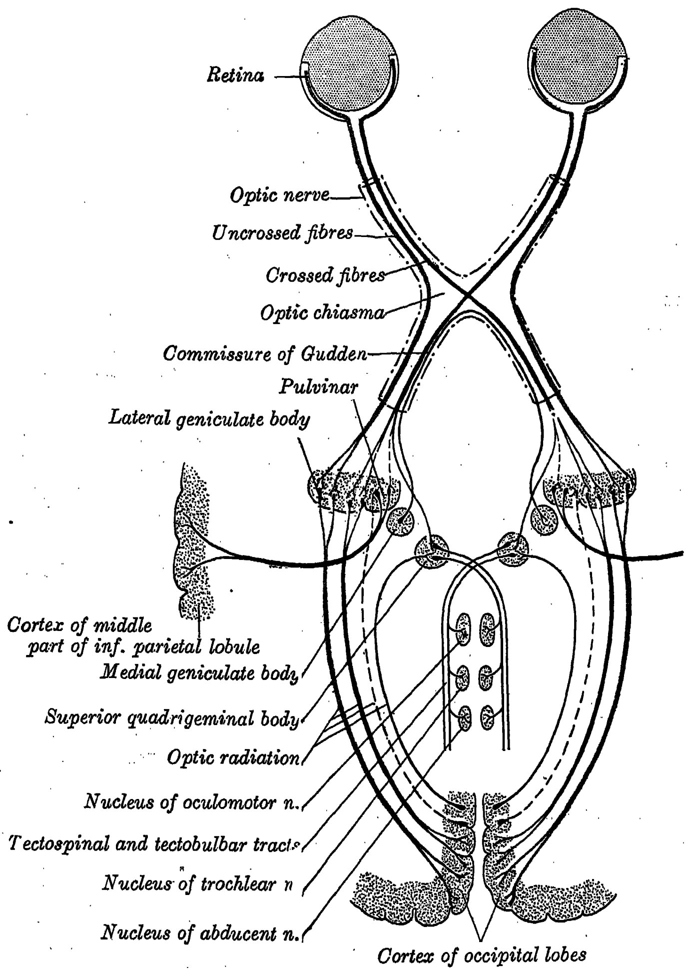
Optic chiasma.—The optic chiasma is a flattened, somewhat quadrilateral, bundle of nerve-fibres situated at the junction of the anterior wall of the third ventricle with its floor. Its anterolateral angles are continuous with the optic nerve, and its posterolateral angles with the optic tracts. The lamina terminalis (p. 968) is attached to its upper surface and is crossed, just above the chiasma, by the anterior communicating artery. Inferiorly the chiasma rests on the diaphragma sellæ just behind the optic groove (sulcus chiasmatis) of the sphenoid bone, and is thus in close relation to the hypophysis cerebri. Posteriorly it is related to the tuber cinereum and the infundibulum, below, and to the third ventricle above. Laterally it is related to the termination of the internal carotid artery and the anterior perforated substance. A small recess of the third ventricle, named the optic recess, passes downwards and forwards over its upper surface as far as the attachment of the lamina terminalis.

Most of the fibres of the optic chiasma take origin in the retina and reach the chiasma through the optic nerves. In the chiasma the fibres from the nasal half of each retina, including the nasal half of the macula, cross the median plane and enter the optic tract of the opposite side, while the fibres from the temporal half do not cross but pass backwards in the optic tract of the same side. The macular fibres from both eyes form a bundle, flattened from above downwards, which occupies the central part of the chiasma and separates the lower nasal quadrant fibres—which lie in the lower part of the chiasma—from the upper nasal quadrant fibres—which lie in the upper part of the chiasma. In the posterior part of the chiasma there is a strand of fibres, sometimes named the *commissure of Gudden*, which is not derived from the optic nerves. Its fibres arise in the medial geniculate body, enter the homolateral optic tract, cross in the chiasma and pass by the contralateral optic tract to reach the inferior corpus quadrigeminum and, possibly, the medial geniculate body of the opposite side. This commissure, therefore, forms no part of the visual pathway, but connects two lower auditory centres to each other.

Optic tracts.—The optic tracts (figs. 876 and 882) are continued backwards and laterally from the posterolateral angles of the chiasma. Each passes between the anterior perforated substance and the tuber cinereum, forming the anterolateral boundary of the interpeduncular space. The tract becomes flattened and winds round the upper part of the cerebral peduncle, to which it adheres closely. In this part of its course it is hidden from view on the basal surface of the brain by the uncus and the hippocampal gyrus. Reaching the

lateral geniculate body it divides into a medial and a lateral root. The medial root comprises the fibres of Gudden's commissure and enters the medial geniculate body. The lateral root consists mainly of afferent fibres which arise in the retina and undergo partial decussation in the optic chiasma, as already described, but it also contains a few fine efferent fibres which are passing forwards to terminate in the retina. Most of the fibres of the lateral root are

Fig. 882.—A scheme showing the connexions of the optic nerves and optic tracts.



The interrupted lines indicate connexions the existence of which is uncertain.

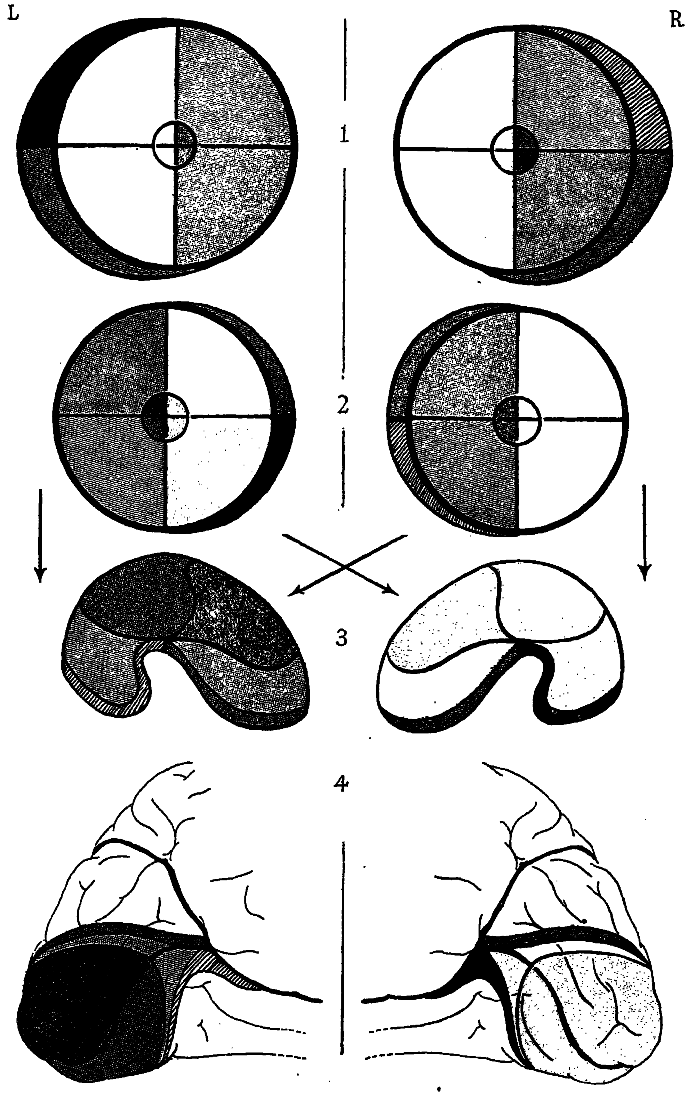
N.B.—*The dividing line between the decussating and the non-decussating fibres of the optic nerve passes vertically through the centre of the macula.*

found to end in the lateral geniculate body, but some sweep over the pulvinar and gain the superior quadrigeminal body.* It is very doubtful whether any of the fibres of the optic tract terminate in the pulvinar. New fibres arise from the nerve-cells in the lateral geniculate body, and pass through the posterior limb of the internal capsule. Emerging from the capsule as a broad bundle termed the optic radiation, the fibres of the second visual neurones sweep backwards and medially to reach the cortex of the occipital lobe of the cerebrum, where the higher or cortical visual centres are situated (p. 993). On their way they are separated from the posterior cornu of the lateral ventricle only by the tapetum of the corpus callosum.

* See footnote on p. 952.

Some of the fibres of the optic radiation take an opposite course, arising from the cells of the occipital cortex and passing to the superior quadrigeminal body, which therefore receives cortical in addition to retinal fibres. From the superior quadrigeminal body new fibres arise and travel by the tectobulbar and

FIG. 883.—A diagram to show the projection of the visual fields on the retinæ, lateral geniculate bodies and striate areas of the cortex. (Modified from S. Polyak, *Publications in Anatomy*, Univ. of California Press.)



1 = Fields of vision. 2 = Retinæ, coloured to correspond with 1. 3 = Coronal section of lateral geniculate body. 4 = Projection of lateral geniculate body on to the visual cortex. The arrows indicate the paths of the fibres in the optic chiasma.

Darker shades are used for the macular areas, and lighter shades for the peripheral retina. The peripheral strips on the nasal side of each retina are differently coloured on the two sides; they are associated with monocular vision only. The corresponding cortical areas for monocular vision are shown for the human brain and may be regarded as somewhat speculative.

tectospinal tracts to reach the nuclei of the third, fourth, sixth and eleventh cranial nerves, and the anterior grey column of the spinal cord. The superior quadrigeminal body constitutes a lower visual centre which is concerned through its retinal fibres with the light reflex * and, possibly, through its cortical

* Some authorities believe that the afferent fibres concerned in the light reflex pass direct from the optic tract to the Edinger-Westphal nucleus.

fibres with the reflex movements of the head and eyes which occur in response to visual stimuli.

The functional significance of the pulvinar with reference to the lower visual centres is explained on p. 958.

The Third Ventricle

The third ventricle (figs. 871, 881, 884), which is the derivative of the vesicle of the primitive fore-brain, is a median cleft between the two thalami. Behind, it communicates with the fourth ventricle through the aqueduct of the mid-brain, and in front with the lateral ventricles through the interventricular foramen. Somewhat triangular in shape with the apex directed backwards, it has a roof, a floor, an anterior and a posterior boundary, and two lateral walls.

The *roof* (fig. 884) is formed by a layer of ependyma which stretches between the upper edges of the lateral walls of the cavity and is continuous with the ependymal lining of the ventricle. It is covered by, and adherent to, a fold of pia mater, named the tela chorioidea of the third ventricle, from the under surface of which a pair of vascular fringed processes, named the *choroid plexuses of the third ventricle,* project downwards, one on each side of the median plane, and invaginate the epithelial roof into the ventricular cavity.

The *floor* (fig. 836) slopes downwards and forwards and is formed mainly by structures which belong to the hypothalamus ; from before backwards these are : the optic chiasma, the infundibulum and tuber cinereum, and the corpora mamillaria. Behind the last the floor is formed by the posterior perforated substance and by the tegmenta of the cerebral peduncles. The ventricle is prolonged downwards into the infundibulum as a funnel-shaped recess, termed the *infundibular recess.* The hypophysis cerebri is attached to the apex of the infundibulum.

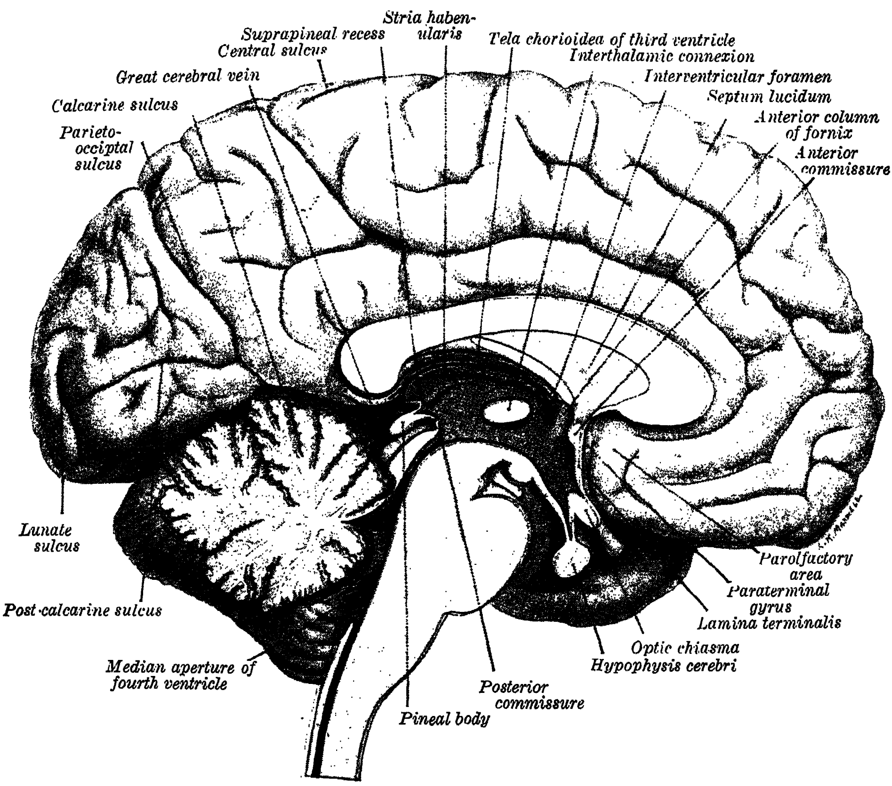
The *anterior boundary* (fig. 881) is constituted below by the *lamina terminalis,* which represents the cephalic end of the primitive neural tube. It forms a thin layer of grey matter stretching from the upper surface of the optic chiasma to the rostrum of the corpus callosum. In its upper part the anterior boundary is formed by the anterior columns of the fornix, which diverge as they pass downwards and sink into the lateral walls of the ventricle, and the anterior commissure (p. 1001), which crosses the median plane in front of them. At the junction of the floor and anterior wall, immediately above the optic chiasma, the ventricle presents a small angular recess or diverticulum, named the *optic recess.* Between the anterior columns of the fornix, and above the anterior commissure, is a second recess, sometimes termed the *vulva.* At the junction of the roof with the anterior and lateral wall of the ventricle is the *interventricular foramen* (foramen of Monro), through which the third and the lateral ventricles communicate with one another. It represents the site of the original diverticular outgrowth from the telencephalon which forms the cerebral hemisphere, and is relatively large and circular in a 10 mm. human embryo. In the adult, however, it is reduced to a somewhat crescentic slit, bounded in front by the curving anterior column of the fornix and behind by the convex anterior tubercle of the thalamus.

The *posterior boundary* (fig. 881) is constituted by the pineal body, the posterior commissure and the aqueduct of the mid-brain. A small recess, named the *pineal recess,* projects into the stalk of the pineal body, whilst in front of and above the pineal body a second recess, named the *suprapineal recess,* consists of a diverticulum of the epithelium which forms the ventricular roof.

Each *lateral wall* consists of an upper portion formed by the medial surface of the anterior two-thirds of the thalamus, and a lower formed by the hypothalamus and continuous with the grey matter of the ventricular floor. These two parts are separated from each other by the *hypothalamic sulcus,* which extends from the interventricular foramen to the aqueduct of the mid-brain, but is not always an obvious feature. The lateral wall is limited above by the ridge covering the stria habenularis (p. 955). The anterior columns of the

fornix curve downwards in front of the interventricular foramen, and then run in the lateral walls of the ventricle, where, at first, they form distinct prominences, but subsequently are lost to sight. The lateral walls are joined to each other across the cavity of the ventricle by a band of grey matter, named the *connexus interthalamicus* (massa intermedia) (p. 955). The area below the

FIG. 884.—A median sagittal section through the brain.



The pia mater, where divided, is shown in *red*; the ependyma is shown in *blue*.

hypothalamic sulcus constitutes an important part of the hypothalamus and has been described on p. 966.

The **interpeduncular fossa** (figs. 836, 887).—This is a somewhat lozenge-shaped area of the base of the brain, limited in front by the optic chiasma, behind by the anterosuperior surface of the pons, anterolaterally by the converging optic tracts and posterolaterally by the diverging cerebral peduncles. The structures contained in it have already been described; from behind forwards they are the posterior perforated substance (p. 963), corpora mamillaria, tuber cinereum, infundibulum, and hypophysis cerebri (p. 964).

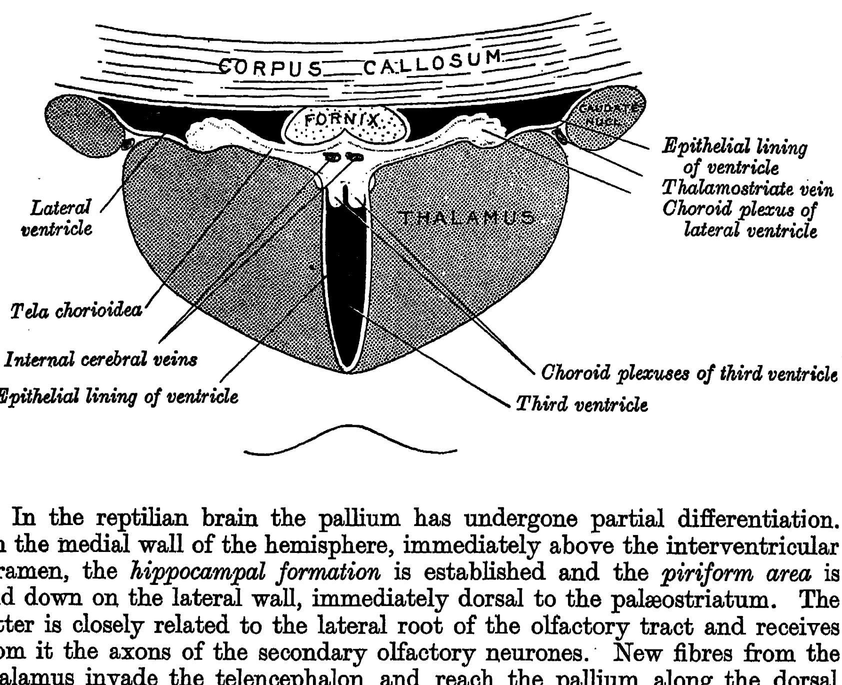
THE TELENCEPHALON

The expansion of the telencephalon or end-brain and the development of the two cerebral hemispheres in the human embryo have already been described (p. 115). In the most primitive vertebrates the anterior part of each cerebral hemisphere is constricted to form the *olfactory lobe*, which may become drawn forwards into a dilated extremity, termed the *olfactory bulb*. The latter is connected by a hollow stalk, named the *olfactory tract*, to an elevation on the wall of the hemisphere, which constitutes the *olfactory tubercle*. In the basal part

of each hemisphere a large nucleus is formed which derives its afferent fibres from the olfactory lobe and from the thalamus, and sends its efferent fibres to the brain-stem and the spinal cord. This basal nucleus is termed the *palæostriatum*, and it constitutes a motor centre where impulses from the olfactory bulb and the thalamus can be co-ordinated to produce the appropriate response. The remainder of the wall of the hemisphere constitutes the *pallium* or mantle, which, in higher forms, becomes elaborated and expanded in a very remarkable manner.

In the lowliest vertebrates the pallium shows very little differentiation, and it is merely a correlation area for gustatory impressions, which ascend from the hypothalamus, and for olfactory impressions, which stream into it not only from the olfactory lobe of the same side but also from the opposite side. Fibres from opposite sides cross in the lamina terminalis and represent the oldest commissures of the fore-brain, viz.: the anterior commissure and the hippocampal commissure.

Fig. 885.—A coronal section through the lateral and third ventricles. The pia mater of the tela chorioidea is shown in *red* and the ependyma in *yellow*. Diagrammatic.



In the reptilian brain the pallium has undergone partial differentiation. On the medial wall of the hemisphere, immediately above the interventricular foramen, the *hippocampal formation* is established and the *piriform area* is laid down on the lateral wall, immediately dorsal to the palæostriatum. The latter is closely related to the lateral root of the olfactory tract and receives from it the axons of the secondary olfactory neurones. New fibres from the thalamus invade the telencephalon and reach the pallium along the dorsal and ventral margins of the piriform area. The latter preponderate at first, and the cells of the pallium in this situation multiply and grow centrally towards the cavity of the ventricle, in which they form a substantial longitudinal ridge. This ingrowth constitutes the *neostriatum* (of Kappers) (hypopallium of Elliot Smith), which lies dorsal to the palæostriatum and intimately related to it. Prior to the invasion of the telencephalon by thalamic fibres the whole behaviour of the animal was dominated by olfactory impressions, but after its invasion by fibres conveying gustatory, visual, tactile and other forms of sensibility, modifying influences are introduced, and it becomes imperative that the activities of the palæostriatum should be inhibited and regulated. This controlling action is exerted by the neostriatum.

At the same time other thalamic fibres reach the pallium along the dorsal and headward borders of the piriform area, and the cells in this situation increase enormously in number, and constitute the *neopallium*, as distinguished from the cortex of the hippocampal formation and the piriform area, which make up the *archipallium*. The cells of the neopallium lie between the hippocampal formation on the medial side and the piriform area on the lateral side.

In mammals the neopallium grows and expands, and in microsmatic animals, such as man, a part of this increase is accomplished at the expense of the archipallium, which is partly relegated to limited areas on the medial and inferior surfaces of the cerebral hemisphere and is partly overlapped and buried. With the appearance of new sensory centres in the neopallium, the simple movements which can be carried out by means of the corpus striatum (palæo- + neo-striatum) are insufficient to meet the demands and higher motor centres are therefore established in the neopallium for the control of the movements of the body. These motor centres are closely connected to the

Fig. 886.—Schematic representations of the cerebral hemisphere of a turtle, after Elliot Smith, *Journal of Anatomy*, vol. liii. (I) Lateral surface; (II) Medial surface; (III) Coronal section through I and II in the plane XY.

sensory centres in the neopallium, and as these connexions increase in number, behaviour becomes less and less affected by olfactory impressions and more and more influenced by other forms of sensibility.

At first the higher sensory centres laid down in the neopallium adjoin one another, but they gradually become separated by the development of association areas, in which at first visual, olfactory and gustatory impressions can be correlated. The association of these different forms of sensibility with one another renders possible the registration of past experience so as to benefit the animal in its pursuit and selection of food. Its movements, therefore, become purposive, and a plastic element is introduced into its behaviour.

The addition of higher auditory centres and the expansion of the somesthetic centres are accompanied by the appearance of new association areas, all of which become linked up with the motor centres. As the neo-

pallium expands for these purposes behaviour becomes still more purposive and plastic.

The association areas have reached a much higher degree of expansion in man than in his nearest relatives, the anthropoid apes, and it is this feature in the structure of the human brain that has rendered possible the complexities of the intellectual life.

The earlier stages of the expansion of the neopallium are the result of the process of *telencephalisation*, by means of which higher centres are shifted forwards into the end-brain. The best example of this process is the appearance of the visual cortex in the occipital lobe, which takes over the higher visual centres formerly situated in the optic lobe or superior corpus quadrigeminum of the mid-brain.

Parts of the telencephalon.—The telencephalon includes: (1) the cerebral hemispheres, the commissures which connect them, and the cavities which they contain, and (2) the anterior parts of the hypothalamus and of the third ventricle (already described on pp. 966-969). Each cerebral hemisphere consists of an outer layer of grey matter, termed the cortex, an inner mass of white fibres, and certain buried basal nuclei. The cortex may further be subdivided into the derivatives of the neopallium and of the archipallium. The latter, with certain outlying structures such as the olfactory bulb, constitutes the rhinencephalon.

The Cerebral Hemispheres

The **cerebral hemispheres** form the largest part of the brain, and, when viewed together from above, assume the outline of an ovoid mass broader behind than in front, the greatest transverse diameter corresponding with a line connecting the two parietal tuberosities. The hemispheres are incompletely separated by a deep median cleft, named the *longitudinal cerebral fissure*, and each possesses a central cavity, termed the lateral ventricle.

The **longitudinal fissure of the cerebrum** contains a sickle-shaped process of dura mater, named the falx cerebri, and the anterior cerebral vessels. In front and behind the fissure completely separates the cerebral hemispheres from each other; in the middle, however, it only extends down to a great central white commissure, named the *corpus callosum*, which connects the hemispheres across the median plane.

The Surfaces of the Cerebral Hemispheres

Each cerebral hemisphere presents three surfaces: superolateral, medial, and inferior.

The *superolateral surface* is convex in adaptation to the concavity of the corresponding half of the vault of the cranium. The *medial surface* is flat and vertical and is separated from that of the opposite hemisphere by the longitudinal fissure and the falx cerebri. The *inferior surface* is of an irregular form, and may be divided into two parts: orbital and tentorial. The orbital part, formed by the orbital surface of the frontal lobe, is concave, and rests on the roof of the orbit and nose; the tentorial part is concavoconvex, and consists of the under surface of the temporal and occipital lobes; anterolaterally it is adapted to the corresponding half of the middle cranial fossa; posteromedially it rests upon the tentorium cerebelli, which intervenes between it and the upper surface of the cerebellum.

The three surfaces are separated by the following borders: (*a*) *superomedial*, between the superolateral and medial surfaces; (*b*) *inferolateral*, between the superolateral and inferior surfaces; the anterior part of this border separates the superolateral from the orbital surface of the frontal lobe, and is known as the *superciliary* border; (*c*) *medial occipital*, between the tentorial and medial surfaces; and (*d*) *medial orbital*, separating the orbital from the medial surface. The anterior end of the hemisphere is named the *frontal pole*; the posterior, the *occipital pole*; and the anterior end of the temporal lobe, the *temporal pole*. About 5 cm. in front of the occipital pole on the inferolateral border there is an indentation or notch, named the *pre-occipital notch*.

The surfaces of the hemispheres are moulded into a number of irregular eminences, named *gyri* or *convolutions*, and separated by furrows termed *sulci*.

The irregular character of the surfaces of the cerebral hemispheres is a very prominent feature, but it must be remembered that up to the end of the fourth month these surfaces are smooth and unbroken, like the surfaces of the brains of reptiles and birds. Thereafter localised depressions become apparent, and they deepen and extend over the surface to form the sulci. In certain situations these sulci develop along lines separating areas which differ from one another in the details of their microscopic structure and therefore probably in the functions which they subserve. Such sulci may therefore be termed *limiting sulci*, since they establish the limits of certain functional areas. The central sulcus (of Rolando) is an admirable example of a limiting sulcus, for it is set between two areas of cortex which differ in thickness so notably that the difference can be appreciated with the naked eye (fig. 891). In other situations sulci develop in the long axis of a rapidly growing homogeneous area and are termed *axial sulci*. The post-calcarine sulcus is situated in the centre of the striate area of the cortex and is related on both sides to the higher visual centres. In other situations, again, a sulcus may be situated between two surface areas of cortex which are structurally different, but its lip and not its floor may form the dividing line between the two areas. In these cases a third area is present in the wall of the sulcus and does not appear on the surface at all. Such a sulcus is termed an *operculated sulcus*, and this type is represented in the human brain by the lunate sulcus, which separates the striate from the peristriate areas on the surface and contains in its wall the submerged parastriate area, which really intervenes between them. These three varieties include all of the sulci which develop on the surface of the brain, with the exception of the lateral sulcus and the parieto-occipital sulcus. The former is the result of the slower expansion of the cortex of the insula and its consequent submersion by the adjoining cortical areas, which eventually come into contact with one another so as to delimit the lateral sulcus. The latter is brought about subsequent to the development of the corpus callosum. The posterior end of this great commissure has to convey not only the fibres from the occipital portions of the brain but also a large number of fibres from the temporal portions. As a result, a number of smaller axial and limiting sulci become crowded together and some of them become buried within the walls of the parieto-occipital sulcus. These two are really secondary sulci, since their occurrence depends on factors other than exuberant growth in closely adjoining areas.

Some of the sulci which indent the hemisphere are deep enough to produce corresponding elevations in the walls of the lateral ventricles. The calcarine sulcus, which produces the calcar avis of the posterior horn, and the collateral, which produces the *collateral eminence* in the inferior horn, are therefore termed complete sulci. There is, however, no special morphological or functional significance to be attached to the fact that while some sulci are complete others are incomplete.

The gyri and their intervening sulci are fairly constant in their arrangement; at the same time they vary within certain limits, not only in different individuals, but in the two hemispheres of the same brain. The convoluted condition of the surface permits of a great increase of the grey matter without the sacrifice of much additional space, and the number and extent of the gyri, as well as the depth of the intervening furrows, appear, within broad limits, to bear a direct relation to the intellectual powers of the individual.

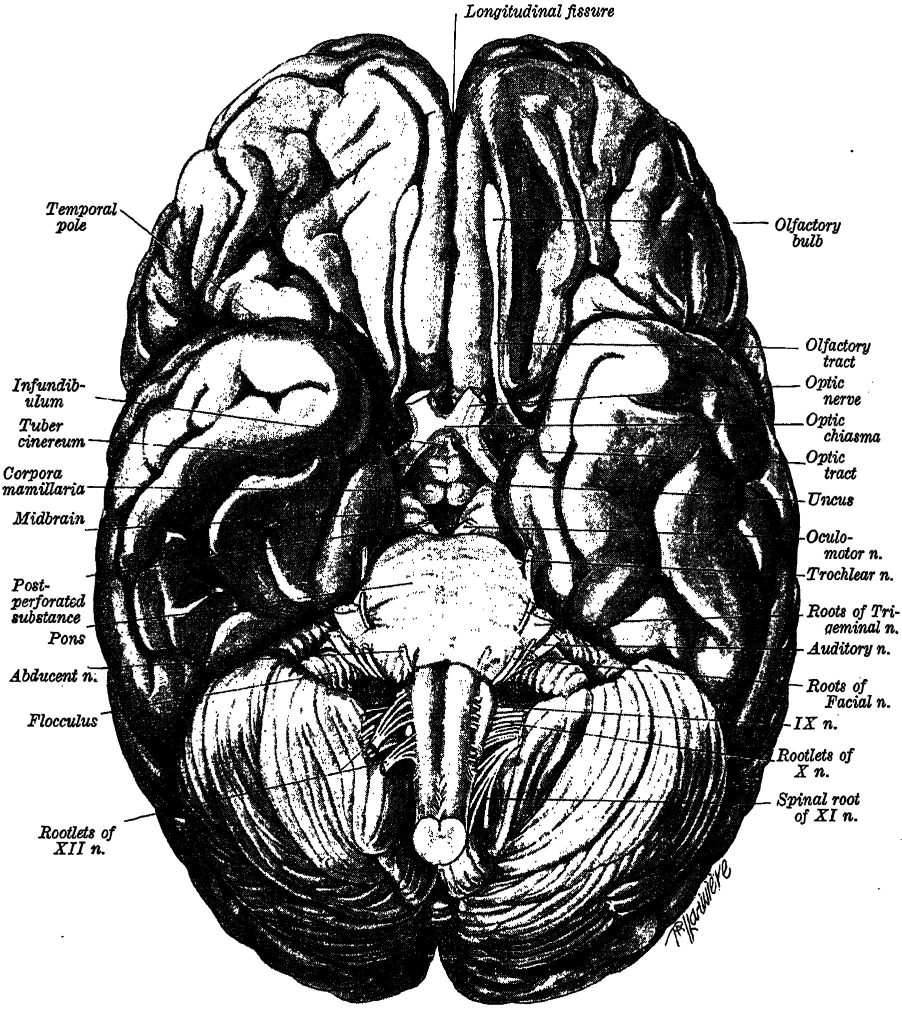
The superolateral surface of the cerebral hemisphere.—It is convenient for ease of description and for ease of reference to separate this surface into a number of lobes, but it must be remembered that this subdivision is purely one of convenience and that the lobes do not precisely correspond in surface extent to the cranial bones from which their names are derived.

The anterior part of the hemisphere is termed the **frontal lobe**, and, on this surface, it comprises the whole of the area which lies in front of the central sulcus and above the lateral sulcus. It is limited above by the superomedial and below and in front by the superciliary margin of the hemisphere.

The **lateral sulcus** (lateral fissure) (figs. 887 and 888) is a deep cleft situated on the inferior and lateral surfaces of the cerebral hemisphere. It consists of

a short stem which ends by dividing into three rami. The *stem* commences on the inferior surface at the lateral angle of the anterior perforated substance and extends laterally between the orbital surface of the frontal lobe and the anterior part of the temporal lobe. On reaching the lateral surface it divides into anterior horizontal, anterior ascending and posterior rami. The *anterior horizontal ramus* runs forwards for 2·5 cm. or less into the inferior frontal gyrus, while the *anterior ascending ramus* runs upwards for about an equal

FIG. 887.—The base of the brain.



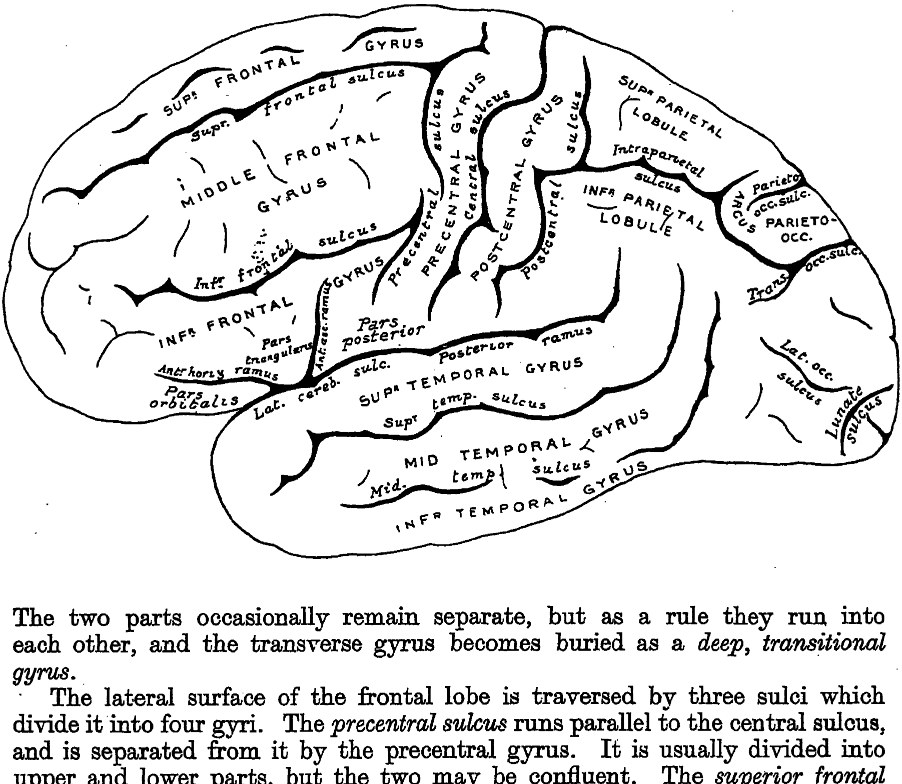
distance into the same gyrus. The *posterior ramus* is the longest division. It courses backwards and slightly upwards across the lateral surface for about 7 cm. before turning upwards to end in the parietal lobe. The floor of this sulcus is formed by the limen insulæ and the insula, and it conducts the middle cerebral vessels from the basal to the lateral aspect of the hemisphere.

The **central sulcus** (fig. 888) commences in or near the superomedial margin of the hemisphere a little behind the mid-point between the frontal and occipital poles. It runs sinuously downwards and forwards and ends a little above the posterior ramus of the lateral sulcus, from which it is always separated by an arched gyrus. The general direction of the sulcus makes an angle of rather less than 70° with the median plane. The central sulcus is a good example of a typical limiting sulcus, for it develops along the line which

separates the motor area of the cerebral cortex from the somesthetic area (p. 993).

When the central sulcus is opened up the opposed walls are found to be marked by a number of small gyri which interlock with one another after the manner of gears in mesh, and are therefore termed *interlocking gyri*. This arrangement provides additional cortical grey matter without any corresponding increase in the surface area on the lateral surface of the hemisphere. Another feature is brought to light by opening up the sulcus. The floor is not the same depth throughout its whole extent, for a little below the middle of the sulcus its walls are usually connected to each other by a buried, transverse gyrus. The explanation of this condition is found in the mode of development of the central sulcus. When it makes its appearance in the sixth month, it does so in two distinct portions, an upper and a lower, which are at first separated by a transverse gyrus connecting the precentral convolution to the postcentral.

Fig. 888.—The superolateral surface of the left cerebral hemisphere. Lateral aspect.



The two parts occasionally remain separate, but as a rule they run into each other, and the transverse gyrus becomes buried as a *deep, transitional gyrus*.

The lateral surface of the frontal lobe is traversed by three sulci which divide it into four gyri. The *precentral sulcus* runs parallel to the central sulcus, and is separated from it by the precentral gyrus. It is usually divided into upper and lower parts, but the two may be confluent. The *superior frontal sulcus* runs forwards and downwards from about the middle of the upper part of the precentral sulcus, while the *inferior frontal sulcus* runs parallel to it at a lower level. The portion of the frontal lobe which lies anterior to the precentral sulcus is thus divided into the superior, middle and inferior frontal gyri.

The *precentral gyrus*, which is bounded behind by the central sulcus and in front by the precentral sulcus, extends from the superomedial border of the hemisphere to the posterior ramus of the lateral sulcus. The large pyramidal cells of its posterior part (giant cells of Betz) give origin to the fibres of the important cerebrospinal (pyramidal) motor tract.

The *superior frontal gyrus* lies above the superior frontal sulcus, and is continuous over the superomedial margin of the hemisphere with the medial frontal gyrus on the medial surface. It is more or less completely subdivided into upper and lower portions by the paramedian sulcus which, however, is frequently interrupted by bridging gyri.

The *middle frontal gyrus* lies between the superior and the inferior frontal sulci. Its surface is broken by two or three small sulci which together constitute the *middle frontal sulcus*. Lesions of this gyrus result in interference with conjugate movements of the eyes.

The *inferior frontal gyrus* lies below the inferior frontal sulcus and is invaded by the anterior horizontal and the anterior ascending rami of the lateral sulcus. The areas grouped around these two rami constitute Broca's area and are associated with the motor element of speech. The portion lying below the anterior horizontal ramus is termed the *pars orbitalis*, and it curves round the superciliary margin to gain the orbital surface of the frontal lobe. The portion between the ascending and the anterior horizontal rami is termed the *pars triangularis*, while the portion lying behind the anterior ascending ramus forms the *pars posterior* (pars basilaris) and is continuous behind with the lowest part of the precentral gyrus.

The **temporal lobe** lies below the lateral sulcus. Behind it is limited by a line drawn from the preoccipital notch (p. 974) to the parieto-occipital sulcus, where it cuts the superomedial margin about 5 cm. in front of the occipital pole. The lateral surface of the temporal lobe is divided into three parallel gyri by two sulci.

The *superior temporal sulcus* begins behind the temporal pole and runs backwards and slightly upwards parallel to the posterior ramus of the lateral sulcus. Its posterior end curves upwards into the parietal lobe. The *inferior* (middle) *temporal sulcus* lies below and parallel to the superior sulcus. It is broken up into two or three short sulci, but its posterior end turns upwards into the parietal lobe, behind and parallel to the upturned end of the superior sulcus.

In this way the lateral surface of the temporal lobe is subdivided into three parallel gyri, the *superior*, *middle* and *inferior temporal gyri*. The superior temporal gyrus is continuous with the gyri which form the floor of the posterior ramus of the lateral sulcus. These are three or four in number, and they extend obliquely forwards and laterally from the circular sulcus which surrounds the insula. They are termed the *transverse temporal gyri* (fig. 890). The higher auditory centres are situated in the anterior transverse temporal gyrus and in the portion of the superior temporal gyrus with which it is in continuity (fig. 897).

The **parietal lobe** is bounded in front by the central sulcus and behind by the line joining the preoccipital notch to the superomedial margin at the point where it is cut by the parieto-occipital sulcus. Above, it is limited by the superomedial margin, and below by the posterior ramus of the lateral sulcus and a line drawn backwards to the posterior boundary from the point where the ramus turns upwards. It will be seen, therefore, that both the posterior boundary and the posterior part of the inferior boundary of the parietal lobe on this surface of the hemisphere are artificial.

The lateral aspect of the parietal lobe is subdivided into three areas by two sulci, termed the *postcentral sulcus*, which lies behind and parallel to the central sulcus, and the *intraparietal sulcus*, which passes backwards from the postcentral sulcus (fig. 889).

The *postcentral sulcus*, which may be divided into upper and lower parts, lies behind and parallel to the central sulcus. Inferiorly it ends above the posterior ramus of the lateral sulcus and in front of its upturned end. It divides the parietal lobe into an anterior part, termed the postcentral gyrus, and a large posterior part which is further subdivided by the intraparietal sulcus. The *intraparietal sulcus* commences in the postcentral sulcus about its middle or at the upper end of its lower subdivision. It extends backwards and downwards across the parietal lobe, dividing it into a superior and an inferior parietal lobule. Posteriorly, as the occipital ramus, it extends into the occipital lobe, where it joins the transverse occipital sulcus at right angles (fig. 888).

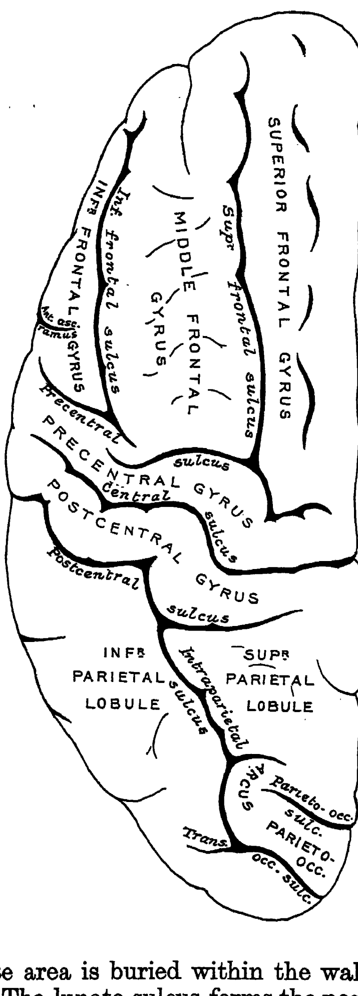
The *postcentral gyrus* lies between the central sulcus in front and the post-central sulcus behind. It contains the important higher centres for somesthetic sensibility (p. 993).

The *superior parietal lobule* extends between the superomedial margin of the

hemisphere and the intraparietal sulcus. In front it is continuous with the postcentral gyrus round the upper end of the postcentral sulcus, while posteriorly it frequently runs into the arcus parieto-occipitalis, which surrounds the external part of the parieto-occipital sulcus.

The *inferior parietal lobule* lies below the intraparietal sulcus and behind the lower part of the postcentral sulcus. It is divided into three parts. The *anterior part* (supra-marginal gyrus) arches over the upturned end of the lateral sulcus; it is continuous in front with the lower part of the postcentral gyrus and below and behind with the superior temporal gyrus. Occasionally it is limited posteriorly by a small sulcus, named the *sulcus intermedius primus*, which descends from the intraparietal sulcus. The *middle part* (angular gyrus) arches over the upturned end of the superior temporal sulcus and is continuous behind and below with the middle temporal gyrus; sometimes a small sulcus intermedius secundus forms its posterior boundary. The posterior part arches over the upturned end of the inferior temporal sulcus and extends on to the occipital lobe.

FIG. 889.—The superolateral surface of the left cerebral hemisphere. Superior aspect.



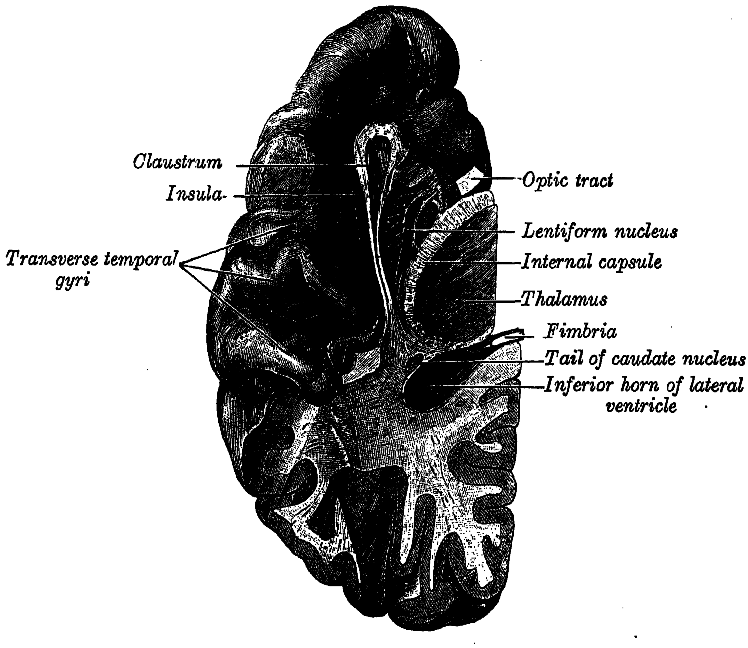
The part of the lateral surface which lies behind the line joining the pre-occipital notch to the parieto-occipital sulcus on the superomedial margin belongs to the occipital lobe. The *transverse occipital sulcus* descends from the superomedial margin behind the parieto-occipital sulcus and is joined about its middle by the intraparietal sulcus. Its upper portion forms the posterior boundary of the *arcus parieto-occipitalis*, an arched gyrus which surrounds the end of the parieto-occipital sulcus. The *lateral occipital* (*prelunate*) *sulcus* is a short sulcus which runs forwards on the lateral aspect of the occipital lobe and divides it into a *superior* and an *inferior occipital gyrus* (fig. 888). The *sulcus lunatus* is situated just in front of the occipital pole, but it is not invariably present. It is placed vertically and sometimes forms a ⊢ with the postcalcarine sulcus, although the two are more often separated from each other. The lips of the lunate sulcus, which is operculated in type, separate the striate from the peristriate area of the cortex, but the parastriate area is buried within the walls of the sulcus and intervenes between them. The lunate sulcus forms the posterior boundary of the *gyrus descendens* (Ecker), which lies behind the superior and inferior occipital gyri. Two curved sulci, named the superior and inferior polar sulci, are often present near the extremities of the lunate sulcus. The *superior polar sulcus* arches upwards on to the medial aspect of the occipital lobe from the neighbourhood of the upper limit of the lunate sulcus; the *inferior polar sulcus* arches downwards and forwards on to the inferior aspect from the lower limit of the same sulcus. These two polar sulci enclose semilunar extensions of the striate area (p. 993) and represent the expansion of the visual cortex in association with the formation of its large macular area * (p. 994).

The insula (fig. 891) lies deeply in the floor of the lateral sulcus and is almost surrounded by a *circular sulcus*. It has been hidden and buried by the over-

* G. Elliot Smith, *Journal of Anatomy*, vol. lxiv. 1930.

growth of the cortical areas which adjoin it, and it can only be seen when the lips of the lateral sulcus are widely separated. These areas of the cortex are therefore termed the *opercula of the insula,* and they are separated from each other by the three rami of the lateral sulcus. The *orbital operculum* lies below the anterior horizontal ramus and is formed by the pars orbitalis of the inferior frontal gyrus. The *frontal operculum* lies between the anterior horizontal and ascending rami, and is formed by the pars triangularis of the inferior frontal gyrus. It may be of small size in cases where the two rami between which it lies arise by a common stem. The *frontoparietal operculum* lies between the anterior ascending and the upturned end of the posterior ramus of the lateral sulcus. It is formed by the pars posterior of the inferior frontal gyrus, by the lower ends of the precentral and postcentral gyri, and by the lower end of the anterior part of the inferior parietal lobule. The *temporal operculum* lies

FIG. 890.—A section showing the upper surface of the left temporal lobe.



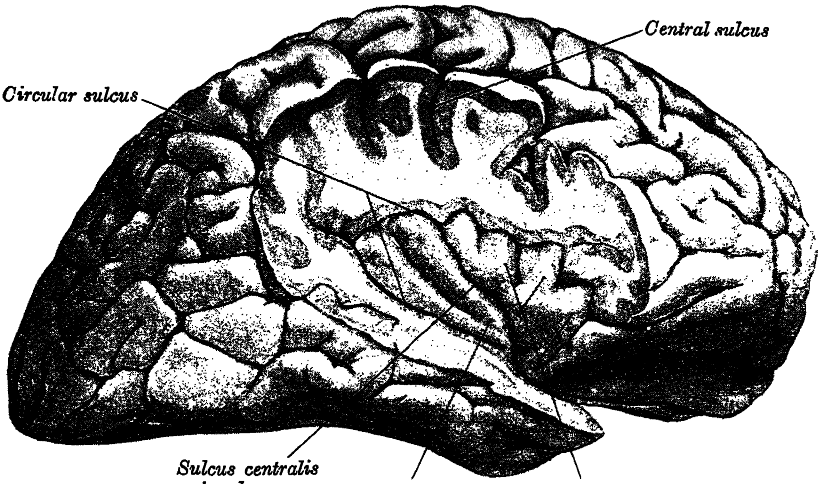
below the posterior ramus and is formed by the superior temporal gyrus and the transverse temporal gyri.

When the opercula have been removed, the insula is seen as a pyramidal eminence, the apex of which is directed towards the anterior perforated substance. In this situation the circular sulcus is deficient and the medial part of the apex is termed the *limen insulæ.* The surface of the insula is divided into a larger anterior and a smaller posterior part by the *sulcus centralis insulæ,* which runs upwards and backwards from the apex of the insula. The anterior part is divided by shallow sulci into three or four *short gyri,* while the posterior part is formed by one long gyrus, which is often divided at its upper end. The cortical grey matter of the insula is continuous with that of the various opercula round the bottom of the circular sulcus. The insula overlies, and is more or less coextensive with the claustrum and the putamen of the lentiform nucleus.

The medial surface of the cerebral hemisphere.—This surface cannot be examined until the two cerebral hemispheres have been separated from each other by the division of (1) the commissures which connect them and (2) the roof, floor, anterior and posterior walls of the third ventricle (fig. 881). The most conspicuous feature on this surface is the great commissure which is termed the *corpus callosum.* It forms a broad arched band which lies in the floor of the central part of the longitudinal fissure. The recurved, anterior end

of the corpus callosum is termed the *genu*. Below, it is continuous with the *rostrum*, which narrows rapidly as it passes backwards to become connected to the upper end of the lamina terminalis ; above, it is continuous with the *trunk*, which a ches upwards and backwards to end in a thickened, rounded extremity, termed the *splenium*. The deep surfaces of the trunk, genu and rostrum give attachment to the laminæ of the septum lucidum, which occupies the interval between them and the fornix—a curved, flattened band of fibres which lies at a lower level. Immediately in front of the lamina terminalis and almost co-extensive with it, there is a narrow, triangular field of grey matter, which is termed the *paraterminal gyrus* (paraterminal body) (p. 986). Anteriorly it is separated from the rest of the cortex by a shallow groove which is named the *posterior parolfactory sulcus*. A little in front of this groove a second, short, vertical sulcus may be present and is termed the *anterior parolfactory sulcus*. The portion of cortex which lies between these two sulci constitutes the *parolfactory area* (fig. 892).

FIG. 891.—The insula of the right side. Exposed by the removal of the opercula.



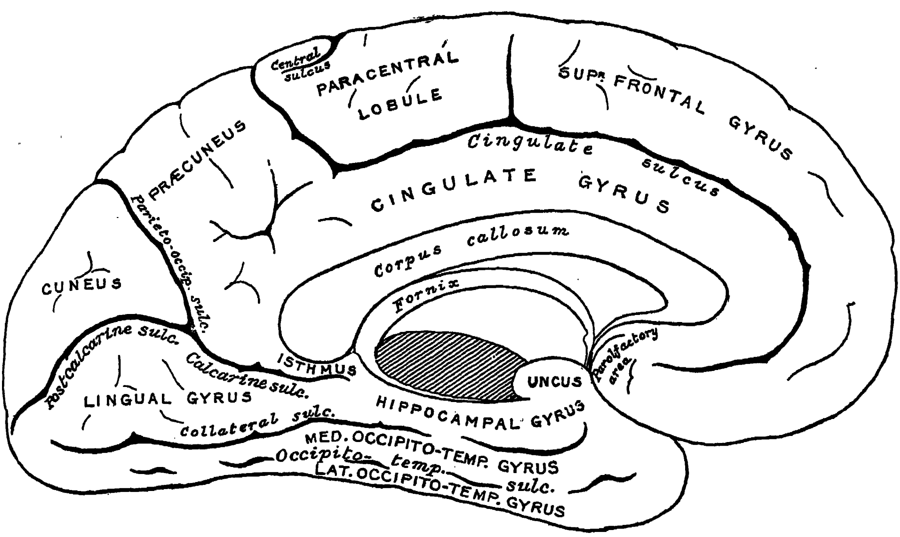
The anterior part of this surface of the hemisphere is divided into an outer and an inner zone by a curved sulcus, termed the *sulcus cinguli*. It commences below the rostrum of the corpus callosum and passes first forwards, then upwards and finally backwards, conforming to the curvature of the corpus callosum. Its posterior end turns upwards to reach the superomedial margin of the hemisphere, about 4 cm. behind the mid-point between the frontal and occipital poles, and lies behind the upper extremity of the central sulcus (fig. 892). The outer zone demarcated by the sulcus cinguli forms a part of the frontal lobe. It is subdivided into a larger anterior portion and a smaller posterior portion by a short fissure which runs upwards from the sulcus cinguli above the middle of the trunk of the corpus callosum. The larger anterior portion is the *medial frontal gyrus*, while the smaller posterior portion is termed the *paracentral lobule*. The upper end of the central sulcus usually cuts into the posterior part of the paracentral lobule and the motor cortex of the precentral gyrus is directly continuous with the cortex of the lobule. This area contains the centres which control the movements of the lower limb and perineal region of the opposite side.

The inner zone which is marked off by the sulcus cinguli constitutes the *gyrus cinguli*. Commencing below the rostrum this gyrus follows the curve of the corpus callosum, from which it is separated by the *callosal sulcus*, and it continues round the splenium on to the inferior surface of the hemisphere to become continuous with the hippocampal gyrus. It is connected with the anterior nucleus of the thalamus both by afferent and by efferent pathways.

The line of the sulcus cinguli is interrupted behind the paracentral lobule, but is partially continued by a short sulcus, of variable form, termed the *suprasplenial sulcus* (subparietal sulcus).

The posterior part of the medial surface of the hemisphere is marked by two deep sulci which converge anteriorly and meet a short distance behind the splenium of the corpus callosum. These are the parieto-occipital and the postcalcarine sulci. The *parieto-occipital sulcus* commences on the superomedial margin of the hemisphere about 5 cm. in front of the occipital pole and is directed downwards and slightly forwards to meet the postcalcarine sulcus. When the lips of the sulcus are widely separated it will be found that, although on the surface of the hemisphere the parieto-occipital and the postcalcarine sulci are apparently continuous, they are in reality separated from each other by a buried gyrus, termed the *gyrus cunei*. In addition, the walls of the sulcus show the presence of two or more vertically disposed sulci. These sulci

FIG. 892.—The medial surface of the left cerebral hemisphere.

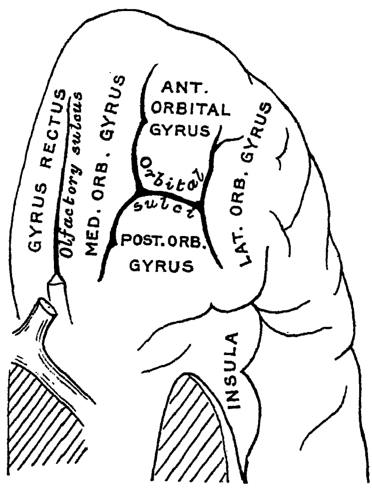


were originally exposed on the medial surface of the hemisphere, but they became buried and included in the parieto-occipital sulcus owing to the growth of the splenium of the corpus callosum (p. 975). The walls of the parieto-occipital sulcus, therefore, resemble the walls of the lateral sulcus, although the contained sulci and gyri are fewer in number and smaller in extent.

The *postcalcarine sulcus* commences in the neighbourhood of the occipital pole. Although the sulcus is usually restricted to the medial surface of the hemisphere its posterior end occasionally extends on to the lateral surface. It runs forwards a little above the inferomedial margin of the hemisphere, taking a slightly curved course with an upward convexity, and joins the parieto-occipital sulcus at an acute angle a little behind the splenium of the corpus callosum. At that point the postcalcarine sulcus is, superficially, directly continuous with the *calcarine sulcus*, but the floor of the sulcus is crossed by the buried anterior cuneolingual gyrus, which separates the two sulci from each other. The calcarine sulcus crosses the inferomedial margin and gains the inferior aspect of the hemisphere, where it cuts into the gyrus cinguli, leaving it connected to the hippocampal gyrus only by a narrow *isthmus*. The postcalcarine sulcus develops as an axial sulcus, set in the long axis of the visual cortex. The calcarine sulcus, however, is a limiting sulcus, and separates the striate, visual cortex from the cortex of the gyrus cinguli. It conforms to the definition of a true sulcus, since it produces an elevation in the medial wall of the posterior horn of the lateral ventricle (the calcar avis).

The quadrilateral area, bounded in front by the upturned end of the sulcus cinguli, behind by the parieto-occipital sulcus, above by the superomedial margin and below by the suprasplenial (subparietal) sulcus, is termed the *precuneus* and, together with the part of the paracentral lobule which lies behind the central sulcus, constitutes the medial surface of the parietal lobe.

FIG. 893.—The orbital surface of the left frontal lobe.



The wedge-shaped area bounded in front by the parieto-occipital sulcus, below by the postcalcarine sulcus and above by the superomedial margin, is termed the *cuneus*. Its surface is usually indented by one or two small irregular sulci, and forms the medial surface of the occipital lobe.

The inferior surface of the cerebral hemisphere.—This surface is subdivided into a smaller, anterior portion, which lies in front of the stem of the lateral fissure, and a larger, posterior portion, which lies behind it. The anterior portion forms the *orbital surface of the cerebral hemisphere.* It is concave from side to side and rests on the cribriform plate of the ethmoid bone and on the orbital plate of the frontal bone. An anteroposterior sulcus traverses this surface near its medial margin and, since it is hidden by the overlying olfactory bulb and tract, it is termed the *olfactory sulcus*. The medial strip of cortex which it marks off is the *gyrus rectus*. The rest of this surface is divided by an H-shaped *orbital sulcus* into four gyri. These are named the anterior, medial, posterior and lateral orbital gyri according to their positions. The last-named is continuous round the superciliary margin with the inferior frontal gyrus.

The posterior portion forms the *tentorial surface* of the hemisphere, and rests partly on the tentorium cerebelli and partly on the floor of the middle cranial fossa. It is traversed by two anteroposterior sulci, the collateral and the occipitotemporal (inferior temporal). The *collateral sulcus* commences near the occipital pole and runs forwards, roughly parallel to the calcarine sulcus, from which it is separated by the *lingual gyrus*. Anteriorly the collateral sulcus may be continued into the *rhinal sulcus*, but the two are usually separated. The *rhinal sulcus* runs forwards in the line of the collateral sulcus and separates the temporal pole from a somewhat hook-shaped elevation which lies posteromedial to it and is termed the *uncus*. This fissure marks the lateral limit of the piriform area of the cortex (p. 985).

The *occipitotemporal* (inferior temporal) *sulcus* lies roughly parallel to the collateral sulcus and on its lateral side. As a rule it does not extend as far back as the occipital pole, and it is frequently divided into two or more parts.

The *lingual gyrus* lies between the calcarine and the collateral sulci. Anteriorly it passes without interruption into the *hippocampal gyrus*, which commences at the *isthmus*, where it is directly continuous with the gyrus cinguli, and passes forwards bounded on its lateral side by the collateral and rhinal sulci. Anteriorly it becomes continuous with the uncus, and as it passes forwards its medial edge abuts on the side of the mid-brain. The *uncus* is the recurved, hook-like, anterior end of the hippocampal gyrus and forms the posterolateral boundary of the anterior perforated substance. The medial part of its hook extends laterally above its lateral part and will be described later (p. 985); its inferior surface cannot be exposed completely until the lateral and more superficial part of the hook has been removed (fig. 895). The uncus forms the bulk of the *piriform area*, which constitutes an important part of the rhinencephalon and is phylogenetically one of the oldest parts of the pallium. It is believed that the higher centres for the sense of taste are situated in the hippocampal gyrus, in the neighbourhood of the uncus.

The *medial occipitotemporal* (fusiform) *gyrus* extends from the neighbourhood of the occipital to the temporal pole. It is limited by the collateral and rhinal sulci on its medial side and by the occipitotemporal sulcus on its lateral side. The lateral part of this area forms the *lateral occipitotemporal gyrus*, which is continuous round the inferolateral margin of the hemisphere with the inferior temporal gyrus.

The Rhinencephalon

The rhinencephalon includes all those portions of the cerebrum which are concerned with the reception and conduction of olfactory impressions. In lower vertebrates the rhinencephalon consists of the olfactory lobe and the archipallium, and includes nearly the whole of the fore-brain. In man, however, the archipallium has been so much reduced by the exuberant growth of the neopallium that many of its derivatives are difficult to recognise with the naked eye. They have been relegated to the medial and inferior surfaces; some have become thinned out into a fine sheet by the growth of the corpus callosum (p. 999), while others have been overgrown and buried by the development of neighbouring neopallial areas.

The constituent parts of the rhinencephalon are: (1) the *olfactory bulb*, in which the primary olfactory neurones end and the secondary neurones begin, (2) the *olfactory tract*, which conveys the secondary olfactory neurones to (3) the *olfactory pyramid*, the *olfactory tubercle*, the *anterior perforated substance* and the *area piriformis*, which give rise to the tertiary olfactory neurones, (4) the *hippocampal formation*, in which the tertiary neurones end, (5) the *paraterminal gyrus*, (6) the *fornix*, which constitutes the efferent pathway from the hippocampal formation and the archipallium in general, and (7) the *nucleus habenulæ*. Some writers include the septum lucidum in the rhinencephalon, but until the details of its development and its morphology are more fully known, it may, perhaps, more justly be considered together with the cerebral commissures to which it owes its existence.

(1) The **olfactory bulb** (see also p. 995) is an oval, reddish-grey mass which lies above the medial edge of the orbital plate of the frontal bone and below the anterior end of the olfactory sulcus on the orbital surface of the frontal lobe. The olfactory nerves pass upwards through the cribriform plate from the olfactory region of the nasal mucous membrane and enter its inferior surface.

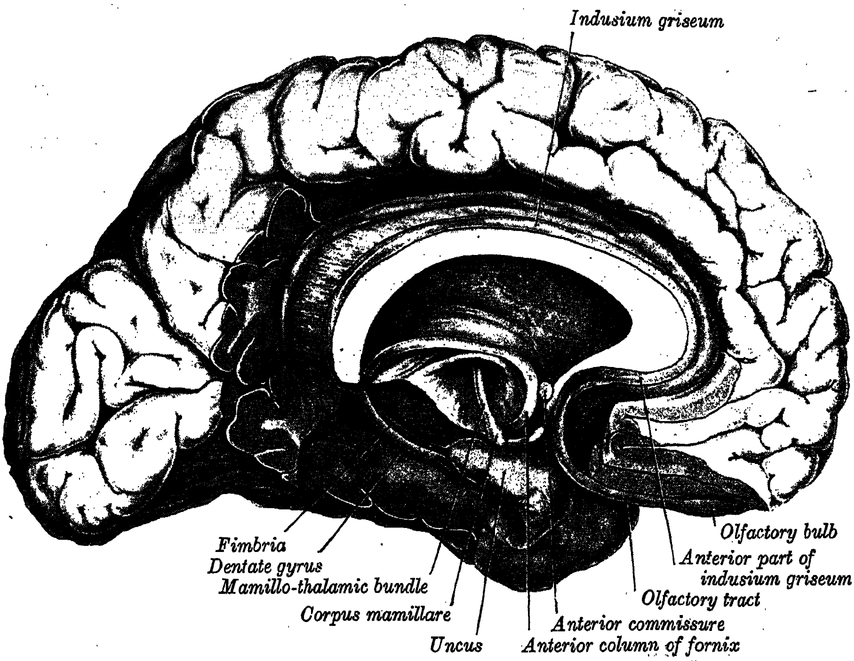
(2) The **olfactory tract** is a narrow, white band which issues from the posterior end of the olfactory bulb and passes backwards on the orbital surface of the frontal lobe, covering the olfactory sulcus. On transverse section it is triangular in outline, the apex being directed upwards. At its somewhat expanded posterior end, which is termed the *olfactory peduncle*, the tract is inserted into the cerebrum. The constituent fibres diverge from one another, forming the lateral and medial roots of the olfactory tract, and enclosing the *olfactory pyramid*. The *lateral root* passes laterally at first in the anterior part of the anterior perforated substance, where its fibres can usually be detected with the naked eye. They are associated with a narrow band of grey matter derived from the piriform area but indistinguishable from the grey matter of the anterior perforated substance. On reaching the limen insulæ (p. 980) the lateral root and its accompanying grey matter bend sharply backwards and medially in the floor of the stem of the lateral sulcus and enter the superolateral part of the uncus. The *medial root of the olfactory tract* turns medially and ascends on the medial aspect of the hemisphere in the posterior part of the parolfactory area and immediately in front of the paraterminal gyrus, which separates it from the upper end of the lamina terminalis. Like the lateral root, it is associated with a strip of grey matter. The primary connexions of the medial root in the human brain are uncertain, but it is probable that the secondary connexions pass to the indusium griseum (p. 999) on the inferior surface of the rostrum of the corpus callosum (fig. 894).

(3) (*a*) The *olfactory pyramid* is a small area of grey matter situated between the diverging roots of the olfactory tract and in front of, and in surface continuity with, the anterior perforated substance.

(*b*) The *olfactory tubercle* lies immediately posterolateral to the olfactory pyramid. Very rarely it is visible in the human brain as a small oval elevation in the anterior perforated substance.

(*c*) The **anterior perforated substance** lies on the basal surface of the cerebral hemisphere in the angle between the optic tract and the uncus. In front it is bounded by the olfactory tubercle and the roots of the olfactory tract. Medially it is continuous, above the optic tract, with the tuber cinereum and, in front of that, with the lower end of the paraterminal gyrus. Laterally it extends to the limen insulæ (p. 980). Its exposed surface is pierced by the central branches of the anterior and middle cerebral arteries and is crossed by the latter vessel. Superiorly it is continuous with the grey matter of the corpus striatum and of the claustrum, and it is separated from the anterior part of

FIG. 894.—A dissection of the left cerebral hemisphere, showing the parts of the rhinencephalon. Drawn from a specimen lent by Professor R. B. Green.



the globus pallidus of the lentiform nucleus by the anterior commissure, the ansa lenticularis and the ansa peduncularis.

(*d*) The **piriform area** includes the anterior part of the *hippocampal gyrus*, the *uncus* and the band of grey matter which reaches it along with the lateral root of the olfactory tract. When the lateral part of the uncus is removed, the inferior surface of its medial part can be examined. It is crossed about its middle by a narrow band of grey matter, continuous at its lateral end with the dentate gyrus, and termed the *tail of the dentate gyrus* (banderella of Giacomini) (fig. 895). The portion of the uncus which lies behind the tail of the dentate gyrus has been termed the *intralimbic gyrus* (hippocampus inversus, of Elliot Smith), and it is morphologically distinct from the part lying anterior to it, which has the histological characters of the piriform cortex (p. 996).

The tertiary olfactory neurones, which arise in the olfactory tubercle and pyramid and in the piriform area, proceed at once into the hippocampal formation, but they do not form any composite tract.

(4) The **hippocampal formation** is formed along the fringe of the pallium on the medial aspect of the hemisphere. It comprises (*a*) the *indusium griseum*, (*b*) the *longitudinal striæ* of the corpus callosum, (*c*) the *dentate gyrus*, and (*d*) the *hippocampus*.

The hippocampal formation is laid down in the embryo on the medial wall of the hemisphere, forming an arch immediately outside the arch of the choroidal

fissure (p. 118). The anterior or upper part of the arch is invaded by the corpus callosum, and the great size of this structure in the human brain reduces the corresponding portion of the hippocampal formation to the mere vestige which is represented by the indusium griseum on the surface of the corpus callosum (fig. 894) and the associated longitudinal striæ. The posterior or lower part of the arch is carried downwards and forwards by the growth of the temporal lobe and so is not affected by the development of the corpus callosum. The *hippocampal sulcus* develops in this part of the hippocampal formation, outside the choroidal fissure, and the strip of cortex which lies between the two forms the dentate gyrus. The cortex at the bottom of the sulcus proliferates rapidly and bulges laterally into the cavity of the inferior horn of the ventricle, constituting the hippocampus.

(*a*) The *indusium griseum* is the thin sheet of grey matter which covers the upper surface of the corpus callosum and is continuous on each side, round the bottom of the callosal sulcus, with the cortex of the gyrus cinguli. It is continuous behind with the *splenial gyrus*, a delicate layer of grey matter which is in continuity with the posterior end of the dentate gyrus (fig. 903). In front it is continued round the genu and on to the inferior surface of the rostrum of the corpus callosum, to become continuous with the parolfactory area and the paraterminal gyrus.

(*b*) The *medial* and *lateral longitudinal striæ* are two ridges which extend forwards on the upper surface of the corpus callosum. The medial stria lies close to the median plane, but the lateral stria is placed under cover of the gyrus cinguli in the floor of the callosal sulcus. They consist of longitudinally running fibres, which sweep round the genu and over the rostrum to enter the paraterminal gyrus (*vide infra*). They represent the white substance of the vestigial indusium griseum.

(*c*) The *dentate gyrus* is a narrow, crenated strip of cortex which lies on the *upper* surface of the hippocampal gyrus, under cover of the fimbria (fig. 895), from which it is separated by the fimbriodentate sulcus. The *hippocampal sulcus* intervenes between it and the hippocampal gyrus, but except at its anterior end this sulcus is not constantly present in the adult human brain. Posteriorly the dentate gyrus is prolonged on to the under-surface of the splenium of the corpus callosum, as the delicate *splenial gyrus* (fig. 903), which in turn becomes continuous with the indusium griseum. Anteriorly the dentate gyrus is continued into the notch of the uncus, and then bends sharply medially across its inferior surface (fig. 895). This transverse portion is termed the *tail of the dentate gyrus*. Unlike the rest of the gyrus it is smooth and featureless, and it becomes lost on the medial aspect of the uncus.

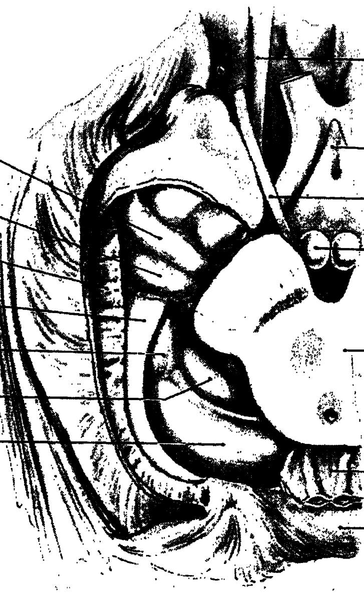
(*d*) The *hippocampus* is a curved elevation, about 5 cm. long, which extends throughout the entire length of the floor of the inferior horn of the lateral ventricle (fig. 910). Its anterior or lower extremity is enlarged and presents two or three shallow grooves separated by digit-like ridges, which give it a paw-like appearance. On this account it is termed the *pes hippocampi*. The elevation itself is usually described as being produced by the hippocampal sulcus, but Elliot Smith maintains that this is not actually the case, and that the elevation owes its presence to the rapid proliferation of the cells of the hippocampal formation in this situation. The ventricular surface of the hippocampus is covered by a layer of white fibres which constitutes the *alveus*, but the great bulk of the elevation is made up of grey matter. Posteriorly the hippocampus, like the dentate gyrus, becomes continuous with the splenial gyrus at the splenium of the corpus callosum.

(5) The *paraterminal gyrus* (subcallosal gyrus of Zuckerkandl) is the triangular area of the cortex which lies immediately in front of the lamina terminalis (fig. 881). Anteriorly it is limited by the posterior parolfactory sulcus, and superiorly it becomes continuous with the indusium griseum on the inferior surface of the rostrum of the corpus callosum. Inferiorly it is connected to the piriform area by a white band, termed the *diagonal band*, which runs laterally and backwards across the posterior part of the anterior perforated substance (fig. 876). The significance of the paraterminal gyrus in the rhinencephalon has not yet been definitely determined.

(6) The **fornix** is the efferent pathway from the cells of the hippocampal

formation, and therefore conveys olfactory fibres of the fourth neurones. The fibres of the cells of the hippocampus pass to its ventricular surface where they form a layer of white matter, termed the *alveus*. The fibres of the alveus converge on the medial border of the hippocampus to form the *fimbria*, a flattened band of white fibres which lies above the dentate gyrus and immediately below the lower part of the choroidal fissure. The disposition of the fimbria is variable. It may project above the dentate gyrus, with a free medial edge and a lateral border which merges into the alveus, or its free border may be twisted over towards the lateral side, uncovering the dentate gyrus (fig. 903). Anteriorly, the fimbria passes into the hook of the uncus (fig. 895). Traced backwards on the floor of the inferior horn of the ventricle, it ascends below the splenium and bends forwards above the thalamus, forming the *posterior column of the fornix*. The two posterior columns are closely applied to the under surface of the corpus callosum and are connected to each other by a number of transverse fibres which pass between the hippocampal formations

FIG. 895.—A dissection of the inferior surface of the brain to display the uncus, the dentate gyrus and the fimbria.



of the two hemispheres and form the *hippocampal commissure*. This commissure presents the appearance of a thin, triangular lamina. Between it and the corpus callosum a horizontal cleft (the so-called *ventricle of the fornix* or *ventricle of Verga*) is sometimes found.

Anteriorly the two posterior columns come together in the median plane and constitute the *body of the fornix*, which is really a symmetrically disposed bilateral structure. The body of the fornix lies above the tela chorioidea and the ependymal roof of the third ventricle (fig. 885) and is attached above to the under surface of the corpus callosum and, more anteriorly, to the lower borders of the laminæ of the septum lucidum. Laterally the body of the fornix overlies the medial part of the upper surface of the thalamus (p. 955) and the choroidal fissure is placed below its free, lateral edge. Through this fissure the choroid plexus in the lateral margin of the tela chorioidea thrusts its way into the body of the lateral ventricle (fig. 885).

Above the interventricular foramen the body of the fornix separates into two *anterior columns*, which bend downwards and backwards, forming the anterior boundary of the interventricular foramen and passing behind the anterior commissure. As they descend, each sinks into the anterior part of the corresponding lateral wall of the third ventricle and reaches the corpus mamillare,

in which it terminates (p. 963). Some of the fibres of the fornix system leave the column near the interventricular foramen and run backwards, as the stria habenularis (p. 961), to reach the nucleus habenulæ of the same or the opposite side. A slender bundle of fibres, named the *olfactory fasciculus*, leaves the anterior column of the fornix and descends in front of the anterior commissure to the base of the brain where it divides into two parts ; one joins the medial root of the olfactory tract ; the other joins the indusium griseum of the corpus callosum and through it reaches the hippocampal gyrus.

The fornix is the efferent pathway for the archipallium, and its fibres, relayed in the corpora mamillaria, pass to the anterior nucleus of the thalamus by the mamillothalamic tract and to the tegmentum of the brain-stem by the mamillotegmental tract (p. 963).

(7) The *nucleus habenulæ* and its afferent and efferent fibres have already been described (p. 961).

THE STRUCTURE OF THE CEREBRAL CORTEX

The nerve-cells of the cerebral cortex show a wide variation in size and shape, and in the mode of behaviour of their dendrites and axons. In all parts of the cortex they are laid down in strata, but the transition from stratum to stratum is not sharp and clear-cut, and, as a result, different observers have adopted different descriptions of the stratification. It must be remembered that many fibres reach the cortex from the underlying white matter and run, for the most part, at right angles to the surface, breaking up the cellular constituents into parallel columns. Others, however, alter direction after penetrating the cortex and, together with intracortical fibres, form two sheets —or in some situations three—which lie parallel to the surface. The most superficial layer of the cortex consists of fibres which run tangentially ; amongst them there are many neuroglial cells, the horizontal cells of Cajal and cells of Golgi, type II. In the substance of the cortex there may be two sheets of fibres parallel to those in the superficial or molecular layer. They appear in sections of the cortex as narrow bands, termed the outer and inner bands of Baillarger ; they vary in thickness in different cortical areas. In the visuosensory cortex, the outer band forms a broad strip which can readily be recognised by the naked eye and is termed the *visual stria*. It is so characteristic a feature that the visuosensory area is named the *striate area*. In many regions the inner band of Baillarger is completely obscured and it may be entirely absent.

The depth of the cortex is always greater on the exposed surfaces of the gyri than it is in the depths of the sulci, and varies from 4 mm. in the precentral gyrus to 1·25 mm. in the occipital lobe.

In the human fœtus at the sixth month three layers can be made out in the cortex, viz.—a superficial or *molecular layer*, consisting mainly of tangential fibres, an intermediate or *granular layer* of cells, and a deep or *infragranular layer* of cells. This three-layered arrangement is typical of the archipallium, and is found in the adult human brain in the hippocampal formation. The granular layer constitutes the receiving mechanism, and the infragranular layer the transmitting mechanism. In the later months of fœtal life the neopallium becomes further differentiated. The advent of additional association and commissural afferent fibres leads to a thickening and differentiation of the granular layer. It gives rise to an *outer granular layer*, which merges into a *pyramidal layer* of cells. Deep to the pyramidal layer there is a fourth layer, consisting of small stellate or granular cells, termed the *inner granular layer*. At the same time, the infragranular layer thickens and differentiates into a deeper, *polymorphous layer*, in which small fusiform cells predominate, and a more superficial *ganglionic layer*, in which the cells are more densely packed and giant pyramidal or stellate cells may be found. The growth of the infragranular layer is contemporaneous with the increase in number of the corticofugal and outgoing commissural fibres.

The adult cortex may therefore be considered as subdivided into six different

strata, which differ in the depths of the various layers and in the number and character of their constituent cells in different parts of the hemisphere.

(1) The *molecular layer* consists of a stratum of medullated fibres (plexus of Exner) that run parallel to the surface. It varies in its depth and in the density of the fibres which it contains. In its deeper part it contains the apical dendrites of the pyramidal cells, the axons of the cells of Martinotti, and fibres derived from the subjacent white substance of the hemisphere. In addition, it contains (*a*) small, irregularly-shaped nerve-cells with short axons and a variable number of dendrites, and (*b*) fusiform cells, lying with their long axes parallel to the surface.

(2) The *outer granular layer* is of approximately the same depth as the first layer. The cells are small, averaging 8μ to 10μ in diameter, having disproportionately large nuclei.

(3) The *pyramidal layer* shows a gradual increase in the size of its constituent cells as they are traced inwards from the surface. Its outer part presents few variations throughout the whole extent of the cortex. The constituent cells are typical pyramidal cells, and are more widely separated from one another than the cells in the second layer.

The inner part of the pyramidal layer shows considerable variations in different areas. Its cells have an average diameter of $25\text{-}30\mu$, and they show a marked increase in the number and size of the contained Nissl's granules. The deepest part of this layer is traversed by the outer band of Baillarger.

(4) The *granular layer* forms a narrower stratum, made up of small stellate cells, which vary in their number and in their density in different cortical areas. They average $8\text{-}10\mu$ in diameter; their axons are short and terminate in the same layer or in the pyramidal layer.

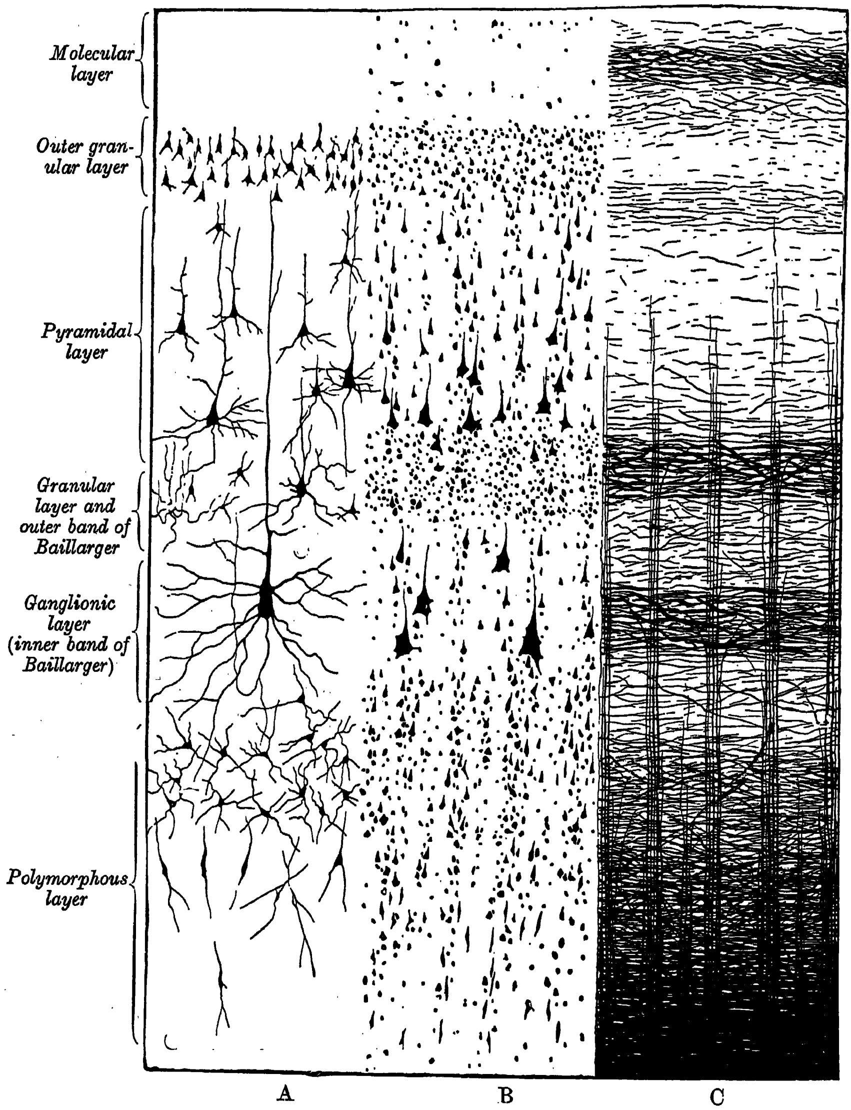
(5) The *ganglionic layer* shows striking differences in different cortical areas. In the motor area the characteristic cells of this stratum are the giant pyramidal cells of Betz, which vary from 35μ by 17μ to 60μ by 25μ (Bevan Lewis), but many smaller cells of varying form are found in the same layer. In other parts of the cortex large cells may be entirely absent, or the large pyramidal cells may be replaced by large stellate cells (visuosensory area, p. 993). In certain situations the inner band of Baillarger is a recognisable feature in this stratum.

(6) The *polymorphous layer* is composed mainly of spindle-shaped or fusiform cells. These are subdivided into columns by sheets of radial fibres which traverse the polymorphous layer on their way to and from the more superficial layers of the cortex. Most of the axons of the polymorphous cells pass into the subjacent white matter, while their dendrites pass towards the surface but do not reach the molecular layer. The cells of Martinotti are found in this layer, as well as in the superposed layers. They are pyramidal in shape, but their bases are directed towards the surface. Their dendrites are short and their axons pass into the molecular layer, where they form an extensive horizontal arborisation. The cells of Martinotti are most numerous in the piriform area. The incoming and outgoing radial fibres vary in density with the fibre wealth of the individual area. They include the efferent axons of the cells of the ganglionic and of the polymorphous layers and the afferent projection, association and commissural fibres together with the axons of the cells of Martinotti. In addition, numerous horizontal fibres intersect the radial fibres. They are derived from (*a*) the branching axons of Golgi cells, type II; (*b*) collaterals of the axons of the large pyramidal and polymorphous cells and of the cells of Martinotti; and (*c*) the collaterals of the incoming fibres.

The cells which constitute the grey matter of the cortex show great variation in their size and shape and in the mode of behaviour of their axons and dendrites. The pyramidal cells, the cells of Martinotti, and the Golgi cells, type II, constitute a very large proportion of the total. (*a*) The pyramidal cells, irrespective of their size and their position, send basal dendrites into the surrounding area, and apical dendrites towards the surface, where they terminate by arborising in the molecular layer. Their axons arise from the base of the cell or from one of the basal dendrites and run centrally into the deeper layers or into the white matter. They give off collaterals, many of which ascend to the more superficial strata. (*b*) The cells of Martinotti may be pyramidal,

ovoid or fusiform in shape. They are characterised by the course of their axons, which ascend to reach the molecular layer and there divide into tangential branches. These cells are found in all the layers of the cortex, but are largest and most numerous in the polymorphous layer. Many of the afferent fibres

FIG. 896.—A diagram showing the layers of cells and fibres in the grey matter of the cortex of the human cerebral hemisphere, according to the histological methods of Golgi, Nissl and Weigert. After Brodmann; from Luciani's *Physiology* (Macmillan & Co., Ltd.).



A. Stained by the method of Golgi. B. by that of Nissl. C. by that of Weigert.

to the cortex terminate by arborising with the dendrites of the cells of Martinotti, and the impulses which they convey are carried by the axons of the same cells to the molecular layer where they establish contact with the dendrites of the pyramidal cells. (*c*) The Golgi cells, type II, vary in size and in position. They are characterised by the shortness of their axons, which never leave the grey substance although they may pass from one layer to another. They establish connexions between cells in the same layer and also between cells in different layers. It is believed that the small cells which form the granular

layers come into synaptic association with the incoming itinerant (projection), commissural and association fibres. They therefore act as the receptors and distributors of afferent impressions to the cortex.

The researches of Bevan Lewis, Bolton, Campbell, Brodmann, Economo and Elliot Smith into cortical structure, the embryological investigations of Flechsig and the experimental work of Sherrington and many others, have shown that the cortex of the cerebral hemispheres can be mapped out into areas which differ from one another in the details of their structure, in the period of the myelination of their efferent fibres and in their functional significance. Economo has mapped out more than 100 different areas as the result of a histological survey of the cortex, and certain of these areas are so important from the functional standpoint that, although the structure of the cortex in general has already been described, further reference must be made to these local variations.

Of the five fundamental types which Economo recognises in the cortical structure of the neopallium, the agranular and the granulous varieties are the most distinctive, as they represent the extremes of the variations which occur. (1) The *agranular type* is marked by the almost complete absence of the granular cells, which are replaced by pyramidal elements. This type of cortex is found in the motor and psychomotor areas. (2) The *granulous type* is marked by the depth and density of the granular layers, by the reduction in the number of the pyramidal elements and by the diminution in the total depth of the cortex. It is found in the strictly sensory areas, viz. the somesthetic, the visuosensory or striate, and the auditosensory areas.*

The **precentral area** includes the precentral gyrus and the posterior portions of the superior, middle and inferior frontal gyri (Campbell). The whole of this area is characterised by the almost complete absence of the granular layer. It is subdivisible into posterior and anterior parts. The posterior part does not reach so far forward as the precentral sulcus, and it is characterised by the giant pyramidal cells of Betz, which are found in the ganglionic layer. These large cells are more numerous in the upper part of the area, and their axons form the great cerebrospinal (pyramidal) motor tract. The whole area shows a great wealth of intracortical fibres, and the molecular layer is unusually dense. Experimental evidence has shown that this area controls the volitional movements of the opposite half of the body, and that the upper end of the precentral gyrus and the adjoining portion of the paracentral lobule control the movements of the lower limb. Below, and in the order given, are found the centres for the trunk, the upper limb, mouth, lips, tongue and larynx.† The largest Betz cells (60μ by 25μ) are found in the lower limb area, and the smallest (35μ by 17μ) in the areas associated with the face and tongue.

Emphasis must be laid on the fact that it is movements and not individual muscles which are represented in the cortex, and in this connexion it may be mentioned that whereas the estimated number of motor cells in the anterior grey column of the spinal cord is between 250,000 and 300,000, the number of Betz cells is estimated at rather less than one-tenth of that figure. It is clear, therefore, that each Betz cell must control the activities of approximately ten anterior column cells.

The anterior part of the precentral area resembles the posterior part in every respect, except for the absence of the giant cells of Betz. The two areas stand in very intimate relationship to each other from the functional standpoint, but the precise relationship is by no means easy to define. Some idea may be conveyed by the statement that, whereas the posterior part of the precentral area is responsible for individual movements, the anterior part is responsible for the control of the orderly series of movements which constitute acts. The young child experiences no difficulty in carrying out individual movements, but he has to learn by repeated efforts how to carry out even the simplest acts such as putting on or buttoning a coat. Every act is a complicated series of movements which must be carried out in their proper order and to their proper extent, and forms a sort of pattern which is capable of registration.

* C. von Economo, *The Cytoarchitectonics of the Human Cerebral Cortex*. Oxford University Press. 1929.

† Immediately in front of the upper limb area, there is an area for the control of the movements of the head and conjugate movements of the eyes.

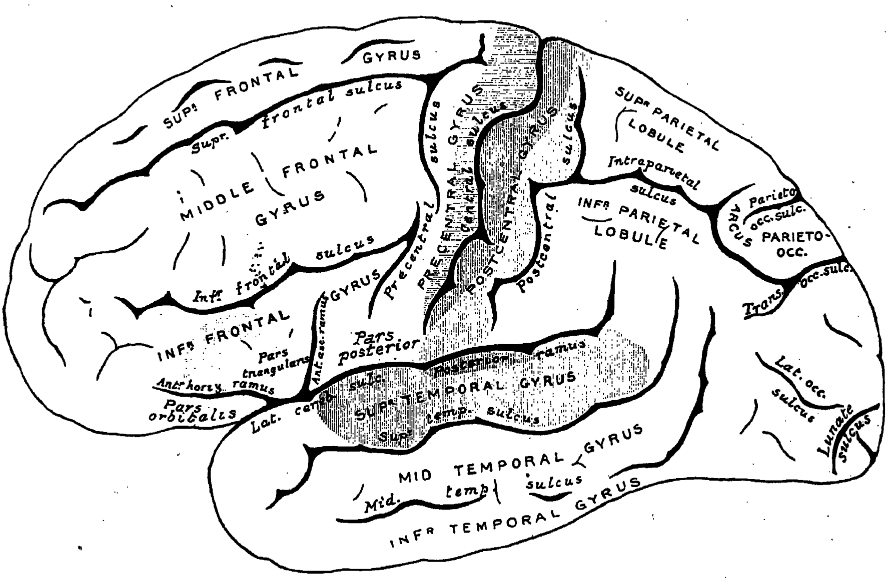
All skilled acts must be learned, and their mastery means that their pattern has been impressed on the cortical cells in the anterior part of the precentral area.

The condition of *apraxia*, which is normal in the young child, is met with in later life as a pathological condition, indicating a cortical or subcortical lesion in the neighbourhood of the area under consideration. Such patients are able to carry out individual movements without difficulty, but they cannot perform a simple act such as lighting a pipe.

These two areas are frequently referred to as the *motor* and the *psychomotor areas*.

The frontal area, which is one of the important association areas of the brain, extends from the psychomotor region to the frontal pole and includes those portions of the frontal lobe which appear on the medial and orbital

FIG. 897.—The areas of localisation on the lateral surface of the left cerebral hemisphere.



Motor area in red. Area of general sensations in blue. Auditory area in green. Visual area in yellow The psychic portions are in lighter tints.

surfaces. It has been subdivided into frontal and prefrontal areas, but in the present state of knowledge of the functions of this wide area little advantage is to be derived from this subdivision.

Histologically this area differs from the adjoining precentral area in the reappearance of the granular layer and in the dimunition of the number of intracortical fibres. The ganglionic layer shows a corresponding reduction in the size and number of its constituent cells. Further, the polymorphous layer is considerably reduced in depth.

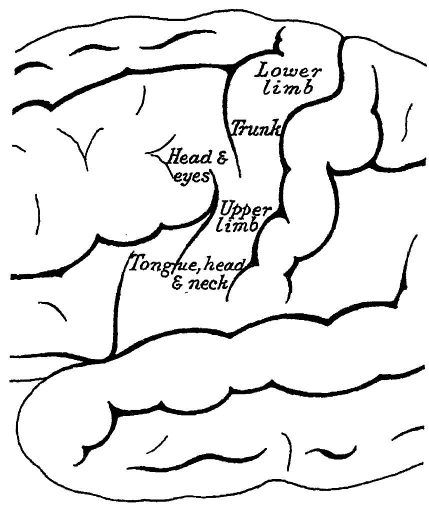
The functions of the frontal area are difficult to analyse and define and, because of the absence of gross symptoms following injury and disease, it was long known as the *silent area* of the brain.

In view of the fact that the frontal area is connected to the somesthetic, visual, auditory and other sensory areas by association fibres and to the thalamus by itinerant fibres, it has been urged that this silent area of the brain analyses the afferent impressions which come to it into those which arouse feelings of pleasure and well-being and those which are unpleasant or distasteful. It determines the personal reaction of the individual according to the alterations in feeling tone, modified or intensified, as the case may be, by the effects of past experience, and it is therefore responsible, in a general way, for behaviour and conduct. It is also concerned with attention and the

power of concentration. This view receives considerable support from clinical evidence. Lesions of the frontal area, whether cortical or subcortical, commonly result in some alterations in the character of the patient—alterations which may be so slight as to be recognised only by his intimates, or may be so gross as to be obvious to any observer.

The **postcentral area** occupies all but the lowest part of the postcentral gyrus and is continued over the supero-medial border into the adjoining part of the paracentral lobule. It is divisible into anterior and posterior parts, which show certain differences in structure and play related though distinct parts in the reception and appreciation of somesthetic impressions. The anterior part is characterised by the number of characteristic cells in the pyramidal layer, by the density of the granular layers and by the breadth of the outer band of Baillarger. The largest cells are found in the ganglionic layer, but they are smaller than the giant cells of Betz and they occur discretely instead of in small clusters. In the posterior part the large pyramidal cells are reduced both in size and number, and the inner granular layer, though rather wider, is not so densely packed with cells.

FIG. 898.—The different parts of the motor area of cerebral cortex.



The postcentral area receives afferent fibres from the thalamus which represent the relays of the somesthetic fibres of the spinal cord and brain-stem. Both exteroceptive and proprioceptive sensations stream into the postcentral area and receive their full recognition in consciousness. The anterior part of the area may be regarded as the actual receiving area for all varieties of somesthetic sensibility, and the posterior part of the area relates them with past experience and so renders possible their evaluation and discrimination. It is therefore responsible for the tactile element in sterognosis, i.e. the recognition of texture, in its widest sense, without the aid of vision.

The **visual area** of the cortex includes the greater part of the occipital lobe, and is subdivided into the *visuosensory* or *striate area* and the *visuopsychic area.*

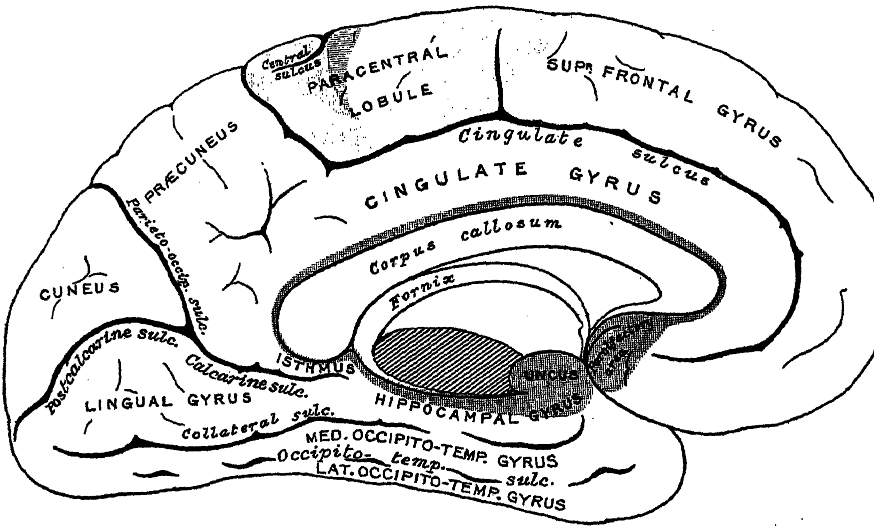
The **visuosensory area** occupies the walls of the postcalcarine sulcus and extends on to the surface of the cuneus above and the lingual gyrus below. Posteriorly it may not extend beyond the occipital pole ; when it does extend on to the lateral surface it is limited by the lunate sulcus in front, and by the polar sulci above and below. Anteriorly the visuosensory area occupies the floor of the calcarine sulcus and the adjoining part of the lingual gyrus. The whole of this area is characterised by the conspicuous *visual stria*, which is quite obvious to the naked eye, and by the shallowness of the cortex. Over the anterior part of the area the stria is broad and a darker strip lies on its inner side. In the polar region and on the lateral aspect of the hemisphere, the stria becomes narrower and the accompanying dark band disappears. This change in the character of the stria corresponds to a difference in the retinal relationships of the striate area (*vide infra*). Histologically the visuosensory area presents four distinguishing features. (1) The deeper part of the pyramidal layer contains a few large stellate cells which almost entirely replace the large pyramidal cells normally found in this position. They are horizontally placed and are regarded by Cajal as specific visual cells. (2) The outer band of Baillarger is broad and conspicuous, constituting the *visual stria* (Gennari). (3) The ganglionic layer contains the solitary cells of Meynert. These are pyramidal in shape, measuring about 30μ, and are arranged in a single, widely spaced, row. (4) The outer and, more especially, the inner granular layers are very conspicuous and the small cells which they contain are closely packed together. The

enormous number of these diminutive elements is a characteristic feature and will be appreciated more fully when it is stated that the striate area contains approximately one-tenth of the total number of the cells in the cerebral cortex. The inner granular layer appears to be duplicated.

The visuosensory area is the cortical receiving centre for visual impressions. Colour, size, form, motion, illumination and transparency are all recognised and appreciated in this area. The recognition and identification of objects, however, requires the co-operation of the adjoining visuopsychic area.

Owing to the partial decussation of the fibres of the optic nerve (p. 967), the visuosensory cortex of one hemisphere receives its impressions from the temporal part of the retina of the same side and from the nasal part of the retina of the opposite side. The upper lip of the postcalcarine sulcus is associated with the upper quadrants indicated, and the lower lip with the lower quadrants (fig. 883). The area for the macula occupies the polar region, extending backwards to the

Fig. 899.—The areas of localisation on the medial surface of the left cerebral hemisphere.



Motor area in red. Area of general sensations in blue. Visual area in yellow. Olfactory area in purple. The psychic portions are in lighter tints.

lunate, upwards to the superior polar and downwards to the inferior polar sulcus. Elliot Smith * estimates that the macular cortical area is as extensive as the whole peripheral retinal area.

The visuopsychic area surrounds the visuosensory area except in its anterior part. In this situation it is restricted to the adjoining lingual and medial occipitotemporal (fusiform) gyri (fig. 899), and does not extend above the calcarine sulcus. The cortex of this area is rather shallower than the cortex of the visuosensory area and is characterised by the breadth of the outer band of Baillarger, which is just as broad as it is in the visuosensory area, though its edges are not quite so sharp. Histologically this area is marked by the number and size of the cells in the deeper part of the pyramidal layer, and by the almost complete absence of large cells from the ganglionic layer.

This area is responsible for the correlation of visual impressions and their association with past experience, leading to the identification and recognition of objects. The determination of distance and the proper orientation of objects in space is effected by the visuopsychic area.

The parietal area is situated between the visual area behind and the post-central area in front, and constitutes one of the large association areas of the hemisphere. Histologically this area is characterised by the absence of large

* *Journal of Anatomy*, vol. lxiv. 1930.

elements from the ganglionic and pyramidal layers and by the breadth of the inner band of Baillarger. The outer and inner granular layers are well developed.

Owing to its position relative to the visual, somesthetic and auditory areas, the parietal area is advantageously situated for the purpose of correlating items of information obtained from these sensory centres. It is through the activities of this part of the brain that accurate knowledge of objects and their significance is obtained and retained. The connexion of the middle part of the inferior parietal lobule (angular gyrus) with the pulvinar (p. 958) has suggested the possibility that it is responsible for the visual element in stereognosis, i.e. it enables tactile impressions to be associated with former visual impressions so that the size and shape of an object can be determined by touch alone and unaided by vision. The associations between the three great sensory areas are so many and complicated that they have defied complete analysis. Reading, for example, demands the association of visual and auditory impressions if it is to convey any intelligent meaning, and the playing of musical instruments requires the association of tactile and auditory impressions.

The **auditory area** of the cortex is associated with the superior temporal gyrus and the transverse temporal gyri. Like the visual area, it can be subdivided into a sensory and a psychic part, the latter adjoining and to a large extent surrounding the former.

The *auditosensory area* occupies the anterior transverse temporal gyrus, which lies in the floor of the posterior ramus of the lateral sulcus (fig. 890), and extends for a short distance and over a limited area on to the lateral surface of the superior temporal gyrus. Histologically this area of the cortex is characterised by the arrangement of its cells in columns set at right angles to the surface, by the thickness of the outer and inner granular layers, and by the great number of fibres which are found throughout its whole depth.

Afferent fibres reach the auditosensory area from the medial geniculate body. After traversing the posterior limb of the internal capsule, these fibres sweep below the posterior part of the lentiform nucleus and form the *auditory radiation*.

In the auditosensory area auditory impressions reach consciousness as sounds, and their loudness, quality and pitch can be differentiated. The direction from which the sound comes and its character, whether rhythmical or arrhythmical, are also determined by this part of the cortex. The significance and the source of the sound, however, require the adjoining auditopsychic area for their elucidation.

The *auditopsychic area* occupies the whole of the remainder of the superior temporal gyrus. Histologically it resembles the auditosensory cortex, but the granular layers are shallower and the pyramidal layer is deeper. In this area auditory impressions receive their interpretation and can be differentiated from one another, as regards their probable source and origin, by association with past experience.

The large *temporal area*, which includes the whole of the middle and inferior temporal gyri, is very similar to the auditopsychic area in its cortical structure. Lesions of this area are accompanied by a more or less marked disturbance of the auditopsychic functions, but it must be confessed that our knowledge of the functional significance of this large part of the cortex is very meagre.

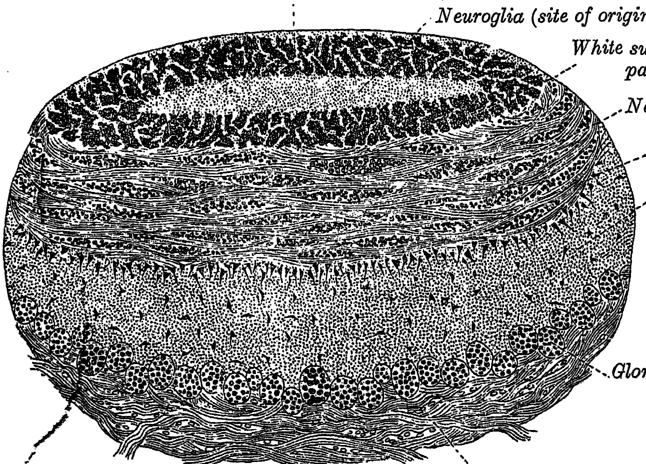
The **insular area** comprises the whole of the insula. Histologically two types of cortex are recognisable. The structure of the cortex of the long gyri show many points of resemblance to that of the temporal area, whereas the cortex of the short gyri is more closely allied to the cortex of the hippocampal gyrus. The functions of this cortical area are unknown.

The structure of the rhinencephalon.—The laminated arrangement which is characteristic of the cerebral cortex is considerably modified in the rhinencephalon. It is found in a different form in the olfactory bulb, but it is almost unrecognisable in the indusium griseum of the corpus callosum, and it is archaic in type in the dentate gyrus and the hippocampus.

The olfactory bulb.—In many animals the olfactory bulb contains a cavity which communicates with the lateral ventricle through a hollow olfactory tract. In man the walls of the bulb become thickened, the ventral wall more so than the dorsal wall, and the cavity is obliterated, and its site is occupied

by a mass of neuroglia. A section through the bulb demonstrates the presence of stratification, and the following layers can be identified: (1) a layer of *olfactory nerve-fibres*.—These fibres are the nonmedullated axons of the olfactory cells in the nasal mucosa, and they reach the bulb by passing through the cribriform plate of the ethmoid bone. They cover the inferior surface of the bulb and penetrate it to end by forming tuft-like synapses with the dendrites of its mitral cells. (2) *Glomerular layer*.—This layer contains numerous spheroidal bodies, termed glomeruli, formed by the branching and interlacement of one or more olfactory nerve-fibres with the descending dendrite of a mitral cell. (3) The *molecular layer*.—This layer consists of a matrix of neuroglia, in which the large, mitral cells form a densely packed stratum. These cells are pyramidal in shape, and from the basal part of each there arises a stout dendrite which descends into the glomerular layer and ends in one of the glomeruli. In addition, the mitral cells give off dendrites which terminate in the molecular layer. Their axons arise from the apices of the cells and proceed upwards into the next layer where they turn backwards to gain the olfactory tract. (4) *Nerve-fibre layer*.—This layer consists chiefly of the medullated axons of the mitral

FIG. 900.—A coronal section through the olfactory bulb. (Schwalbe.)



cells; a certain number of afferent fibres are also present, passing to end in the molecular layer. Most of these are derived from the olfactory bulb of the opposite side and cross the median plane in the anterior commissure. (5) *Neuroglial layer*.—A flattened ovoid mass of neuroglia occupies the site of the original cavity of the bulb, and is covered on its dorsal or upper aspect by a thin layer of scattered grey and white matter.

The regions of the olfactory pyramid and tubercle and, in fact, the whole of the anterior perforated substance, are irregularly broken up by bands of fibres and blood-vessels so that their structure shows no constant or regular arrangement. They are poorly developed areas in the human brain.

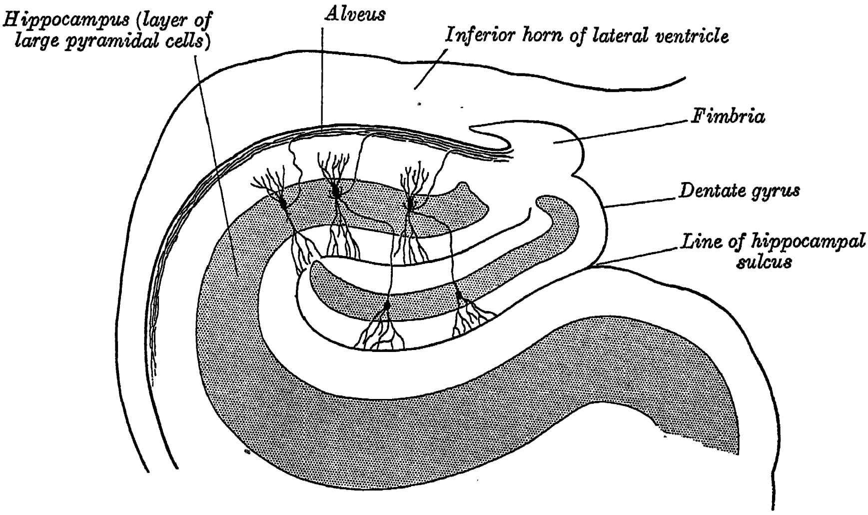
The **piriform area** shows a definitely stratified arrangement, which differs in certain respects from the cortex of the neopallium. The molecular layer is unusually deep and contains a large number of tangential fibres. The adjoining layer contains two varieties of cells, each arranged in clumps or cell-nests. The larger cells average 28μ in diameter, are stellate in form and poor in Nissl's bodies. The smaller cells, though pyramidal in form, are smaller than the most superficial of the pyramidal cells in the neopallium. The third layer is deep, and the cells which it contains are chiefly pyramidal in shape, and their apices point obliquely to the surface. These cells are especially rich in basal dendrites. The fourth layer is much shallower and contains remarkably few cells, some resembling those of the third layer, while others are small and stellate in shape. The fifth layer is thicker and contains cells which resemble

the pyramidal elements of the third layer. A sixth, deeper, layer of fusiform cells is also present.

This area receives the olfactory neurones of the second order and gives rise to those of the third order, which proceed to the hippocampal formation.

The hippocampus is more primitive in its structure than the piriform area and consists essentially of three layers. It represents a portion of the cortex which has been rolled into the inferior horn of the lateral ventricle and its superficial cortical layer lies in relation to the hippocampal sulcus anteriorly and to the dentate gyrus posteriorly. The superficial or *molecular layer* is unusually deep and is densely packed with tangential fibres. It is usually described as consisting of a superficial part, named the stratum moleculare, and a deep part, named the stratum lacunosum. This is succeeded by a thick layer of *large pyramidal cells,* which give off long apical dendrites into the molecular layer. Their basal axons run centrally through the succeeding polymorphous

FIG. 901.—Diagram of a coronal section through the hippocampus. After Villiger.



layer and pass into the subjacent white matter, which here constitutes the *alveus*. The numerous apical dendrites which are crowded together in the superficial part of this pyramidal layer have given rise to its subdivision into a *stratum radiatum* (or dendritic part) and a *stratum lucidum* (or cellular part). The third layer contains *polymorphous cells* some of which are cells of Martinotti. Here, as elsewhere, they send their axons into the molecular layer. Others are aberrant pyramidal cells, while others, again, send their axons into the pyramidal layer, where they end by arborising around the pyramidal cells.

The white fibres of the alveus cover the polymorphous layer and separate it from the ependyma on the free, ventricular surface of the hippocampus (fig. 901).

The *dentate gyrus* also consists of three layers, viz. a molecular layer, a granular layer and a polymorphous layer. The *molecular stratum* is well developed, and receives the dendrites of the cells of the second layer. These are, for the most part, small granule-cells, but a number of large pyramidal cells are found amongst them. The axones of these cells traverse the third, or polymorphous layer, and then enter the adjoining molecular layer of the hippocampus (fig. 901), through which they pass to reach the pyramidal layer, where they terminate by arborising round the large pyramidal cells. These axons are characterised by small varicosities which are placed on them as they run in the pyramidal layer. The third, or polymorphous layer, contains many Golgi cells, type II, and many cells which send their axons through the adjoining layers of the hippocampus to reach the alveus.

The curious interlocking which occurs in the region of the hippocampus and the dentate gyrus (fig. 901) requires explanation. As the hippocampal form-

ation becomes defined, the cells which ultimately form the dentate gyrus lie on the fringe of the pallium and immediately adjoin the choroidal fissure. The constituent cells of the formation proliferate rapidly, and as a result they form an elevation which protrudes into the cavity of the ventricle. The cells which form the intermediate layer of the hippocampus are directly continuous with the granular layer of the neopallium on the one hand and with the intermediate layer of the dentate gyrus on the other. As growth proceeds, however, the continuity with the cells of the dentate gyrus is broken, and the latter, as seen on transverse section (fig. 901), forms an isolated strip which has all the appearance of being inserted, secondarily, into the infolded cortex of the hippocampus. As a result, the molecular layer of the dentate gyrus is in direct contact with the corresponding layer of the hippocampus. The hippocampal sulcus, when it is present, intervenes between them. The polymorphous layer of the dentate gyrus is also in contact with the molecular layer of the hippocampus, which has extended over its dorsal, or superior, aspect (fig. 901).

MYELINATION

Flechsig has shown that the white fibres of the cerebral hemisphere do not all acquire their myelin sheaths at the same period. The process commences in the eighth month of intra-uterine life and involves first the afferent fibres passing to the somesthetic area in the postcentral gyrus and the afferent fibres to the hippocampal formation. While the nerve-fibres in these areas are receiving their medullary sheaths, the process commences in the afferent fibres leading to the visuosensory and the auditosensory cortical areas. Myelination of the great, efferent cerebrospinal pathway is not completed until the middle of the third month after birth. As it is generally believed that nerve-fibres are incapable of conducting impulses until they have acquired their myelin sheaths, it follows that all the movements which the infant carries out in the first two months of life are reflex movements, depending on the spinal cord and the brain stem. Subsequently the fibres of the psychic portions of the motor and somesthetic areas and of the visuo- and auditopsychic areas acquire their sheaths, and it is not until this process is well established that the child is able to benefit by past experience or is able to perform voluntary acts as distinct from reflex movements. Last of all, the fibres of the large association areas (frontal, parietal and temporal) become myelinated and in these areas the process may not be finally completed until the eighteenth year or even later. Complete mental development is not possible until these areas can be utilised, and it would appear that there is considerable individual variation in the age period at which the myelination of the fibres of the association areas is completed. (See also p. 1022.)

THE CEREBRAL COMMISSURES AND THE SEPTUM LUCIDUM

At the end of the second month of development the two cerebral hemispheres, whose large cavities communicate with the anterior part of the third ventricle, are connected to each other by the anterior wall of the third ventricle (*lamina terminalis*) and by the anterior parts of its roof and floor. The roof at this stage is formed of a single layer of ependyma only and remains so throughout life. It therefore does not offer any pathway to fibres which, arising on one side of the cerebrum, are seeking to reach the other. The floor, on the other hand, is actively concerned with the development of the optic chiasma, the tuber cinereum and the hypophysis cerebri. It is therefore to the undeveloped region of the lamina terminalis that the commissural fibres travel in order to gain the opposite side. The earliest commissural fibres to develop are associated, as might be expected, with the rhinencephalon, and they constitute two distinct bundles. The *anterior commissure* occupies the lower part of the lamina terminalis and consists of fibres which connect the olfactory bulbs, the olfactory pyramids and the piriform areas. The second commissural bundle

connects the two fornix systems, and through them the hippocampal formations, and naturally traverses the upper part of the lamina. It is termed the *hippocampal commissure.* The development of these commissures leads to local thickenings of the lamina terminalis, and when the commissural fibres of the neopallium develop, they follow the paths which have already been prepared. A few fibres from the temporal area join the anterior commissure, but the bulk of the neopallial fibres accumulate on the dorsal aspect of the hippocampal commissure and develop into the *corpus callosum.* In the fifth month the corpus callosum forms a curved band which projects forwards from the upper part of the lamina terminalis and is in close relationship at its posterior end with the upper and posterior part of the hippocampal commissure. The cortical area which occupies the angular interval below the projecting anterior end of the corpus callosum is named the *paraterminal gyrus* and it extends downwards in front of the whole length of the lamina terminalis. With the subsequent formation of the rostrum, which recurves downwards and backwards, the connexion between the upper part of the paraterminal gyrus and the rest of the area becomes severed. The included portion is thinned out and stretched by the general growth of the corpus callosum and the fornix and becomes the *septum lucidum* * (septum pellucidum). While these changes, which have not yet been observed in their entirety, are occurring at the anterior end of the corpus callosum, its posterior end increases rapidly in bulk and together with the hippocampal commissure is carried backwards above the epithelial roof of the third ventricle. As it passes backwards, it lies above the line of the choroidal fissure and invades the upper part of the hippocampal formation, which consequently becomes thinned out on its surface to form the indusium griseum. Owing to this backward growth, the corpus callosum and the hippocampal commissure form an additional and secondary roof for the third ventricle. It must be remembered, however, that the narrow interval between the commissures above and the epithelial roof of the third ventricle below is really an extra-cerebral space and that the transverse fissure, which lies below the splenium of the corpus callosum and leads into this interval, is not a cerebral fissure in the true sense of the words.

In its backward growth the corpus callosum does not extend so far as the lower part of the choroidal fissure, and it therefore makes no inroad into that part of the hippocampal formation which is associated with the inferior horn of the ventricle and which gives rise to the dentate gyrus and the hippocampus. In the light of the development of the corpus callosum, the continuity of the hippocampus and the dentate gyrus with the indusium griseum (p. 985) becomes intelligible.

The **corpus callosum** is the great transverse commissure which connects the cerebral hemispheres and roofs in the lateral ventricles. A good conception of its position and size is obtained by examining a median sagittal section of the brain (fig. 884). It forms an arched structure about 10 cm. in length, its anterior end being about 4 cm. from the frontal poles and its posterior end about 6 cm. from the occipital poles of the hemispheres.

The *genu*, which forms the anterior end, is bent downwards and backwards in front of the septum lucidum and, diminishing rapidly in thickness, is prolonged backwards to the upper end of the lamina terminalis as the *rostrum.* The *trunk* arches backwards with an upward convexity and terminates posteriorly in the *splenium*, which is the thickest part of the corpus callosum. A sagittal section of the splenium shows that the posterior end of the corpus callosum is bent forwards acutely, the upper and lower parts being applied closely to each other.

The upper surface of the *trunk* of the corpus callosum, which is 2·5 cm. wide, is covered by a thin layer of grey substance, termed the *indusium griseum.* This grey covering extends round the genu to the inferior surface of the rostrum, and in it are imbedded two fine longitudinal bundles of fibres on each side, which are termed the medial and lateral longitudinal striæ (p. 986).

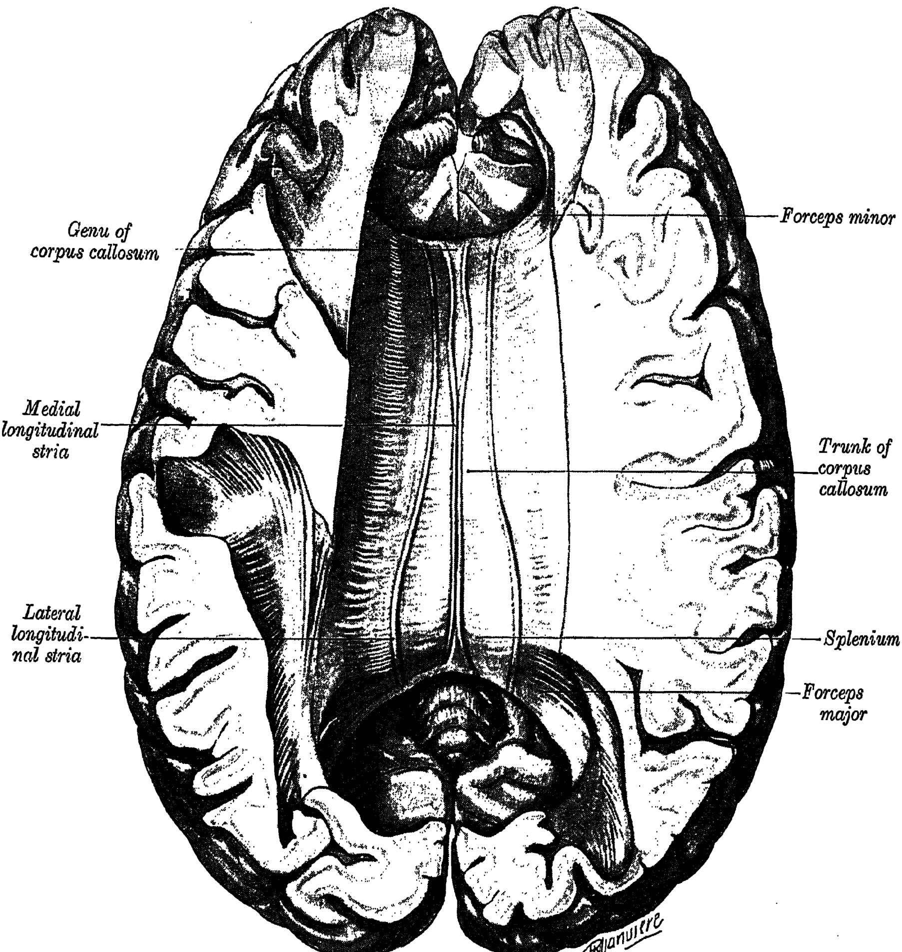
In the median plane the trunk of the corpus callosum forms the floor of the longitudinal fissure, and is related to the anterior cerebral vessels and to the lower border of the falx cerebri, which may come into actual contact with it

* A somewhat different view of the origin of the septum lucidum is given by J. Maclaren Thompson, *Journal of Anatomy*, vol. lxvii.

posteriorly. On each side of the median plane the trunk is overlapped by the gyrus cinguli, from which it is separated by the slit-like callosal sulcus.

The inferior surface of the trunk is concave in its long axis and convex from side to side. In the median plane, it gives attachment to the septum lucidum anteriorly, and the extent of this attachment depends on the length of the septum (fig. 884). Posteriorly it is fused with the body of the fornix and the hippocampal commissure. On each side of the median plane, the inferior surface of the trunk forms the roof of the lateral ventricle (fig. 904) and is covered with the ventricular ependyma.

FIG. 902.—The corpus callosum. Exposed from above.



The *genu* is continuous above with the trunk and below with the rostrum. Its anterior surface, which is in relation to the anterior cerebral vessels, is covered with the indusium griseum and the longitudinal striæ. Its posterior surface gives attachment to the septum lucidum in the median plane, and on each side it forms the anterior wall of the anterior horn of the lateral ventricle.

The *rostrum* connects the genu to the upper end of the lamina terminalis. In the median plane its superior surface gives attachment to the septum lucidum and, on each side, forms the narrow floor of the anterior horn of the lateral ventricle (fig. 916). On the inferior surface of the rostrum the indusium griseum and the longitudinal striæ are carried backwards to the upper end of the paraterminal gyrus.

The *splenium* overhangs the posterior ends of the thalami, the pineal body and the tectum of the mid-brain. It is, however, separated from them by a number of structures. On each side of the median plane the posterior column

(crus) of the fornix and the splenial gyrus (fasciola cinerea) (fig. 903) curve upwards to reach the splenium. The posterior column of the fornix continues forwards on the under surface of the trunk, but the splenial gyrus passes round the splenium, rapidly tapering off and fading away into the indusium griseum. In the median plane, the tela chorioidea passes forwards below the splenium through the transverse fissure and the internal cerebral veins emerge from between its two layers and unite to form the great cerebral vein. Superiorly the splenium is covered with the indusium griseum and is related to the falx cerebri and the inferior sagittal sinus in the median plane, and to the gyrus cinguli on each side. Posteriorly the splenium is related to the free margin of the tentorium cerebelli, the great cerebral vein and the commencement of the straight sinus.

The fibres of the corpus callosum radiate into the white matter of the hemisphere on each side and pass to the various parts of the cerebral cortex.

FIG. 903.—A dissection of a coronal section of the brain to display the splenium of the corpus callosum from in front.

The posterior portions of the thalami have been removed. Observe that the arrangement of the fimbria relative to the dentate gyrus was different on the two sides of this specimen.

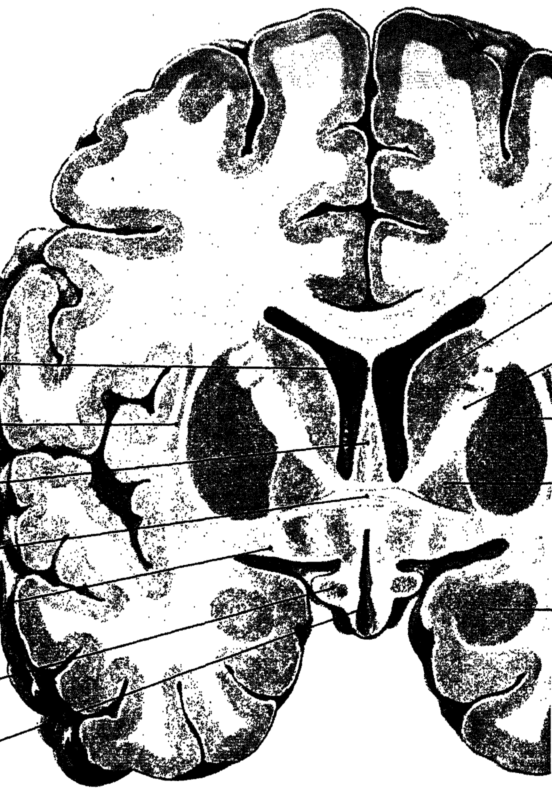
The fibres of the rostrum pass laterally below the anterior horns of the lateral ventricles, and connect the orbital surfaces of the two frontal lobes. The fibres of the genu curve forwards and connect the lateral and medial surfaces of the two frontal lobes, constituting the *forceps minor* (forceps anterior). The fibres of the trunk pass laterally and intersect the itinerant fibres of the corona radiata (fig. 873). They connect wide cortical areas of the two hemispheres to one another. Those fibres of the body and of the splenium which together form the roof and lateral wall of the posterior horn, and the lateral wall of the inferior horn of the ventricle constitute the *tapetum* (p. 1004). The remaining fibres of the splenium curve backwards and medially into the occipital lobes and form the *forceps major* (forceps posterior). This large bundle of fibres bulges into the upper part of the medial wall of the posterior horn of the ventricle and forms a curved elevation which is termed the bulb of the posterior cornu.

The **anterior commissure** is a bundle of white fibres which crosses the median plane in front of the columns of the fornix in the anterior wall of the third ventricle (fig. 881). On sagittal section it is oval in shape, its long diameter being vertical and measuring about 5 mm. Its constituent fibre bundles are twisted like the strands of a rope, and they curve backwards and laterally, forming a deep groove on the inferior aspect of the anterior part of the corpus striatum

(fig. 904). Many of the fibres belong to the rhinencephalon and connect the olfactory bulbs and pyramids and the piriform areas. Others belong to the neopallium and can be traced into the temporal lobes, where they spread out like the frayed end of a rope so that their precise connexions are difficult to determine.

The **hippocampal commissure** forms a thin sheet of transverse fibres which connects the medial edges of the posterior columns of the fornix and is closely applied to the under surface of the posterior part of the trunk of the corpus callosum. Its constituent fibres are derived from the pyramidal cells of the hippocampus and traverse the alveus and the fimbria in order to reach the posterior column of the fornix. Having crossed the median plane in the commissure, they retrace their course on the opposite side and terminate in the

Fig. 904.—A coronal section passing through the brain just behind the optic chiasma and exposing the anterior commissure as it crosses the median plane.



molecular layer of the hippocampus. This commissure therefore functions as the pallial commissure of the rhinencephalon.

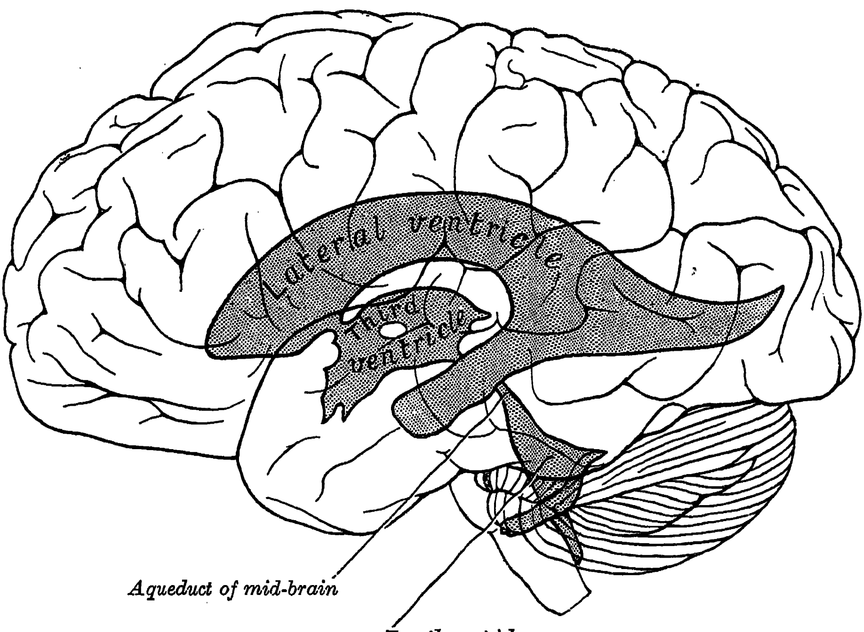
The **septum lucidum** (septum pellucidum) is a thin vertical partition, consisting of two laminæ, separated throughout a greater or lesser part of their extent by a narrow interval, termed the *cavity of the septum lucidum,* which does not communicate with the ventricles of the brain. It is triangular in form, with its base in front and its apex behind. It is attached above to the inferior surface of the trunk of the corpus callosum; below and behind, to the anterior part of the fornix; below and in front, to the upper surface of the rostrum of the corpus callosum. The lateral surface of each lamina takes part in the formation of the medial wall of the anterior horn and body of the lateral ventricle, and is therefore covered with ependyma.

The laminæ contain both grey and white matter, but they are so thin that the arrangement of their constituents does not afford much help in determining their phylogenetic history. The development of the septum lucidum is referred to on p. 999.

THE INTERIOR OF THE HEMISPHERES

The lateral ventricles (figs. 907-910).—The two lateral ventricles are irregular cavities situated in the lower and medial parts of the cerebral hemispheres, one on each side of the median plane. They are almost completely separated from each other by a median vertical partition, termed the *septum lucidum*, but they communicate with the third ventricle and indirectly with each other through the *interventricular foramen* (p. 969). They are lined with ciliated epithelium (*ependyma*), and contain cerebrospinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a *central part* and three *cornua* or *horns* (anterior, posterior and inferior) (figs. 907, 908).

FIG. 905.—A scheme showing the relations of the ventricles to the surface of the brain.



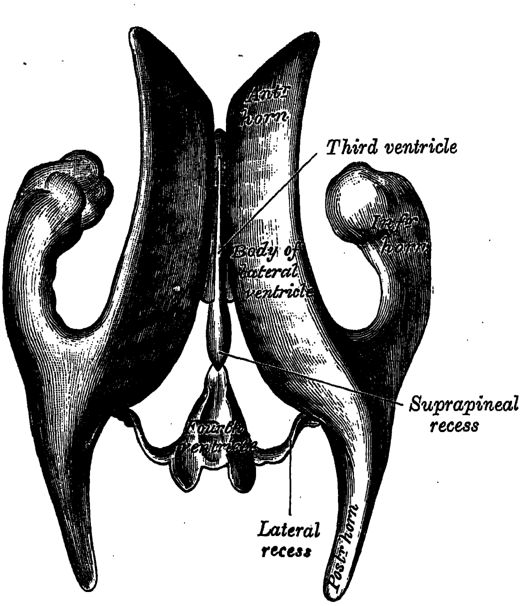
The **central part** (fig. 907) of the lateral ventricle extends from the interventricular foramen to the splenium of the corpus callosum. It is an irregularly curved cavity, triangular on transverse section, with a roof, a floor, and a medial wall. The roof is formed by the under surface of the corpus callosum ; the floor, which is slightly concave upwards and medially, by the following parts, named in their order of position from the lateral to the medial side : the caudate nucleus of the corpus striatum, the stria semicircularis (stria terminalis) and the thalamostriate vein (vena terminalis), the lateral portion of the upper surface of the thalamus, the choroid plexus, and the lateral part of the fornix. The caudate nucleus becomes rapidly narrower as it is traced backwards in the floor, and its long axis is directed laterally as well as posteriorly. The stria semicircularis, a small bundle of white fibres (p. 1014), and the thalamostriate vein occupy a narrow groove which follows the medial border of the caudate nucleus and separates it from the lateral margin of the upper surface of the thalamus. The latter may be almost entirely hidden by the vascular fringe of the choroid plexus, which invaginates the ependyma into the cavity through the slit-like interval between the lateral margin of the fornix and the upper surface of the thalamus. This ependymal invagination constitutes the choroidal fissure. The body of the fornix becomes wider as it is traced backwards, and its thin, lateral margin lies parallel with the groove for the stria semicircularis.

The medial wall is formed by the posterior part of the septum lucidum. Posteriorly, where the septum lucidum ends, the roof and the floor meet one another on the medial wall.

The **anterior cornu** (fig. 907) passes forwards, laterally and slightly downwards, into the frontal lobe, curving round the large swelling caused by the head or anterior end of the caudate nucleus. In a coronal section it appears as a triangular slit below the anterior part of the corpus callosum, and it is bounded anteriorly by the posterior surface of the genu of the corpus callosum. The greater part of the floor is formed by the rounded head of the caudate nucleus, but, in its medial portion, a small part is formed by the upper surface of the rostrum of the corpus callosum (fig. 916).

The **posterior cornu** curves backwards and medially into the occipital lobe. Its roof and lateral wall are formed by fibres of the tapetum of the corpus callosum, which separate them from the optic radiation (p. 1010). The splenial fibres which constitute the forceps major pass medial to the posterior cornu as they sweep backwards into the occipital lobe. In this part of their course they produce a rounded ridge in the upper part of the medial wall, which is named the *bulb* of the posterior cornu. Below the bulb, a second elevation may be identified on the medial wall. It receives the fanciful name of the *calcar avis*, and it corresponds to the infolded cortex of the calcarine sulcus (fig. 908). Posteriorly the lateral and medial walls meet each other.

Fig. 906.—A drawing of a cast of the ventricular cavities. Superior aspect. (Retzius.)



The **inferior cornu** (fig. 910), the largest of the three, traverses the temporal lobe, forming in its course a curve round the posterior end of the thalamus. It passes at first backwards, laterally, and downwards, and then curves forwards to within 2·5 cm. of the apex of the temporal lobe, its position being fairly well indicated on the surface of the brain by the superior temporal sulcus. Its roof is formed chiefly by the inferior surface of the tapetum of the corpus callosum, but the tail of the caudate nucleus and the stria semicircularis (stria terminalis) also extend forwards in the roof, at the extremity of which they end in a mass of grey matter, named the *amygdaloid nucleus*. Its floor presents the following parts : the choroid plexus, the fimbria hippocampi, the hippocampus and the collateral eminence. The choroid plexus is a vascular fringe which covers the upper surface of the fimbria and the hippocampus. It invaginates the ependymal medial wall of the inferior cornu and so forms the lower part of the choroidal fissure.

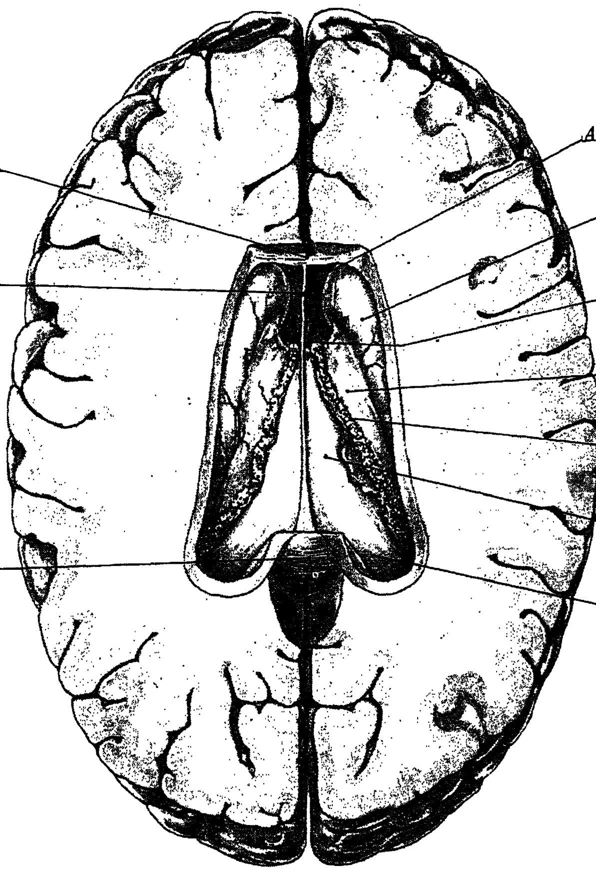
The fimbria and the hippocampus have already been considered (pp. 986 and 987), and a full description of the choroid plexus will be found on p. 1014.

The *collateral eminence* (fig. 910) is an elongated swelling lying lateral to and parallel with the hippocampus. It corresponds with the middle part of the collateral sulcus, and its size depends on the depth and direction of this sulcus. It is continuous behind with a flattened triangular area, named the *trigonum collaterale,* situated between the posterior and inferior cornua.

The white matter of the hemispheres.—If the upper parts of the hemisphere be sliced off about 1·25 cm. above the corpus callosum, the central white matter of the hemisphere is seen as an oval area surrounded by a narrow convoluted margin of grey matter, and studded with red dots (puncta vasculosa)

produced by the escape of blood from divided blood-vessels. If the hemispheres be sliced off at the level of the corpus callosum, the white matter of that structure will be seen in continuity with the white matter of the hemisphere on each side. The white matter consists of medullated fibres, of varying size, supported by neuroglia. These fibres may be divided, according to their course and connexions, into three systems: (1) The commissural fibres connect corresponding areas in the two hemispheres to each other. (2) The association fibres connect different cortical areas of the same hemisphere to one another;

FIG. 907.—The central parts and the anterior cornua of the lateral ventricles. Exposed from above.



some of them are collateral branches of the itinerant (projection) and commissural fibres, but the majority are the axons of independent cells. (3) The itinerant (projection) fibres connect the cerebral cortex with the brain-stem and the spinal cord.

(1) The **commissural fibres** have already been considered (p. 998).

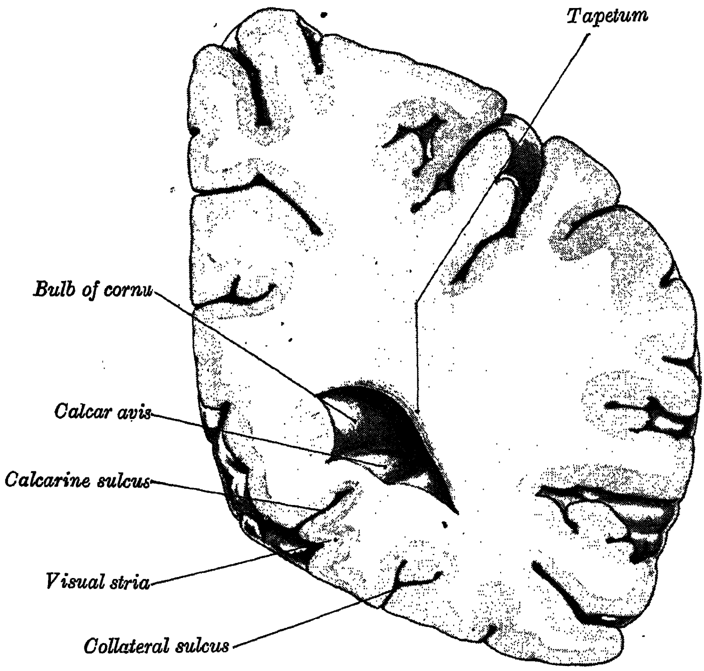
(2) The **association fibres**, which are all homolateral, are of two kinds: (*a*) short association fibres, connecting adjacent gyri to one another; (*b*) long association fibres, connecting more widely separated gyri to one another.

The *short association fibres* may be intracortical or they may lie immediately beneath the cortex and connect adjacent gyri, some merely passing from one wall of a sulcus to the other.

The *long association fibres* group themselves, somewhat indistinctly, into bundles, which can be dissected in the formalin-hardened brain after the cortex and the subjacent short association fibres have been removed. The fibres in each fasciculus show considerable variation in length, and the longest are always situated in the deepest part of the bundle. The following fasciculi can

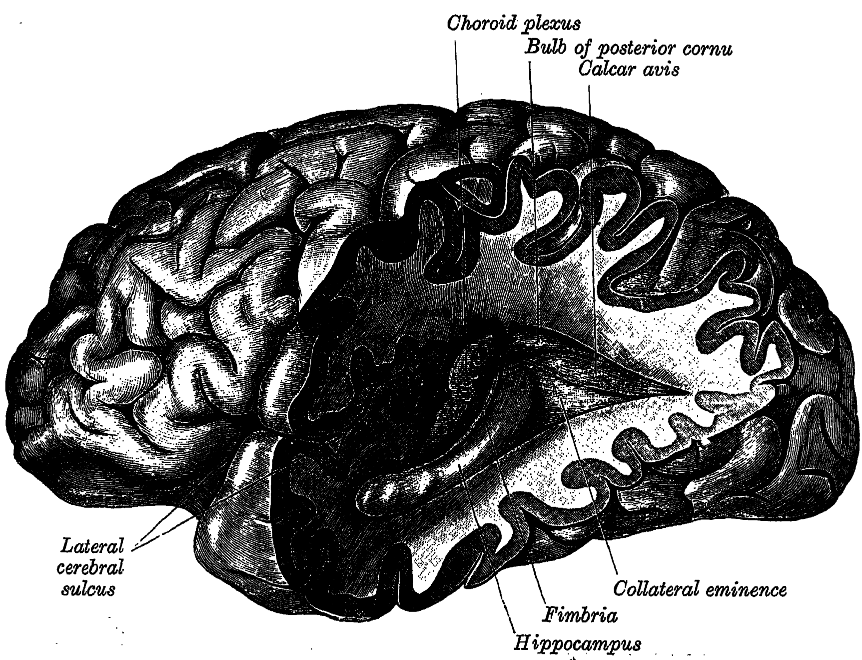
be distinguished : (*a*) the uncinate fasciculus ; (*b*) the cingulum ; (*c*) the superior longitudinal fasciculus ; (*d*) the inferior longitudinal fasciculus ; (*e*) the fronto-occipital fasciculus.

Fig. 908.—A coronal section through the posterior cornu of the left lateral ventricle. Anterior aspect.



(*a*) The *uncinate fasciculus* connects the gyri on the orbital surface of the frontal lobe with the anterior part of the temporal lobe. The fibres follow a

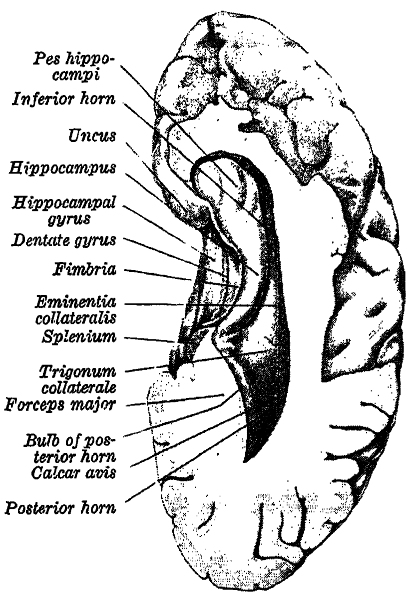
Fig. 909.—The posterior and inferior horns of the left lateral ventricle. Exposed from the side.



sharply curved course and cross the floor of the stem of the lateral sulcus. They are related to the antero-inferior part of the insular area.

(*b*) The *cingulum* is a long, curved bundle which commences on the medial surface of the hemisphere below the rostrum of the corpus callosum. It lies within the gyrus cinguli and so follows the curve of that gyrus. Inferiorly it enters the hippocampal gyrus and spreads out so as to reach the adjoining parts of the temporal lobe.

Fig. 910.—The posterior and inferior horns of the right lateral ventricle. Exposed from above.

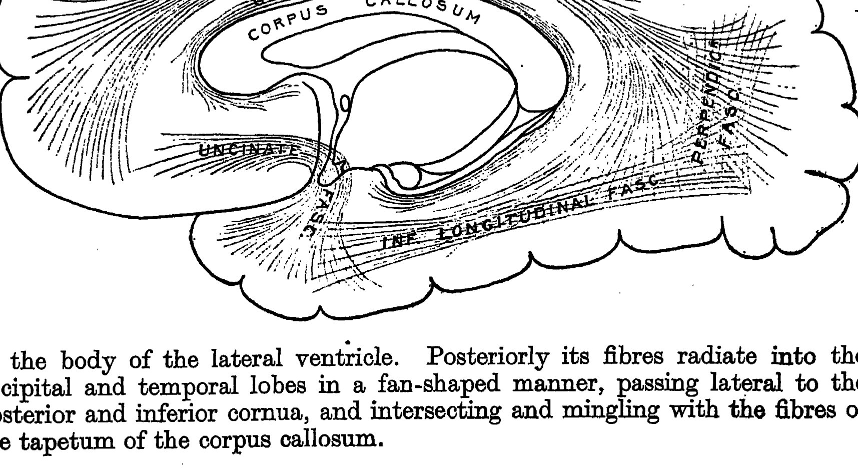


(*c*) The *superior longitudinal fasciculus* is the largest of all the association bundles. It commences in the anterior part of the frontal region and arches backwards above the insular area and lateral to the base of the corona radiata (p. 1009). After giving off a number of fibres to the occipital cortex, it curves downwards and forwards behind the insular area and spreads out into the temporal lobe.

(*d*) The *inferior longitudinal fasciculus* commences near the occipital pole and its fibres are derived from the whole extent of the occipital cortex. They sweep forwards, separated from the posterior horn of the lateral ventricle by the fibres of the optic radiation and the commissural fibres of the tapetum, and after being crossed by the superior longitudinal fasciculus, are distributed throughout the temporal lobe.

(*e*) The *fronto-occipital fasciculus* commences at the frontal pole and passes backwards on a deeper plane than the superior longitudinal fasciculus and separated from it by the base of the corona radiata (p. 1009). It associates itself with the lateral border of the caudate nucleus, and is therefore closely related

Fig. 911.—A diagram showing the principal system of association fibres in the cerebrum.



to the body of the lateral ventricle. Posteriorly its fibres radiate into the occipital and temporal lobes in a fan-shaped manner, passing lateral to the posterior and inferior cornua, and intersecting and mingling with the fibres of the tapetum of the corpus callosum.

Fig. 912.—A dissection showing some of the long association bundles of the right cerebral hemisphere.

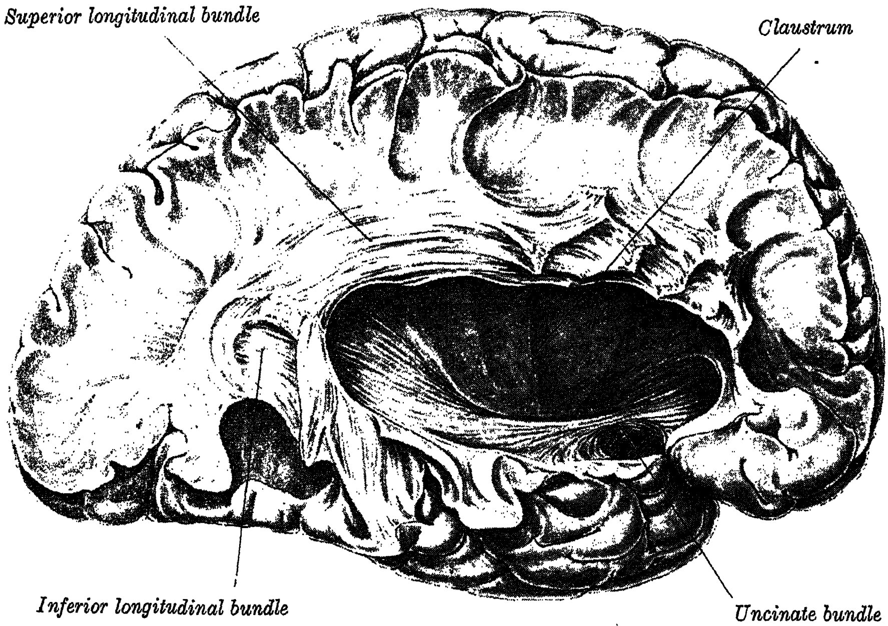


Fig. 913.—A dissection showing the course of the cerebrospinal fibres. (E. B. Jamieson.)

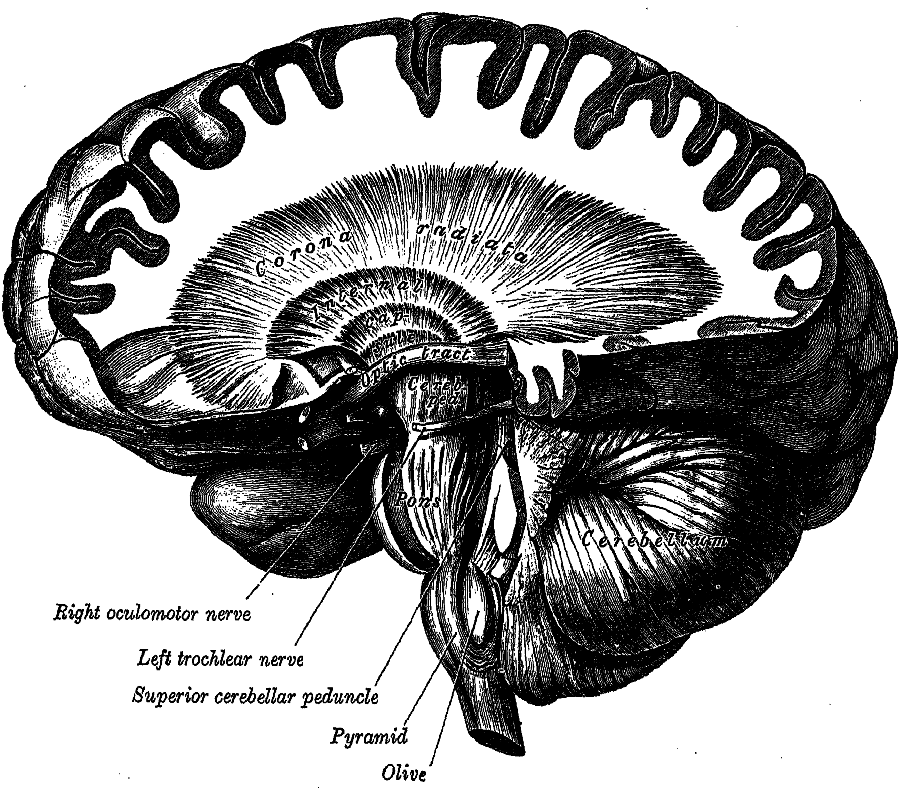
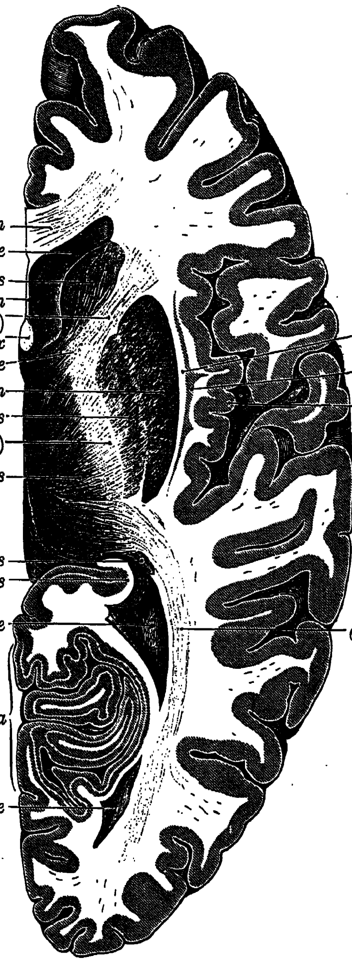


(3) The **itinerant fibres** (projection fibres) connect the cerebral cortex with the lower parts of the brain (including the diencephalon) and the spinal cord, and include both corticofugal and corticopetal fibres.

The *itinerant fibres of the archipallium* form the *fornix*, which has been considered elsewhere (p. 986).

The *itinerant fibres of the neopallium* converge from all directions on the corpus striatum (fig. 914). For the most part they lie deep to the association fibres, and they intersect the commissural fibres of the corpus callosum and the

FIG. 914.—A horizontal section through the right cerebral hemisphere. Superior aspect.



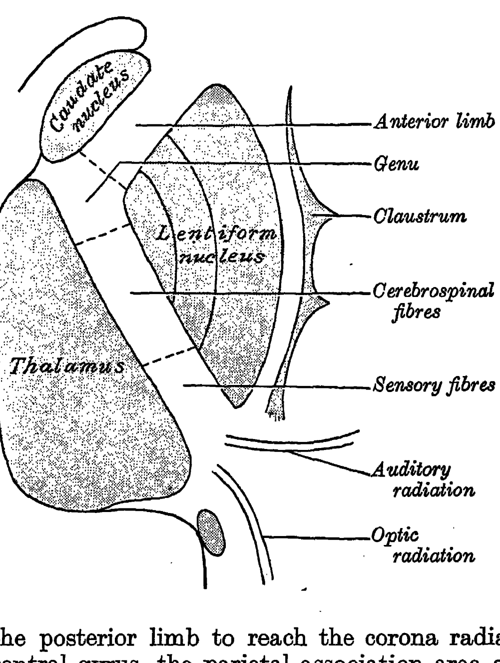
anterior commissure. As they approach the periphery of the corpus striatum, they emerge from this intersection and form the *corona radiata*. The medial aspect of the corona radiata is separated from the lateral ventricle by the fronto-occipital fasciculus, and its lateral aspect is covered by the superior longitudinal fasciculus. Below, the corona radiata is directly continuous with the internal capsule, a thick, curved band of white matter which comprises all the itinerant fibres of the neopallium, and which cuts into the corpus striatum, dividing it almost completely into two parts, viz. the lentiform and the caudate nuclei.

A transverse, horizontal section through the cerebral hemisphere shows the **internal capsule** as a broad band of white fibres, bent with an outward concavity, which accommodates itself to the convex medial surface of the lentiform nucleus (fig. 914). It can therefore be divided into an *anterior limb* (frontal

part), a *genu*, a *posterior limb* (occipital part) and a *retrolentiform part*. The anterior limb is interposed between the lentiform nucleus on the lateral side and the head of the caudate nucleus on the medial side. The posterior limb has the thalamus on its medial side and the lentiform nucleus on its lateral side. The fibres of the internal capsule continue to converge as they pass downwards, and at the same time the frontal fibres tend to pass backwards and medially, while the occipital fibres pass forwards and laterally. At the lower limit of the lentiform nucleus, they are crossed by the optic tract and enter the mid-brain. The corticofugal fibres enter the base of the cerebral peduncle, where the frontal fibres are placed to the medial side and the occipital fibres to the lateral side. The corticopetal fibres ascend from the tegmentum.

The *anterior limb* of the internal capsule contains: (1) *frontopontine fibres*, which arise in the cortex of the frontal area and are relayed in the nuclei pontis to the cerebellar hemisphere of the opposite side; (2) *thalamocortical fibres*, which arise, for the most part, in the medial nucleus of the thalamus and proceed to the frontal area.

Fig. 915.—Scheme showing the different parts of the internal capsule.



The *genu, posterior limb* and *retrolentiform part* contain: (1) the *great motor pathway*, which arises from the Betz cells of the precentral area. These fibres occupy the genu and rather more than the anterior half of the posterior limb. Experimental work has shown that the fibres are grouped in a definite manner in the internal capsule. The eyes, head, mouth, tongue and larynx are represented in the genu and adjoining part of the posterior limb; posterior to these are the fibres which represent the neck, upper limb, trunk and lower limb, in that order.

(2) *Thalamocortical fibres*, which arise in the lateral nucleus of the thalamus and traverse the posterior limb to reach the corona radiata and, subsequently, the postcentral gyrus, the parietal association area and the lips of the lateral sulcus. Many of these fibres are intermingled with the motor fibres, but others occupy a more posterior position.

(3) *Temporopontine fibres*, which arise in the cortex of the temporal lobe and are relayed in the nuclei pontis to the opposite side of the cerebellum.

(4) *Fibres of the auditory radiation*, which arise in the medial geniculate body and traverse the posterior part of the internal capsule. They sweep laterally and forwards, below and behind the lentiform nucleus, to gain the auditosensory area.

(5) *Fibres of the optic radiation*, which arise in the lateral geniculate body and sweep backwards through the retrolentiform part of the internal capsule, to reach the visuosensory area. In their course they are intimately related to the posterior horn of the ventricle and are only separated from it by the tapetum (fig. 914). Some of the fibres of the optic radiation are corticofugal and are destined for the superior corpus quadrigeminum and, possibly, the pulvinar (p. 958).

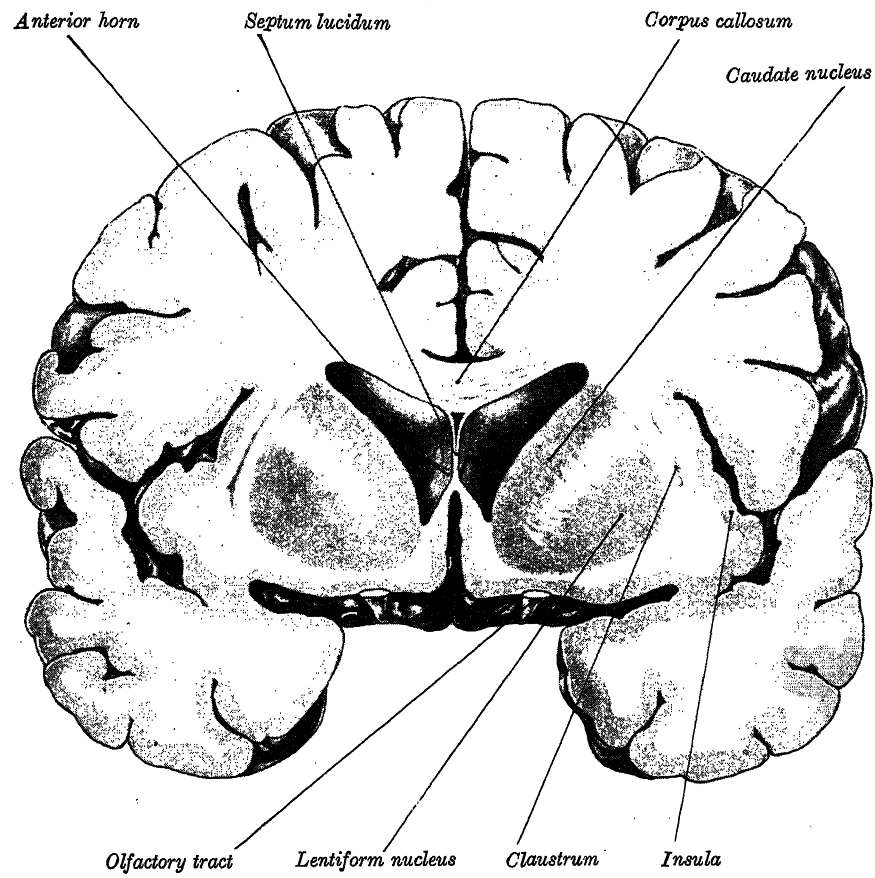
(6) *Corticothalamic fibres*, which arise chiefly in the temporal and occipital areas and pass to the lateral nucleus of the thalamus.

THE BASAL NUCLEI

The **basal nuclei** (basal ganglia) include those subcortical masses of grey matter which are found within the cerebral hemisphere. They comprise the corpus striatum, incompletely subdivided into the lentiform and the caudate nuclei, the amygdaloid nucleus and the claustrum.

The **corpus striatum** is a mass of grey matter which develops in the ventral part of the primitive hemisphere in the area immediately adjoining the interventricular foramen. It is therefore not far distant from that part of the lateral wall of the diencephalon which gives rise to the thalamus. At first the

FIG. 916.—A coronal section through the anterior horns of the lateral ventricles.



corpus striatum is separated from the thalamus by a deep groove on the surface of the brain, but as the two masses enlarge, the groove is filled out. The thalamus and the corpus striatum therefore come into close contact with each other. When the itinerant fibres (projection fibres) develop (p. 121) they cut into the corpus striatum and, save in its most anterior part, separate it into a lateral part, the lentiform nucleus, and a medial part, the caudate nucleus. The cleft so formed passes through the corpus striatum obliquely so that the itinerant fibres of the internal capsule separate the lentiform nucleus completely from the thalamus.

The **caudate nucleus** is an arcuate mass of grey matter, which has already been seen in the floor of the anterior horn and body of the lateral ventricle and in the roof of the inferior horn. Its massive, rounded *head* projects into the cavity of the anterior horn, forming the greater part of its floor. This surface is covered with the ventricular ependyma, and is related above to the

corpus callosum. Laterally it is separated from the lentiform nucleus by the anterior limb of the internal capsule, but this separation is complete only in its upper part. Below, the lateral aspect of the head is directly continuous with the putamen of the lentiform nucleus, and over the intermediate area strands of grey matter traverse the internal capsule and connect the two nuclei to each other (fig. 916). The striped appearance which this region presents has given origin to the term corpus striatum. Superiorly the margin of the head is related to the fronto-occipital association bundle (p. 1007). Posteriorly the head rapidly diminishes in bulk and becomes continuous with the body of the nucleus, which lies in the lateral part of the floor of the lateral ventricle.

The *body* arches upwards, backwards and laterally. Its medial aspect is covered with ependyma and related to the thalamostriate vein (vena terminalis), the stria semicircularis (stria terminalis) and the thalamus. Laterally it is related to the fronto-occipital bundle above, and to the corona radiata below. Posteriorly it turns downwards at the posterior extremity of the thalamus and becomes continuous with the tail.

The *tail* of the caudate nucleus runs forwards in the roof of the inferior horn of the lateral ventricle, with the stria semicircularis to its medial side (fig. 903). As the body curves downwards and forwards into the tail it passes below the corona radiata, the globus pallidus of the lentiform nucleus and the ansa lenticularis (p. 963). Anteriorly the tail of the caudate nucleus is continuous with the amygdaloid nucleus.

The **lentiform nucleus** is shaped like a biconvex lens, but the curvature of its medial surface is sharper than the curvature of its lateral surface. Cut on section, it is seen to consist of two portions, which differ from each other in their colour. The larger lateral portion, which is dark in colour, is termed the *putamen* ; the smaller medial portion is of a lighter tint, and is termed the *globus pallidus*.

The lentiform nucleus is completely buried in the substance of the hemisphere. Laterally it is covered by a thin layer of white matter which constitutes the *external capsule*. This sheet is covered on its lateral side by the *claustrum*, which intervenes between it and the subcortical white matter of the insula. Medially the lentiform nucleus is in relation to the internal capsule, which separates it from the thalamus behind, and from the head of the caudate nucleus in front. Round its anterior, superior and posterior margins the nucleus is related to the corona radiata. The inferior part of the lentiform nucleus is deeply grooved by the anterior commissure as it passes backwards and laterally into the temporal lobe (fig. 904), and anteriorly it is continuous with the head of the caudate nucleus. A little in front of the groove, the grey matter of the corpus striatum is continuous with the grey matter of the anterior perforated substance, and the lateral striate arteries, which enter the brain there, run laterally and then turn upwards, in close contact with the lateral surface of the lentiform nucleus, before they pierce its substance. The lentiform nucleus lies above the inferior horn of the lateral ventricle and is separated from it by the fibres of the external capsule as they pass medially towards the subthalamic region (p. 1014), the tail of the caudate nucleus and the stria semicircularis (stria terminalis). More anteriorly, it is separated from the amygdaloid nucleus by the ansa peduncularis (p. 957).

Structure.—The caudate nucleus and the putamen of the lentiform nucleus are very similar in their histological features, and both differ very conspicuously from the globus pallidus. Their constituent nerve-cells are small and they show a poverty of nerve-fibres, those that are present forming a finely medullated plexus. The globus pallidus on the other hand is characterised by the possession of large cells, not unlike the motor cells of the anterior grey column of the spinal cord. In addition, it is rich in medullated fibres, which are visible to the unaided eye where they form the external and internal medullary laminæ. The external lamina separates the globus pallidus from the putamen, and the internal lamina subdivides it into a larger lateral and a smaller medial portion (fig. 917).

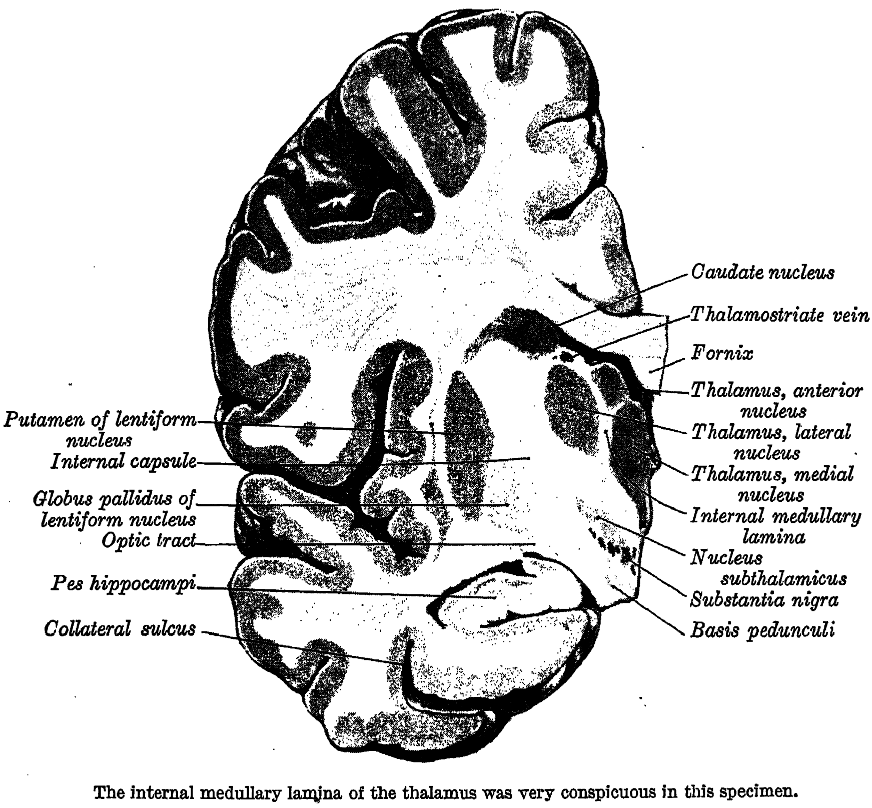
Connexions.—*Afferent fibres* reach the corpus striatum from the thalamus and are distributed to the caudate nucleus, the putamen, and, probably, the globus pallidus. There is no clear evidence that cortical fibres either terminate

in, or give collaterals to the corpus striatum, and it would appear that the thalamus is the principal source of supply.

The *efferent fibres* all arise in the globus pallidus, and they pass through the internal capsule to reach (1) the thalamus, (2) the hypothalamus and (3) the red nucleus. They possess medullated sheaths, but they can be distinguished from the fibres of the internal capsule by their smaller size. Many of these fibres appear on the inferior aspect of the globus pallidus and pass medially, constituting the *ansa lenticularis*.

Internuncial fibres connect the caudate nucleus and the putamen to each other and to the globus pallidus. They are finely medullated, and in the globus pallidus are responsible for the medullary laminæ.

FIG. 917.—A coronal section through the right cerebral hemisphere. Anterior aspect.



The internal medullary lamina of the thalamus was very conspicuous in this specimen.

Functional significance of the corpus striatum.—The palæostriatum of fishes, which corresponds to the globus pallidus in man, receives its afferent fibres from the olfactory pathways, and its efferent fibres establish connexions with the motor centres in the brain-stem and the spinal cord. There is no doubt that it functions as a higher motor centre, enabling olfactory impressions to exert a preponderating influence on the animal's movements. The addition of the neostriatum in the reptilian brain is, as has been seen (p. 972), synchronous with the passage into the telencephalon of new fibres of thalamic origin, and it has been suggested that, owing to the presence of the neostriatum and its connexions with both the thalamus and the palæostriatum, visual, tactile and other impressions are able to modify the responses which would otherwise result from olfactory stimuli.

It is clear that the evolution of the neopallium and the process of telencephalisation have relegated the corpus striatum to a subsidiary role. Despite the intimate topographical relationship between it and the insula, no fibre connexions have been shown to exist between it and the cerebral cortex. Kappers is of opinion that the corpus striatum in the mammalian brain is

associated with the sympathetic nervous system, but this view receives little support from clinical evidence. Experimental evidence is largely of a negative character. Ramsay Hunt, Kinnier Wilson and others have investigated cases of degeneration and atrophy of the corpus striatum. Rigidity, which is due to hypertonicity, and tremor, which is independent of the rigidity, are constant features, whether the neostriatum or the globus pallidus is affected. This evidence points to the association of the corpus striatum with the motor apparatus. Ramsay Hunt finds that automatic associated movements are lost when the globus pallidus is involved and that they are increased and accompanied by uncontrolled athetoid * movements when the disease affects the neostriatum only. It must be confessed, however, that very little definite knowledge is available concerning the functional significance of the large nuclear mass formed by the caudate and lentiform nuclei.

The **amygdaloid nucleus** is a mass of grey substance which is situated in the anterior end of the roof of the inferior horn of the lateral ventricle. Anteriorly and superiorly it is continuous with the grey matter of the piriform area and the anterior perforated substance, respectively. Posteriorly it is continuous with the tail of the caudate nucleus. It receives afferent fibres from the olfactory pathway, probably secondary olfactory neurones, and sends its efferent fibres backwards in the roof of the inferior horn as the stria semicircularis (stria terminalis).

The amygdaloid nucleus represents the archistriatum, which is differentiated in the reptilian brain prior to the neostriatum. Its precise functional significance is obscure.

The *stria semicircularis* (stria terminalis) is a small collection of medullated nerve-fibres which issues from the posterior end of the amygdaloid nucleus and runs backwards in the roof of the inferior horn of the lateral ventricle on the medial side of the tail of the caudate nucleus. It follows the curve of the nucleus and runs forwards in the floor of the body of the ventricle, occupying the groove which separates the caudate nucleus from the thalamus. Below the interventricular foramen it gives off some fibres to the anterior commissure and turns downwards to enter the hypothalamus, where it ends by sending fibres to several of the hypothalamic nuclei. It may therefore be regarded as a pathway for the association of olfactory and visceral stimuli.

The **claustrum** is a thin sheet of grey matter, co-extensive with the insula and the putamen of the lentiform nucleus, from which it is separated by the fibres of the external capsule. It is thickest below and in front, where it becomes continuous with the anterior perforated substance. Regarded by some authorities as belonging to the corpus striatum and by others as a detached portion of the insular cortex, it is undoubtedly of cortical origin, but its connexions and functions are quite unknown.

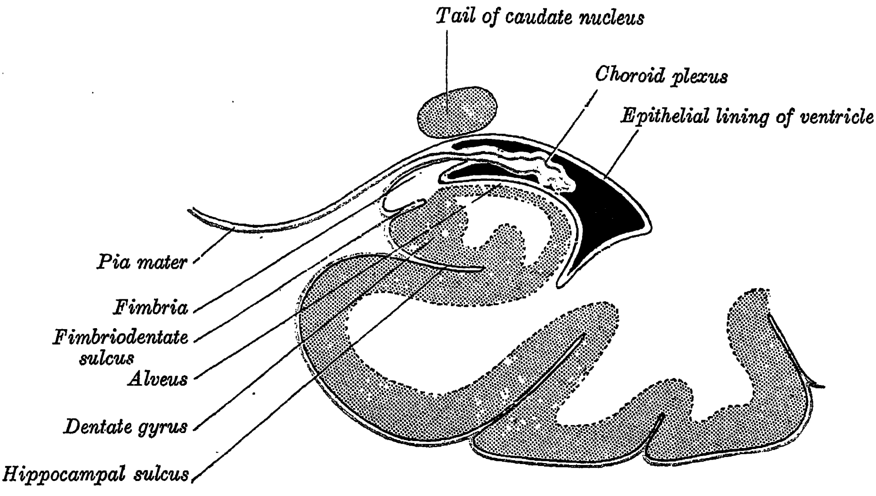
The **external capsule** is a thin layer of white matter which is interposed between the lateral aspect of the lentiform nucleus and the claustrum. According to Meynert the fibres of the external capsule are derived from the fronto-parietal operculum of the insula and, after passing across the lateral surface of the lentiform nucleus, they turn medially below the nucleus and the ansa lenticularis. Their subthalamic connexions are uncertain. Some of the fibres of the anterior commissure are believed to traverse the external capsule.

The choroidal fissure and the choroid plexus of the lateral ventricle.—The *choroid plexus* of the lateral ventricle is a highly vascular fringe of pia mater which projects into the ventricular cavity, invaginating the ependymal medial wall of the ventricle before it and receiving from it a complete investment (fig. 885). It extends as far forwards as the interventricular foramen, where it is continuous with the corresponding plexus of the opposite side. Posteriorly it is carried round the posterior end of the thalamus into the inferior horn as far as the pes hippocampi. The ependyma which covers the choroid plexus is an infolded part of the medial wall of the hemisphere, and this infolding constitutes the *choroidal fissure*. The lips of the fissure are the lateral edge of the fornix and the upper surface of the thalamus, in the body of the ventricle (fig. 885), and the edge of the fimbria and the stria semicircularis (stria terminalis) in the inferior horn (fig. 918). The two parts of the fissure

* The term 'athetoid movements' is used to describe repeated, deliberate movements of a purposeless character.

are directly continuous with each other round the posterior end of the thalamus. It will be remembered that the choroidal fissure is the first fissure to appear on the surface of the hemisphere (p. 118), and coronal sections across the brain of a two-months' embryo show that the floor of the upper part of the fissure is directly continuous with the ependymal roof of the third ventricle, and that the vascular pia mater which covers the latter is continued into the choroidal fissure on each side. At this stage, and prior to the development of the commissures and the expansion of the lamina terminalis, only one layer of pia mater covers the roof of the third ventricle (fig. 152). When the corpus callosum grows backwards, it passes above the line of the choroidal fissure and carries with it on its under surface a second layer of pia mater (fig. 884). In this way two layers of pia mater come to lie above the ependymal roof of the third ventricle and on each side they pass into the choroidal fissure to enclose the vessels of the choroid plexus (fig. 885). Posteriorly these two layers separate from each other. The lower layer follows the roof of the third ventricle to

FIG. 918.—A coronal section through the inferior horn of the lateral ventricle. Diagrammatic.



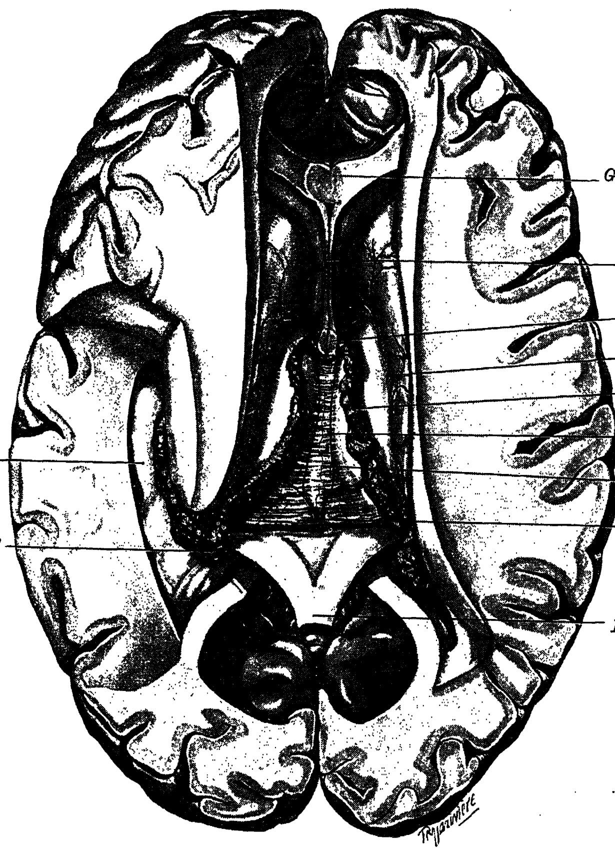
the pineal body and the tectum of the mid-brain, while the upper layer ascends on the back of the splenium and is continuous with the pia mater on the upper surface of the corpus callosum (fig. 884).

These two layers of pia mater constitute the *tela chorioidea of the third ventricle.* Viewed from above, they form a triangular fold, the rounded apex being situated at the interventricular foramen (fig. 919). The edges are irregular and contain the vascular fringes of the choroid plexuses of the lateral ventricles. The posterior or basal angles are continuous with the vascular fringes of pia mater which are invaginated into the inferior horns, but over the central and wider part of the base the two constituent layers separate from each other as already explained. When the splenium of the corpus callosum is viewed from behind, a transverse slit is seen below it. This slit is termed the *transverse fissure* of the brain, but it must be remembered that it is not really a cerebral fissure in the true sense of the term, for it does not correspond to any infolding of the cerebral cortex. Before the pia mater is removed, the transverse fissure leads into the interval between the two layers of the tela chorioidea, and this interval is a portion of the extra-cerebral space which has been enclosed by the backward growth of the corpus callosum.

The choroid plexus consists of minute and highly vascular villous processes, each possessing an afferent and an efferent blood-vessel. The *arteries* of the plexus are: (*a*) the anterior choroid artery, a branch of the internal carotid artery, which enters the plexus at the anterior end of the inferior horn; and (*b*) the posterior choroid, one or two small branches of the posterior cerebral artery, which pass into the upper part of the choroidal fissure. The *veins* of the plexus unite to form a single tortuous vessel (choroid vein) which begins

in the inferior horn of the ventricle and courses in the plexus to the interventricular foramen and there joins the thalamostriate vein (p. 814) to form the corresponding *internal cerebral vein*. The two internal cerebral veins run backwards close to the median plane between the two layers of the tela chorioidea of the third ventricle. When the two layers separate below the splenium of the corpus callosum, the two veins unite to form the *great cerebral vein*, which curves backwards and upwards behind the splenium to join the straight sinus.

FIG. 919.—The tela chorioidea of the third ventricle and the choroid plexus of the lateral ventricle.



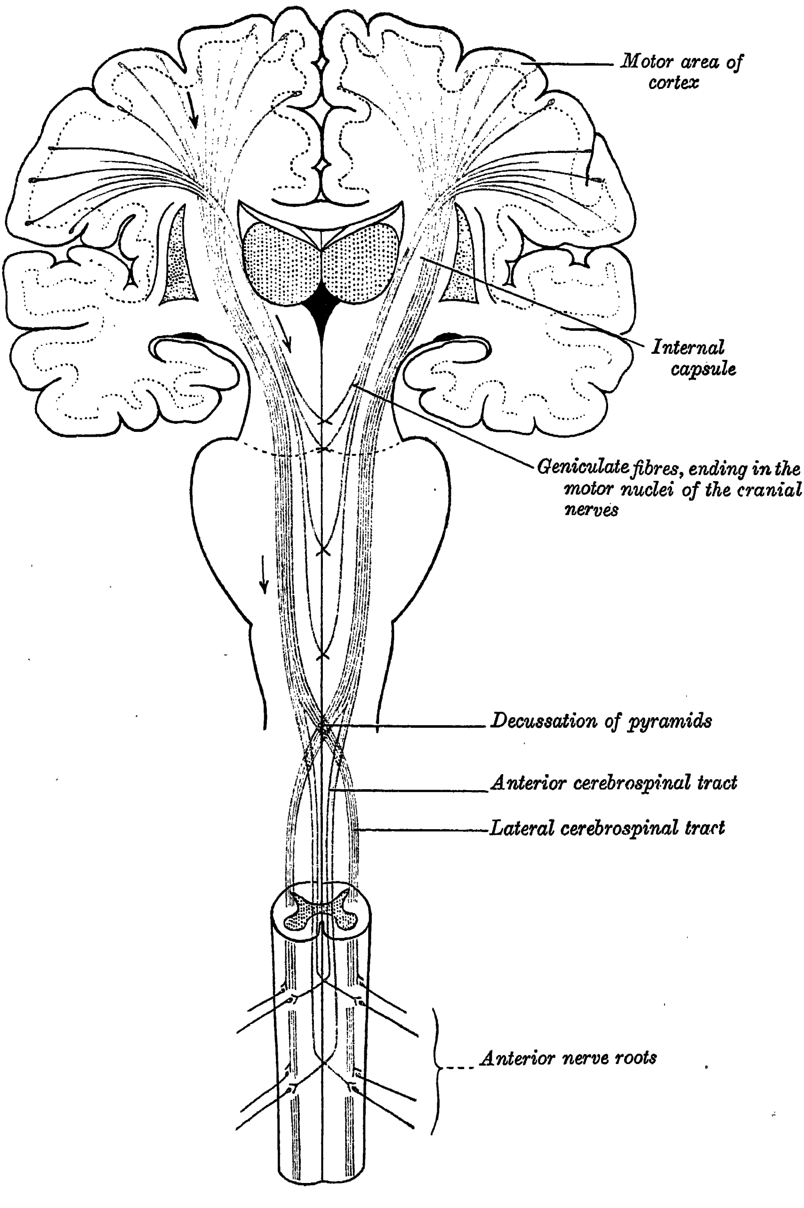
The trunk of the corpus callosum has been removed and the body of the fornix has been cut across anteriorly and turned backwards.

The weight of the brain.—The average weight of the brain, in the adult male, is about 1380 gms.; that of the female, about 1250 gms. In the male, the maximum weight out of 278 cases was 1840 gms. and the minimum weight 964 gms. The maximum weight of the adult female brain, out of 191 cases, was 1585 gms. and the minimum weight 879 gms. The brain increases rapidly during the first twelve months of life, and the brain of a year-old child is on the average two and a half times as heavy as the brain of a newly-born infant. By the sixth year the brain has reached 85 per cent. or more of its weight in the adult. This increase is attributable to the medullation of the nerve-fibres. As age advances, the brain decreases slowly in weight; in old age the decrease takes place more rapidly, and may amount to about 28 gms.

Applied Anatomy.—The *internal capsule* is often the seat of hæmorrhage from the lateral striate artery (Charcot's 'artery of cerebral hæmorrhage'), or of thrombosis, in patients whose vessels are weakened by old age or disease. A 'stroke,' or 'apoplexy,'

is the result; blood is effused from the ruptured vessels and tears up the surrounding brain tissue, and also interferes with the neighbouring fibres by the compression set up by its mass. If the hæmorrhage is sudden and at all large, rapid and complete loss of consciousness follows, with paralysis of the opposite side of the body and loss of control over the sphincters, together with a variable degree of hemianæsthesia. If it is the posterior

FIG. 920.—The principal motor tracts. (Modified from Poirier.)



limb of the internal capsule that is involved, the paralysis will be more marked in the leg than in the arm, and will be associated with homonymous hemianopia or blindness of the corresponding halves of the two retinæ, the patient being unable to see objects on the opposite side of the body.

THE CHIEF NERVE TRACTS

The anatomy of the various parts of the central nervous system having been described, a short summary will now be given of the chief ascending and descending nerve tracts connecting the brain and the spinal cord. This may be effected most conveniently by grouping them as follows: (*a*) the motor (descending) tracts, (*b*) the sensory (ascending) tracts, and (*c*) the cerebellar systems (ascending and descending).

The Motor Tracts

Included under this heading are (*a*) the principal motor tracts, originating in the cerebral cortex, and (*b*) the secondary motor tracts originating in the basal nuclei.

The principal motor tracts (fig. 920).—The constituent fibres of these tracts are the axis-cylinder processes of the cells of Betz situated in the motor area of the cortex. The fibres converge as they descend through the corona radiata, and pass between the lentiform nucleus and thalamus, in the genu and in the anterior two-thirds of the posterior limb of the internal capsule; those in the genu are named the geniculate fibres, the others the cerebrospinal fibres. Both sets of fibres proceed downwards, through the middle three-fifths of the base of the cerebral peduncle, and then the geniculate fibres cross the median plane, and end by arborising around the cells of the motor nuclei of the cranial nerves. The cerebrospinal fibres are continued downwards into the pyramid of the medulla oblongata, and thence proceed by two paths. The fibres nearest to the anterior median fissure cross the median plane, intersecting the corresponding fibres from the opposite side and forming the *decussation of the pyramids*, and descend in the lateral white column of the opposite side of the spinal cord, as the lateral cerebrospinal fasciculus (crossed pyramidal tract). Throughout the length of the spinal cord, fibres from this tract pass into the grey matter, to end by arborising around cells of the anterior horn, or (according to Sharpey-Schafer, p. 899) by arborising around cells of the posterior horn. The more laterally placed cerebrospinal fibres do not decussate in the medulla oblongata, but descend as the anterior cerebrospinal fasciculus (direct pyramidal tract); in each segment of the upper half of the spinal cord some of these fibres cross in the anterior white commissure, with the result that all end in the grey matter of the opposite side. There is considerable variation in the extent to which decussation takes place in the medulla oblongata; about two-thirds or three-fourths of the cerebrospinal fibres usually decussate in the medulla oblongata and the remainder in the spinal cord.

The secondary motor tracts.—While the presence of a motor path distinct from the principal motor tracts has for some time been surmised on clinical grounds, it is only recently that anatomical details of it have become available, and many of these are still under investigation. In this summary it will be sufficient to indicate that the chief nuclei on the efferent pathway are the globus pallidus of the corpus striatum and the red nucleus of the mid-brain. The main pathway is from the globus pallidus to the red nucleus, and thence to the opposite side of the spinal cord by the rubrospinal tract. Subsidiary pathways begin in the globus pallidus and run to the subthalamic nucleus and formatio reticularis, and proceed by successive neurones downwards to the spinal cord. All these descending fibres ultimately reach and arborise round the motor cells of the cranial nerve nuclei or of the anterior grey column of the spinal cord. These pathways are, for the most part, entirely independent of the cerebral cortex, and are activated through the substantia nigra, the thalamus and the hypothalamus. All the tracts concerned are often grouped together under the term, the *extrapyramidal system*.

The axons of the motor cells in the cranial nuclei proceed through the cranial nerves, while those of the cells in the anterior grey column of the spinal cord pass out in the anterior roots of the spinal nerves, forming thus in each instance a *final common motor pathway*, along which impulses are conducted to the muscles of the head, trunk and limbs. For clinical purposes the neurones constituting the final motor pathway are grouped as the *lower motor neurones*, while the other neurones of the motor pathway form the group of *upper motor neurones*.

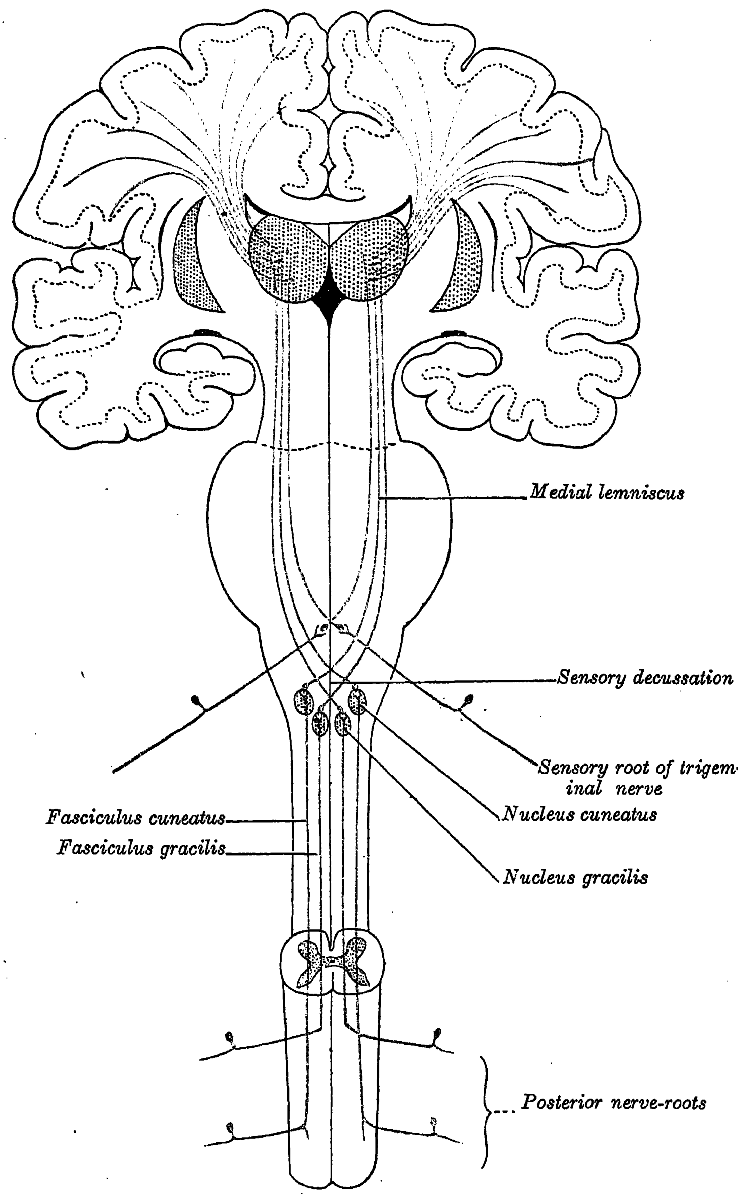
The Sensory Tracts

The sensory impulses traversing the cerebrospinal axis may be resolved into the following groups: (1) *interoceptive*, arising in the viscera; (2) *proprioceptive*, arising in the muscles, tendons, joints, etc.; and (3) *exteroceptive*, initiated on the surface of the body. Exteroceptive sensibility may be subdivided into a cruder (protopathic), and a finer, discriminative variety.

(1) Little is known concerning the pathway followed by the interoceptive fibres. (2) The proprioceptive fibres are accompanied throughout by the fibres which convey the discriminative variety of exteroceptive sensibility (p. 883). They enter the spinal cord through the posterior roots of the spinal nerves, and at once divide into descending and ascending branches; the descending branches soon enter and ramify in the grey matter; the majority of the ascending branches are continued into the posterior white columns, where they join the fasciculus gracilis and fasciculus cuneatus. These fasciculi end by arborising around the cells of the nucleus gracilis and nucleus cuneatus in the medulla oblongata (fig. 921), and from these cells the fibres of the medial lemniscus take origin and cross to the opposite side in the sensory decussation. In its further course the medial lemniscus receives fibres from the terminal nuclei of the ordinary sensory cranial nerves of the

opposite side. Ascending through the cerebral peduncle the medial lemniscus is carried into the thalamus, where its fibres end. From the cells of the thalamus the fibres of the third link in the chain arise and pass to the cerebral cortex behind the central sulcus. It is important to observe that these fibres do not cross the median plane until they reach the medulla oblongata, and, therefore, unilateral lesions of the spinal cord involving the post-

FIG. 921.—The pathway of the fibres conveying proprioceptive and discriminative sensibility. (Modified from Poirier.)



erior white column, are accompanied by *homolateral* loss of proprioceptive and discriminative sensibility.

(3) Fibres conveying the cruder type of exteroceptive sensibility ascend through two pathways in the spinal cord. (*a*) *Fibres conveying painful and thermal stimuli* are relayed in the substantia gelatinosa and the adjoining head of the posterior grey column and *cross the median plane at or a little above the level at which they enter the spinal cord.* They then join the lateral spinothalamic tract. (*b*) *Fibres conveying tactile and pressure stimuli* are relayed in the head of the posterior grey column and then ascend for a varying number of segments

before they cross the median plane and pass into the anterior spinothalamic tract.* Both spinothalamic tracts ascend through the spinal medulla to the medulla oblongata, where they meet and form the *spinal lemniscus*. At a slightly higher level they are joined by the *trigeminal lemniscus*, which conveys the same varieties of sensibility from the trigeminal area. In its course through the pons and mid-brain, the spinal lemniscus is closely related to the medial lemniscus and it terminates above in the lateral nucleus of the thalamus. There the fibres are relayed and the fibres of the third neurones pass through the posterior limb of the internal capsule to reach the postcentral gyrus.

It is important to observe that the fibres conveying painful and thermal sensations cross the median plane soon after entering the spinal cord. Unilateral lesions of the spinothalamic tracts are accompanied by contralateral loss of painful and thermal sensibility. Lesions in the neighbourhood of the commissural grey matter, on the other hand, will cause bilateral loss of both forms of sensibility, but the areas affected will correspond to the segments involved in the spinal cord.

It will be observed that in most cases there are three cell-stations interposed in the course of the sensory impulses; for clinical purposes, therefore, three groups of neurones are recognised: (1) the *lowest sensory neurones*, which comprise the cells of the posterior root ganglia, and their peripheral and central processes; (2) the *intermediate sensory neurones* between these and the thalamus; and (3) the *highest sensory neurones*, which are the cells of the thalamus and the fibres passing from them to the cerebral cortex.

The Cerebellar Systems

The cerebellum exercises such an important influence on muscle tone (p. 937) that impulses must be able to reach it from all parts of the cerebral cortex as well as from the spinal cord, while impulses are conveyed from it to other co-ordinating and motor nuclei in the cerebrospinal axis. Only the larger tracts can be summarised here.

Afferent tracts.—A considerable number of afferent impulses reach the cerebellum by way of the spinal cord through the fibres of the posterior nerve-roots. In the spinal cord there are three main pathways. The entering fibres may end around the cells of the thoracic nucleus; the fibres from these cells form the posterior spinocerebellar tract of the same side, and are carried up to the medulla oblongata, where they enter the inferior cerebellar peduncle and are conveyed to the cortex of the vermis of the cerebellum. A second group of entering fibres arborises around the cells of the posterior grey column of the spinal cord; of the fibres of these cells some cross to the opposite side while others pass up the same side, forming an anterior spinocerebellar tract, which traverses the spinal cord on the surface of the lateral white column, runs through the medulla oblongata and pons, and then turns downwards and backwards to reach the cortex of the vermis by way of the superior cerebellar peduncle. The third group of entering fibres runs up in the fasciculus gracilis and fasciculus cuneatus, and ends in the nucleus gracilis and nucleus cuneatus; relayed there, the fibres pass in the inferior cerebellar peduncle to reach the cerebellar cortex.

Three important afferent tracts to the cerebellum run from the brain-stem, viz. the vestibulocerebellar, the olivocerebellar and the tectocerebellar. The vestibulocerebellar tract arises from the vestibular nuclei in the floor of the fourth ventricle, and runs in the inferior cerebellar peduncle to the cerebellar cortex. The olivocerebellar tract arises in the olivary nucleus, crosses the median plane, and gains the cerebellum through the inferior cerebellar peduncle. The tectocerebellar tract has its origin in the cells of the corpora quadrigemina and enters the cerebellum through the superior cerebellar peduncle.

Of the remaining afferent fibres to the cerebellum the most important group is that of the cerebro-ponto-cerebellar tracts. These fibres arise from cells of the cerebral cortex, travel downwards through the internal capsule and cerebral peduncle, and end by arborising round the cells of the nuclei pontis. New fibres arise from the cells of these nuclei, cross the median plane, pass through the middle cerebellar peduncle, and end in the cortex of the cerebellar hemispheres.

Efferent tracts.—The efferent tracts from the cerebellar cortex originate from the Purkinje cells and run to arborise around cells of the cerebellar nuclei; with the possible exception of the flocculus, no fibres pass directly from the cerebellar cortex to the rest of the brain or to the spinal cord. Several small groups of fibres arising from the cerebellar nuclei run to various nuclei in the cerebrospinal axis, but the chief efferent tract is that which forms the greater part of the superior cerebellar peduncle, crosses the median plane, and runs mainly to the red nucleus, giving some fibres to the thalamus. From the red nucleus the rubrospinal tract arises, crosses to the opposite side, and travels down in the pons and medulla oblongata to the lateral white column of the spinal cord, where it ultimately ends around the motor cells in the anterior grey column.

Other efferent fibres from the cerebellar nuclei pass to the nuclei of the vestibular nerve, and are relayed to the spinal cord in the vestibulospinal tract.

* It should be stated that, whereas the evidence for the existence of the lateral spinothalamic tract is full and convincing, the evidence for the existence of the anterior spinothalamic tract is by no means complete.

Myelination of the Fibre Groups of the Spinal Cord and Brain-stem

According to Lucas Keene and Hewer * the process of myelination in the spinal cord and the brain-stem occurs in four distinct stages. During the fourteenth week of intra-uterine life myelination commences in the anterior and posterior roots of the spinal nerves, in all the cranial nerves (with the exceptions of the optic, the cochlear and the sensory part of the trigeminal nerve (p. 1035) and in many of the tracts. Between the twenty-second and the twenty-fourth weeks additional fibre groups become affected. The process receives a fresh impetus at or just before birth and again about eight months later.

Depending on the number and on the length of the fibres involved, the period over which the process extends may last for from two to ten weeks or more.

The tracts become myelinated in the following order:

In the first period: (1) fasciculus cuneatus, (2) posterior spinocerebellar, (3) anterior spinocerebellar, (4) lateral spinothalamic, (5) spinotectal, (6) anterior intersegmental and (7) the medial longitudinal bundle.

In the second period: (1) fasciculus gracilis, (2) posterior intersegmental, (3) lateral intersegmental, (4) medial lemniscus, (5) olivocerebellar and (6) fasciculus retroflexus.

In the third period: (1) posterolateral, (2) lateral cerebrospinal (crossed pyramidal), (3) rubrospinal, (4) anterior cerebrospinal (direct pyramidal), (5) external arcuate fibres, (6) ponticerebellar fibres and (7) corticipontine fibres.

In the fourth period: the bulbospinal tract (p. 900).

Applied Anatomy.—The chief symptoms of diseases of the brain and spinal cord depend upon the particular systems of neurones picked out for attack, and some of them may be briefly summarised as follows. *Motor paralysis* of the *spastic* type, with rigidity of the muscles and increased reflexes, follows destruction of the upper motor neurones; *flaccid* paralysis, with loss of the reflexes and rapid muscular atrophy, follows destruction of the lower motor neurones. *Sensory paralysis* follows injury to any part of the sensory path; in tabes it is due to injury of the lowest sensory neurones, in hemiplegia to destruction of the highest sensory axon as it traverses the posterior limb of the internal capsule. *Dissociation of sensations,* or the loss of some forms of sensation while others remain unimpaired, is seen in a number of conditions such as tabes and syringomyelia; it shows that the paths through which various forms of sensation travel to the brain are different. *Abnormalities of reflex actions* are of very great help in the diagnosis of nervous complaints. The numerous *superficial or skin reflexes* (e.g. the plantar, tickling the sole of the foot brings on plantar flexion of the toes), if present, show that the reflex arcs on whose integrity their existence depends are intact; but they are often absent in health and so cannot be trusted to indicate disease. The *deep reflexes or tendon reactions,* such as the knee-jerk, or the tendo calcaneus jerk, are increased in chronic degeneration of, or gradually increasing pressure on, the cerebrospinal fibres (upper motor neurone). They are lost when the lower motor or lower sensory neurones are diseased, and in a few other conditions; absence of the knee-jerk is very rare in health, and suggests disease in some part of its reflex arc, in the third and fourth lumbar segments of the cord, or else, more rarely, grave intracranial or spinal disease cutting off the lower from the higher nervous centres. The *organic reflexes* of the pupil, bladder, and rectum are of the greatest practical importance. The commonest defect in the reflexes of the pupil is reflex iridoplegia, or failure to contract on exposure to light, without failure to contract on convergence or accommodation (' Argyll Robertson ' pupil). The pupil is also contracted (miosis), and may or may not dilate when the skin of the neck is pinched (the ciliospinal reflex). Micturition is a spinal reflex much under the control of the brain; if the centre for micturition in the second sacral segment is destroyed the sphincter and the walls of the bladder are paralysed, the bladder becomes distended with urine, and incontinence from overflow results. If this centre escapes injury but is cut off more or less completely from impulses descending to it from above there will be more or less interference with micturition. This varies in degree from the ' precipitate micturition ' of tabetic patients, who must perforce hurry to pass water the moment the impulse seizes them, to the state of ' reflex incontinence,' when the bladder automatically empties itself from time to time, almost without the patient's knowledge. Defæcation is a very similar spinal reflex, and is liable to very similar disorders of function.

The *upper motor neurone* (p. 1018) is affected in hemiplegia, the *lower motor neurone* (p. 1018) in infantile spinal paralysis; both these systems of neurones are diseased together in the somewhat rare disorders known as amyotrophic lateral sclerosis and progressive muscular atrophy. The chief symptom here is wasting and weakness in certain groups of muscles; the palsy will be flaccid, with loss of the reflexes, or spastic, with increased reflexes, according as the degeneration mainly involves the lower or the upper motor neurone. The sphincters are affected only in the later stages of these diseases.

Pathological changes in the *lowest sensory neurone* are the cause of tabes dorsalis or locomotor ataxy, which occurs almost entirely in adults who have had syphilis. In the

* M. F. Lucas Keene and E. E. Hewer, *Journal of Anatomy,* vol. lxvi. 1931.

early or pre-ataxic stage the patient may exhibit the Argyll Robertson pupil (see above) and loss of knee-jerks, and complain of sharp, stabbing pains ('lightning pains') in the limbs, difficult or precipitate micturition, and sometimes of severe and painful attacks of indigestion (gastric crises). In the second or ataxic stage, coming on perhaps years later, he will complain, in addition, of interference with his powers of getting about and turning, although his muscular strength is well preserved. He is unable to stand steady with his eyes shut or in the dark, his gait becomes exaggerated and stamping in character, he has to use a stout stick to walk with, and he may suffer from painful crises in various parts of the body. Control over the sphincters is further weakened, and on examination there will be found marked incoordination of the limbs, zones of anæsthesia about the trunk or down the limbs, and marked analgesia (or insensitiveness to pain) when pressure is applied to the bones, tendons, trachea, tongue, eyeballs, mammæ and testes.*

THE MEMBRANES OF THE BRAIN AND SPINAL CORD

The brain and the spinal cord are enveloped by three membranes [meninges], named from without inwards: the dura mater, the arachnoid mater and the pia mater.

The Dura Mater

The **dura mater** is a thick and dense inelastic membrane. The portion of it which encloses the brain (cerebral dura mater) differs in several particulars from that which surrounds the spinal cord (spinal dura mater), and therefore it is necessary to describe them separately; the two parts, however, form one complete membrane, and are continuous with each other at the foramen magnum.

The **cerebral dura mater** lines the interior of the skull, and serves the twofold purpose of an internal periosteum to the bones, and a protective membrane for the brain. It is composed of two layers, an inner or meningeal and an outer or endosteal; these are closely united, except along certain lines where they are separated by the venous sinuses which drain the blood from the brain (p. 814). The dura mater adheres to the inner surfaces of the cranial bones, and sends blood-vessels and fibrous processes into them, the adhesion being most marked at the sutures, at the base of the skull, and around the foramen magnum. The blood-vessels and fibrous processes are torn across when the dura mater is detached from the bones, and consequently the outer surface of the membrane presents a rough and fibrillated appearance; the inner surface is smooth and lined by a layer of mesothelium. The dura mater is continuous through the sutures with the pericranium, and through the superior orbital fissure with the periosteal lining of the orbital cavity. It provides tubular sheaths for the cranial nerves as the latter pass through the foramina at the base of the skull; outside the skull these sheaths fuse with the epineurium of the nerves; the sheath of the optic nerve is continuous with the sclera of the eyeball.

The cerebral dura mater sends inwards four processes or septa which divide the cranial cavity into a series of freely communicating spaces for the lodgment of the subdivisions of the brain. These processes are named the falx cerebri, the tentorium cerebelli, the falx cerebelli and the diaphragma sellæ. They are covered on their free surfaces by mesothelium, and they contain a variable quantity of white fibrous and yellow elastic tissue.

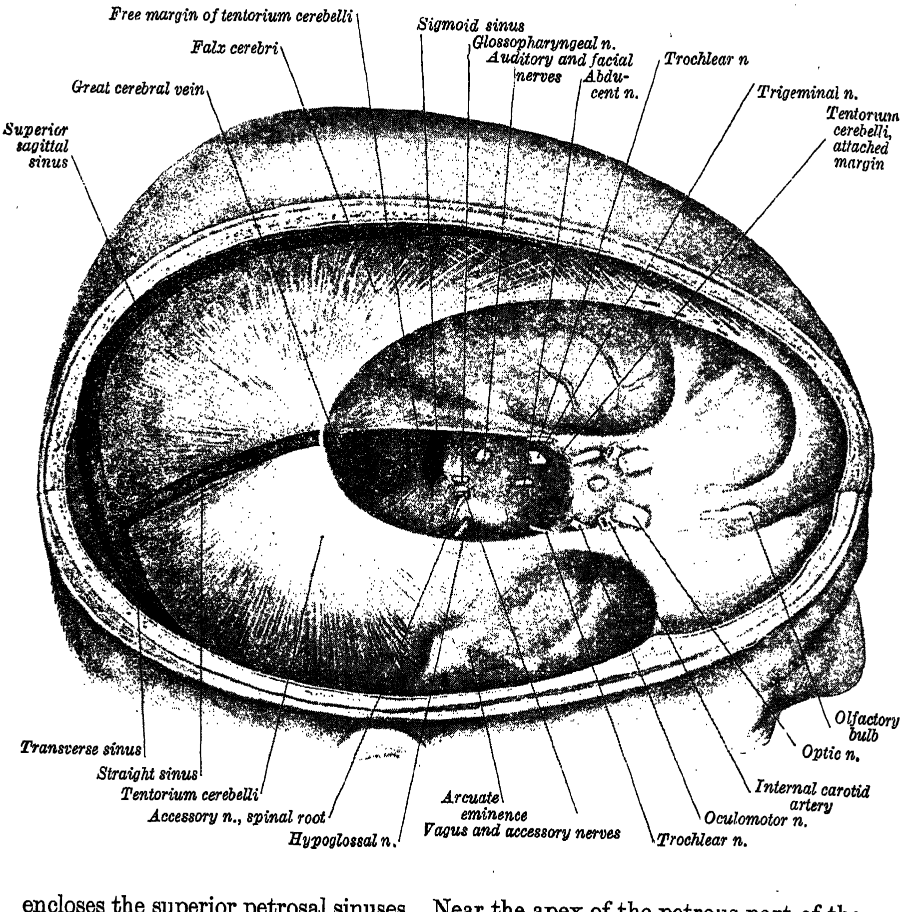
The *falx cerebri* (fig. 922), so named from its sickle-like form, is a strong, arched process of dura mater which descends vertically in the longitudinal fissure between the cerebral hemispheres. It is narrow in front, where it is fixed to the crista galli of the ethmoid bone; and broad behind, where it is attached in the median plane to the upper surface of the tentorium cerebelli; the narrow, anterior part is thin, and is frequently perforated by numerous apertures. The upper margin of the falx cerebri is convex, and attached to the inner surface of the skull on each side of the median plane, as far back as the internal occipital protuberance; the superior sagittal sinus runs along this

* J. Grasset, *Le Tabes, Maladie de la Sensibilité profonde*; Montpellier, 1909.

margin. Its lower margin is free and concave, and contains the inferior sagittal sinus. The straight sinus runs along its attachment to the tentorium cerebelli.

The *tentorium cerebelli* (fig. 923) is a crescentic, arched lamina of dura mater which covers the cerebellum, and supports the occipital lobes of the cerebrum. Its concave, anterior border is free, and between it and the dorsum sellæ of the sphenoid bone there is a large oval opening, named the *tentorial notch*, which is occupied by the mid-brain. Its convex border is attached (*a*) posteriorly, to the lips of the transverse sulci of the occipital bone and the postero-inferior angles of the parietal bones, and lodges the transverse sinuses; (*b*) laterally, to the superior borders of the petrous parts of the temporal bones, where it

FIG. 922.—The dura mater and its processes. Exposed by the removal of a part of the right half of the skull, and the brain.



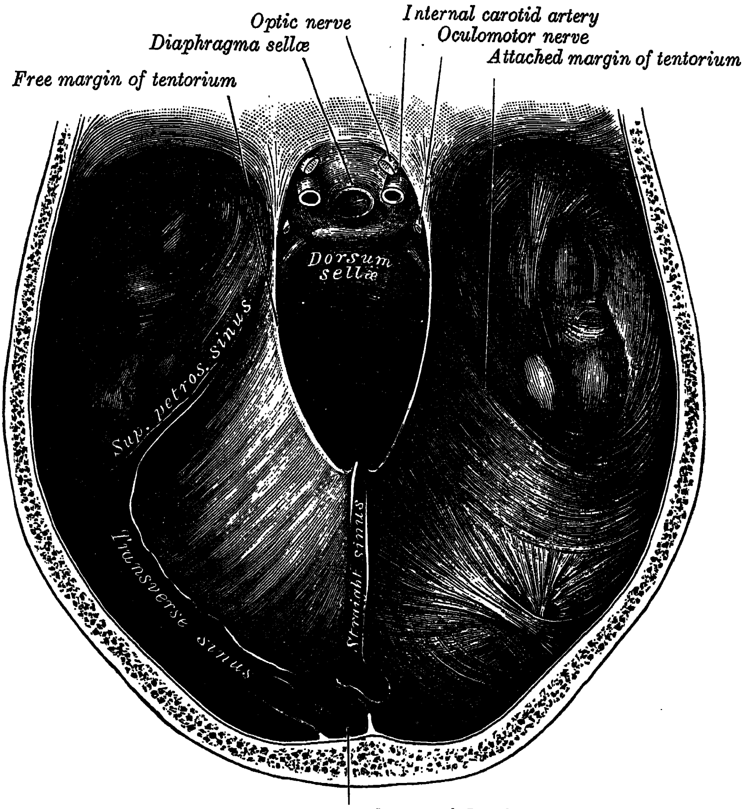
encloses the superior petrosal sinuses. Near the apex of the petrous part of the temporal bone the lower layer of the tentorium is carried forwards and laterally, below the superior petrosal sinus and the dura mater in the floor of the middle cranial fossa, to form the roof of the recess in which the trigeminal (semilunar) ganglion and the adjoining parts of the roots and divisions of the trigeminal nerve are lodged. This little recess is termed the *cavum trigeminale*. Lateral to the ganglion, its roof becomes reflected on to the trigeminal impression on the apex of the petrous part of the temporal bone and so becomes continuous with the dura mater on the posterior aspect of that bone. Anteriorly the recess comes into relation with, and projects into, the cavernous sinus, up which it extends for at least one-half of its height.* The lateral wall of the recess is adherent to the deep surface of the dura mater which forms the lateral wall of the cavernous sinus. At the apex of the petrous part of the temporal bone the

* R. D. Lockhart, *Journal of Anatomy*, vol. lxii. 1927.

free and attached borders of the tentorium cross each other ; the free borders are fixed to the anterior, and the attached borders to the posterior, clinoid processes of the sphenoid bone. As already described, the straight sinus runs in the line of attachment of the posterior part of the inferior border of the falx cerebri to the tentorium cerebelli.

The *falx cerebelli* is a small, sickle-shaped process of dura mater which is situated below the tentorium cerebelli, and projects forwards into the posterior cerebellar notch. Its base, directed upwards, is attached to the posterior part of the inferior surface of the tentorium cerebelli, in the median plane ; its posterior margin contains the occipital sinus, and is fixed to the internal occipital

Fig. 923.—The tentorium cerebelli. Superior surface.



crest ; its apex frequently divides into two small folds, which are lost on the sides of the foramen magnum.

The *diaphragma sellæ* (fig. 923) is a small, circular, horizontal fold of dura mater, which forms a roof for the sella turcica and almost completely covers the hypophysis cerebri ; a small opening in its centre transmits the infundibulum.

Structure.—The cranial dura mater consists of white fibrous tissue and elastic fibres arranged in flattened laminæ, which are imperfectly separated by lacunar spaces and blood-vessels into the endosteal and meningeal layers, already referred to. The endosteal layer is the internal periosteum for the cranial bones, and contains the blood-vessels for their supply. At the margin of the foramen magnum it is continuous with the pericranium. The meningeal later is lined on its inner surface by a layer of nucleated mesothelium.

The *arteries* of the dura mater are very numerous. Those in the anterior fossa of the skull are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries, and a branch from the middle meningeal artery. Those in the middle fossa are the middle and accessory meningeal branches of the maxillary artery ; a branch from the ascending pharyngeal artery, which enters the skull through the foramen lacerum ; branches from the internal carotid artery, and a recurrent branch from the lacrimal artery. Those in the posterior fossa are meningeal branches from the occipital

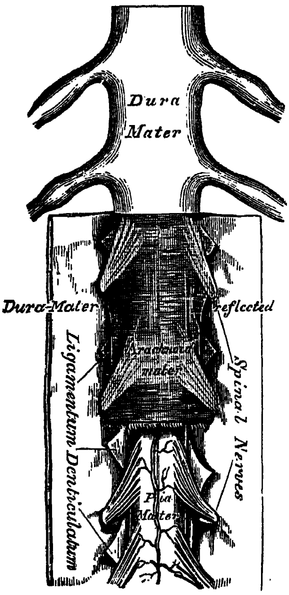
artery, one entering the skull through the jugular foramen, and another through the mastoid foramen; the posterior meningeal branches of the vertebral artery; occasional meningeal branches from the ascending pharyngeal artery, entering the skull through the jugular foramen and anterior condylar canal.

The *veins* returning the blood from the cranial dura mater anastomose with the diploic veins and end in the cranial blood-sinuses. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of *venous lacunæ* (fig. 926). These lacunæ are found on each side of the superior sagittal sinus, especially near its middle portion, and are often invaginated by arachnoid granulations; they communicate with the diploic and emissary veins.

The *nerves* of the cerebral dura mater are filaments from the ganglion of the trigeminal nerve, from the ophthalmic, maxillary, mandibular, vagus, and hypoglossal nerves, and from the sympathetic.

The spinal dura mater (figs. 924, 927) forms a loose sheath around the spinal cord, and represents only the inner, or meningeal, layer of the cerebral dura mater; the outer, or endosteal, layer ceases at the foramen magnum, its place being taken by the periosteum lining the vertebral canal. The spinal dura mater is separated from the wall of the vertebral canal by a space, named the *extradural space*, which contains a quantity of loose areolar tissue and a plexus of veins; the situation of these veins between the spinal dura mater and the periosteum of the vertebræ corresponds to that of the cranial sinuses between the meningeal and endosteal layers of the cerebral dura mater. The spinal dura mater is attached to the circumference of the foramen magnum, and to the second and third cervical vertebræ; it is also connected by fibrous slips to the posterior longitudinal ligament of the vertebræ, especially near the lower end of the vertebral canal. The subdural cavity ends at the lower border of the second sacral vertebra; below this level the dura mater closely invests the filum terminale of the spinal cord and descends to the back of the coccyx, where it blends with the periosteum. The dura mater sends tubular prolongations on the roots of the spinal nerves and on the complete spinal nerves as they pass through the intervertebral foramina. These prolongations are short in the upper part of the vertebral column, but gradually become longer below.

Fig. 924.—A portion of the spinal cord, showing its membranes.



Structure.—The spinal dura mater resembles in structure the meningeal layer of the cerebral dura mater; it consists of white fibrous and elastic tissue arranged in bands or lamellæ which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is smooth and covered by a layer of endothelium. It is sparingly supplied with blood-vessels and nerves.

The **subdural space** is a potential cavity or space between the dura mater and the arachnoid mater. It contains a minute quantity of serous fluid which moistens the smooth surfaces of the opposed membranes. It does not communicate with the subarachnoid space, but is continued for a short distance on the cranial and spinal nerves, and is in free communication with the lymph-spaces of the nerves. On the optic nerve it is continued as far as the back of the eyeball.

The Arachnoid Mater

The **arachnoid mater** is a delicate membrane enveloping the brain and spinal cord and lying between the pia mater internally and the dura mater externally. It is separated from the dura mater by the *subdural space*, but here and there this space is traversed by isolated connective tissue trabeculæ which are most numerous on the posterior surface of the spinal cord. It is separated from the pia mater by the *subarachnoid space*, which is filled with cerebrospinal fluid.

The arachnoid mater surrounds the cranial and spinal nerves, and encloses them in loose sheaths as far as their points of exit from the skull and vertebral canal.

The *cerebral part of the arachnoid mater* invests the brain loosely, and does not dip into the sulci between the gyri, nor into the fissures, with the exception of the longitudinal. On the upper surface of the brain it is thin and transparent; at the base it is thicker, and slightly opaque towards the central part, where it extends between the two temporal lobes in front of the pons, so as to leave a considerable interval between it and the pia mater. It cannot be identified in the hypophyseal fossa.

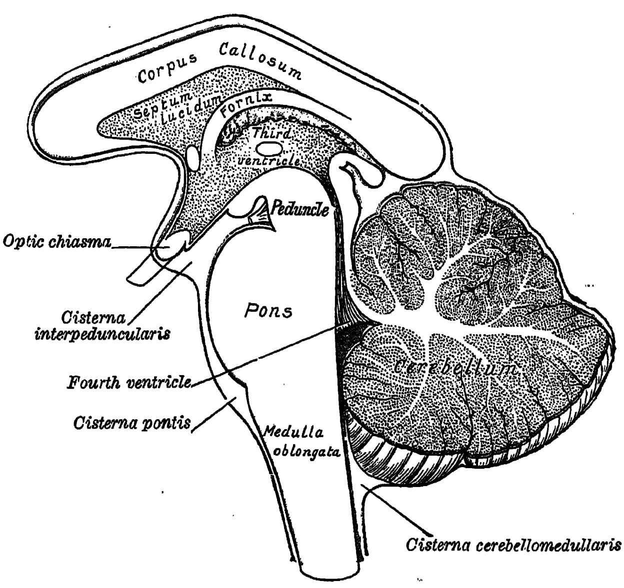
The *spinal part of the arachnoid mater* (figs. 924, 927) is a thin, delicate, tubular membrane loosely investing the spinal cord. Above, it is continuous with the cerebral arachnoid; below, it widens out, invests the cauda equina, and ends at the level of the lower border of the second sacral vertebra.

Structure.—The arachnoid mater consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor root of the trigeminal, the facial, and the accessory nerves, are found in the cerebral part of the arachnoid.

The **subarachnoid space** is the interval between the arachnoid and pia mater. It contains the cerebrospinal fluid and the larger blood-vessels of the brain, and is traversed by a network of delicate connective tissue trabeculæ, which connect the arachnoid to the pia mater. The pia and the arachnoid mater are in close contact on the summits of the cerebral gyri; but where the arachnoid bridges the sulci, angular spaces are left, in which the subarachnoid trabecular tissue is found. At certain parts of the base of the brain, the arachnoid mater is separated from the pia mater by wide intervals, which communicate freely with each other and are named *subarachnoid cisternæ*; in these the subarachnoid tissue is less abundant.

The **subarachnoid cisternæ** (fig. 925).—The *cisterna cerebellomedullaris* is triangular on sagittal section, and is formed by the arachnoid mater bridging the interval between the medulla oblongata and the under surface of the cerebellum; it is continuous below with the subarachnoid space of the spinal cord. The *cisterna pontis* is an extensive space on the ventral surface of the pons. It contains the basilar artery, and is continuous below with the subarachnoid space of the spinal cord, behind with the cerebellomedullary cisterna, and in front of the pons with the cisterna interpeduncularis. As the arachnoid mater extends across between the two temporal lobes, it is separated from the cerebral peduncles and the structures in the interpeduncular fossa by the *cisterna interpeduncularis*, which contains the circulus arteriosus. Anteriorly the interpeduncular cisterna is continued in front of the optic chiasma and is prolonged on the surface of the corpus callosum; here the arachnoid mater stretches between the cerebral

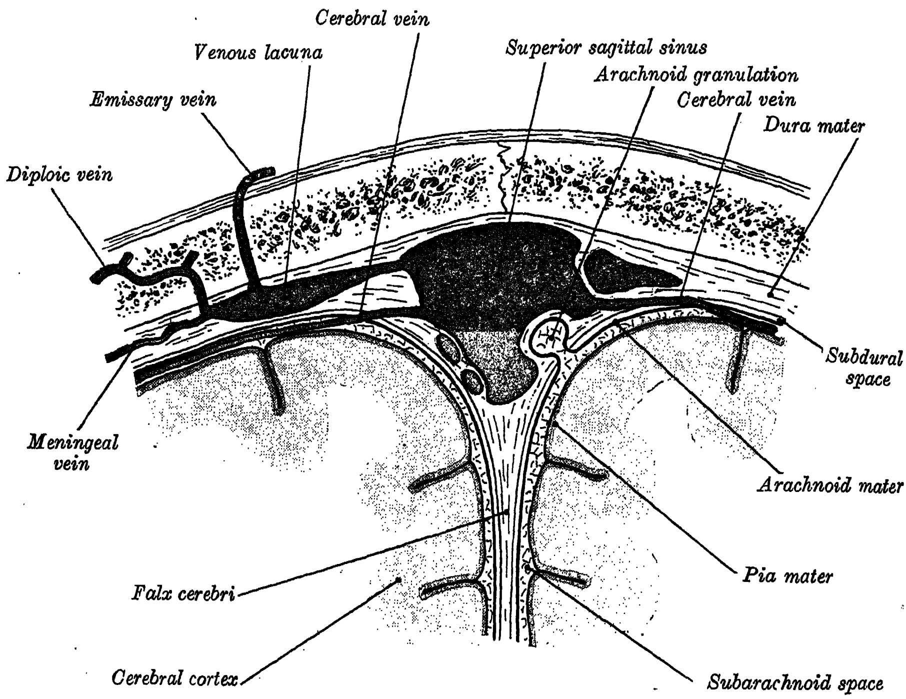
FIG. 925.—A diagram showing the positions of the three principal subarachnoid cisternæ.



hemispheres immediately below the free border of the falx cerebri, and this leaves a space in which the anterior cerebral arteries are contained. The *cisterna of the lateral sulcus* contains the middle cerebral artery, and is formed in front of each temporal lobe by the arachnoid mater bridging the lateral cerebral sulcus. The *cisterna venæ magnæ cerebri* occupies the interval between the splenium of the corpus callosum and the superior surface of the cerebellum ; it contains the great cerebral vein.

The subarachnoid space communicates with the general ventricular cavity of the brain by three openings : one, the *median aperture*, is in the median plane at the inferior part of the roof of the fourth ventricle ; the other two are at the extremities of the lateral recesses of that ventricle, behind the upper roots of the glossopharyngeal nerves (p. 940). There is no direct communication between the subdural and subarachnoid spaces. Communications exist between

FIG. 926.—A coronal section through the top of the skull, showing the membranes of the brain, etc. Diagrammatic. (Modified from Testut.)



the tissue spaces in the nasal mucous membrane and the subarachnoid space through channels which are present along the course of the olfactory nerves.

The spinal part of the subarachnoid space is a wide interval, and is largest at the lower part of the vertebral canal, where the arachnoid mater encloses the nerves which form the cauda equina. Above, it is continuous with the cranial subarachnoid space ; below, it ends at the level of the lower border of the second sacral vertebra. It is partially divided by a longitudinal septum, named the *subarachnoid septum*, which connects the arachnoid with the pia mater opposite the posterior median sulcus of the spinal cord, and forms a partition, incomplete and cribriform above, but more complete in the thoracic region. The spinal subarachnoid cavity is further subdivided by the *ligamentum denticulatum* (p. 1030).

The **arachnoid granulations** (fig. 926) are small fleshy-looking elevations, usually collected in clusters, which are present in the vicinity of the superior sagittal, transverse, and some other sinuses. When the sagittal sinus and the venous lacunæ on each side of it are opened, granulations will be found protruding into their interior. On close inspection they may be seen at the age of eighteen months, " and at the age of three they are disseminated over a considerable area " ; they increase in number and size as age advances. They are enlarged, or distended, normal villi of the arachnoid mater ; they cause

absorption of the bone, and so produce the pits or depressions on the inner aspect of the skull-cap.

Structure.—The growth and structure of the arachnoid granulations have been described by le Gros Clark.* Histologically each granulation appears as a diverticulum of the subarachnoid space, penetrating into the interstices of the dura mater, and covered by a layer of flattened cells containing large oval nuclei and lightly staining protoplasm. In the subarachnoid space there is a reticulum of fine fibrous tissue, the density of which is as a rule greater at the periphery than at the centre of the granulation; in advanced age it frequently contains calcareous nodules.

At the summit of the granulation the endothelial cells proliferate and form a cap which penetrates the surrounding dura mater, and fuses with the endothelial lining of one of the intradural venous sinuses; in doing so it pulls out a little stalk of arachnoid mater containing a diverticulum of the subarachnoid space. Except at the point of fusion with the endothelial lining of the sinus, the granulation is surrounded by the subdural space and the dura mater; the latter, covered on its cerebral surface by a layer of endothelium, is invaginated into the venous sinus by the protrusion of the granulation.

Fluid injected into the subarachnoid space passes into these granulations, and it has been found experimentally that fluid passes by osmosis from the arachnoid villi into the venous sinuses of the dura mater.

The cerebrospinal fluid is a clear, slightly alkaline fluid, with a specific gravity of about 1007. It contains in solution inorganic salts similar to those in the blood-plasma, and also traces of protein and glucose. The cerebrospinal fluid is secreted into the ventricles of the brain by the choroid plexuses and into the subarachnoid space by the choroid plexuses of the lateral recesses of the fourth ventricle (p. 940). From the ventricles it passes through the median aperture and the foramina of the lateral recesses of the fourth ventricle and so gains the subarachnoid space in the cisterna cerebellomedullaris and the cisterna pontis. Within the cranium the cerebrospinal fluid flows upwards through the gap in the tentorium cerebelli and then forwards and laterally over the inferior surface of the cerebrum. Finally it ascends over the lateral aspect of each hemisphere to reach the arachnoid villi associated with the superior sagittal sinus, and so is able to pass back again into the bloodstream. Within the vertebral canal there is no active flow, but the process of diffusion and alterations of posture serve to maintain the character of the fluid constant throughout the whole extent of the subarachnoid space. The cerebrospinal fluid supports and protects the delicate structure of the brain and spinal cord, and it maintains a uniform pressure upon them. In addition, since the perforating branches of the cerebral arteries are accompanied by perivascular channels which communicate with the subarachnoid space, on the one hand, and perineuronal spaces on the other, the cerebrospinal fluid comes into intimate relation with the nerve-cells of the cortex and basal nuclei. Our knowledge of the circulation of the cerebrospinal fluid and of the arachnoid villi has been greatly extended by the work of Weed and his collaborators.†

Applied Anatomy.—Diseases of the central nervous system and its membranes are often reflected in alterations of the cells which are normally found in the cerebrospinal fluid or in alterations in the concentration of its chemical constituents. Interference with the circulation of the fluid is indicated by variations in the pressure within the meninges. The determination of these alterations and variations is often of service in diagnosis.

Specimens of the cerebrospinal fluid may be obtained by the operation of *lumbar puncture*, which is performed through the interval between the laminæ or spines of the third and fourth (or fourth and fifth) lumbar vertebræ. A fine trocar and cannula is inserted at the point of intersection of the intertubercular plane with the posterior median line and is passed obliquely upwards and forwards above the upper border of the spine of the fourth lumbar vertebra. It is carried through, or parallel to, the supraspinous and interspinous ligaments into the vertebral canal. The dura mater and the arachnoid are punctured and the instrument is introduced into the subarachnoid space below the lower end of the spinal cord (p. 887). When the trocar is withdrawn, the cerebrospinal fluid escapes through the cannula at the rate of one drop per second, under normal conditions, but when the fluid is under increased pressure it escapes in an almost continuous stream. If it is suspected that the cerebrospinal fluid is under increased pressure at the time of a lumbar puncture, a manometer is attached to the cannula, lest the sudden fall in pressure, which would otherwise occur, should lead to impaction of the medulla oblongata in the foramen magnum, causing sudden death.

The Pia Mater

The pia mater closely invests the brain and spinal cord; it is a vascular membrane, consisting of a minute plexus of blood-vessels held together by an

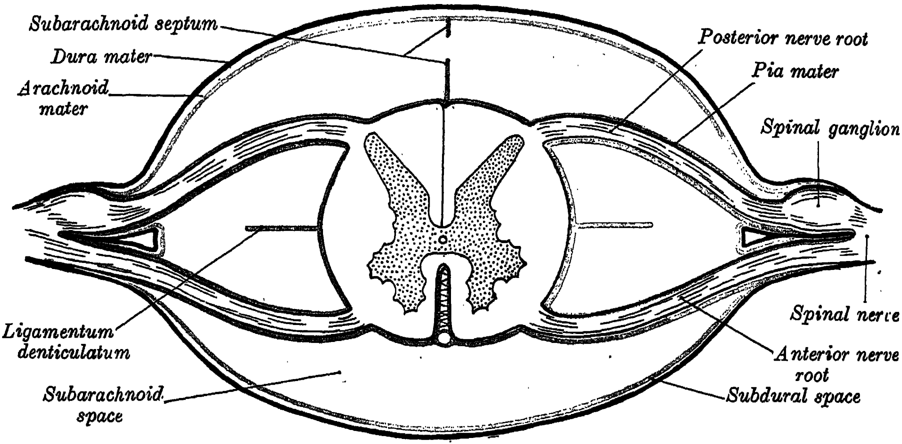
* W. E. le Gros Clark, *Journal of Anatomy*, vol. lv. 1920.

† Lewis H. Weed, Carnegie Institute of Washington; *Contributions to Embryology*, vol. 9, 1920.

extremely fine areolar tissue. The *cerebral pia mater* invests the entire surface of the brain, dips between the cerebral gyri and between the cerebellar laminæ, and is invaginated to form the tela chorioidea of the third ventricle, and the choroid plexuses of the lateral and third ventricles (pp.1014 to 1016); as it passes over the roof of the fourth ventricle, it forms the tela chorioidea and the choroid plexuses of this ventricle (p. 940). Upon the surfaces of the hemispheres it gives off from its deep surface a multitude of sheaths around the minute vessels that run perpendicularly for some distance into the cerebral substance. On the cerebellum the membrane is more delicate ; the vessels from its deep surface are shorter, and its relations to the cortex are not so intimate. Like the arachnoid mater, the pia mater cannot be identified in the hypophyseal fossa.

The *spinal pia mater* (figs. 924, 927) is thicker, firmer, and less vascular than the cerebral pia mater ; this is due to the fact that it consists of two layers, the outer or additional one being composed of bundles of connective tissue fibres, arranged for the most part longitudinally. Between the layers are cleft-like spaces which communicate with the subarachnoid space, and a

FIG. 927.—A transverse section through the spinal cord and its membranes. Diagrammatic.



number of blood-vessels. The spinal pia mater covers the spinal cord, and is intimately adherent to it ; in front it sends a septum into the anterior median fissure. A longitudinal fibrous band, called the *linea splendens*, extends along the median plane anteriorly, and a somewhat similar band, named the *ligamentum denticulatum*, is situated on each side. Below the conus medullaris the pia mater is continued as a long slender filament, named the *filum terminale* (p. 876).

The pia mater forms sheaths for the cranial and spinal nerves ; these sheaths are closely connected with the nerves, and blend with their common membranous investments.

The **ligamentum denticulatum** (figs. 839, 927) is a narrow, fibrous band situated on each side of the spinal cord, between the anterior and the posterior nerve-roots. Its medial border is continuous with the pia mater at the side of the spinal cord. Its lateral border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on each side. The first process crosses behind the vertebral artery at the point where that vessel pierces the dura mater, and is separated by the artery from the anterior root of the first cervical nerve ; it is attached to the dura mater immediately above the margin of the foramen magnum, 1·26 cm. behind the hypoglossal nerve, and the spinal part of the accessory nerve ascends on its posterior aspect. The last process is between the exits of the twelfth thoracic and first lumbar nerves, and consists of a narrow oblique band running downwards and laterally from the conus medullaris (Parsons *).

* *Proceedings of the Anatomical Society of Great Britain and Ireland*, 1915.

THE PERIPHERAL PART OF THE NERVOUS SYSTEM

The peripheral nervous system comprises the afferent, or centripetal, fibres which connect the sensory end-organs to the central nervous system, and the efferent, or centrifugal, fibres which connect the central nervous system to the effector apparatus. It includes the twelve pairs of cranial nerves which arise from the brain, and the thirty-one pairs of spinal nerves which arise from the spinal cord. The sympathetic trunks with their various ganglia and branches belong to this system, but they will be dealt with in a separate section.

In the lowest vertebrates the spinal cord gives rise to a series of ventral nerve-roots, arising from the anterior grey column and motor in function, and a series of dorsal nerve-roots, connected to the posterior grey column and sensory in function. The ventral and dorsal nerve-roots do not unite, and they do not correspond in position. The ventral nerve-root is segmental and is distributed to the myotome which corresponds to the neuromere from which it arises. The dorsal nerve-root is intersegmental in position and runs in the intersegmental connective tissue to reach its cutaneous distribution. In the majority of fishes and in all higher forms the corresponding ventral and dorsal nerve-roots which emerge from the spinal cord unite with one another to constitute the individual spinal nerves. The arrangement of the spinal nerves, therefore, follows a very primitive pattern and has not undergone much modification in the process of evolution.

The arrangement of the cranial nerves, on the other hand, has been very profoundly modified. The development and modification of the branchial system and the suppression of segments owing to the elaborate changes which occur in the region of the head have been largely responsible for this modification. There is every reason to suppose that the brain, like the spinal cord, represents a number of neuromeres, and that in the ancestral form of vertebrates each neuromere was provided with a ventral nerve and each interneuromeric interval with a dorsal nerve. In the brain, corresponding ventral and dorsal nerves never fuse, although adjoining ventral or dorsal nerves may and actually do unite. Owing to the complete disappearance of certain myotomes the corresponding ventral nerves become completely suppressed. Further, the dorsal nerves, originally sensory nerves supplying chiefly the skin of the head and the mucous membrane of the mouth and pharynx, acquire motor fibres which they distribute to the musculature arising in the lateral mesodermic plates in the branchial region. With the growth and modification of the brain and the consequent elaboration of the head region, the cutaneous areas of the head are transferred from one nerve to its neighbour, so that the functions of the individual dorsal nerves become altered.

The incorporation of some of the precervical segments in the head leads to the fusion of the corresponding ventral nerves, and the hypoglossal nerve so formed becomes added to the cranial nerves.

As a result of these changes the reference of the individual cranial nerves to their appropriate neuromeres and somites becomes a matter of great difficulty and complexity, and in the account which follows the nerves will be described in their numerical order.

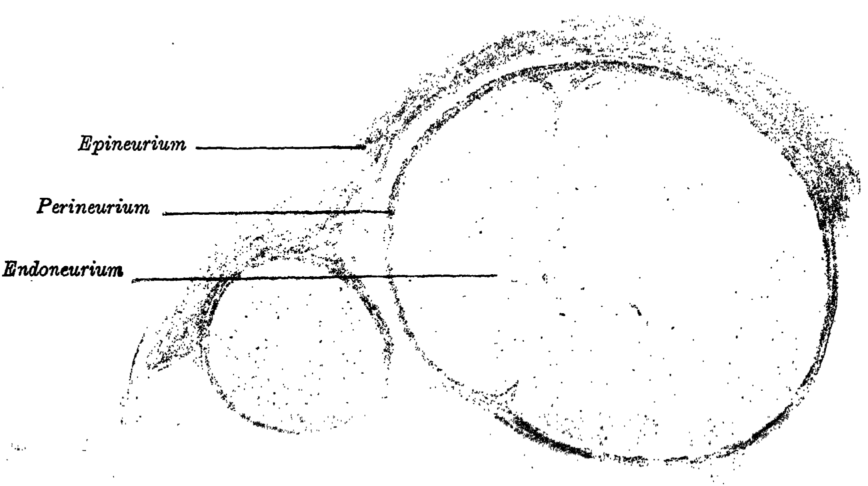
The Structure of the Peripheral Nerves and Ganglia

The **cerebrospinal nerves** consist of numerous nerve-fibres collected into bundles, which are enclosed in membranous sheaths (fig. 928) ; a small bundle of fibres is called a *funiculus*. Each funiculus is surrounded by a sheath, named the *perineurium* ; this consists of a fine, smooth, transparent membrane, made up of connective tissue which has a lamellar arrangement ; the sheath may be easily separated, in the form of a tube, from the fibres it encloses. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue called the *endoneurium* ; it is continuous with septa which pass inwards from the perineurium, and shows a ground substance in which are imbedded fine bundles of fibrous connective tissue running for the most part

longitudinally. If the nerve is small, it may consist of only a single funiculus; but if large, it consists of several funiculi held together and invested by connective tissue; this investment is known as the *epineurium*. The cerebrospinal nerves consist almost exclusively of medullated nerve-fibres, only a very small proportion of non-medullated fibres being present.

The blood-vessels supplying a nerve end in a minute plexus of capillaries which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine, non-medullated, vasomotor nerve-fibres accompany these vessels, and break up into fine fibrils which form a network around them. Medullated fibres, termed *nervi nervorum*, run in the epineurium and terminate in oval or bulbous corpuscles (p. 1216).

Fig. 928.—A transverse section through two funiculi of a human nerve. Stained with hæmatoxylin. × 30.



The cerebrospinal nerve-fibres pursue an uninterrupted course from the centre to the periphery, but in separating a nerve into its component funiculi, it may be seen that bundles of fibres from one funiculus occasionally join, at a very acute angle, another funiculus proceeding in the same direction.

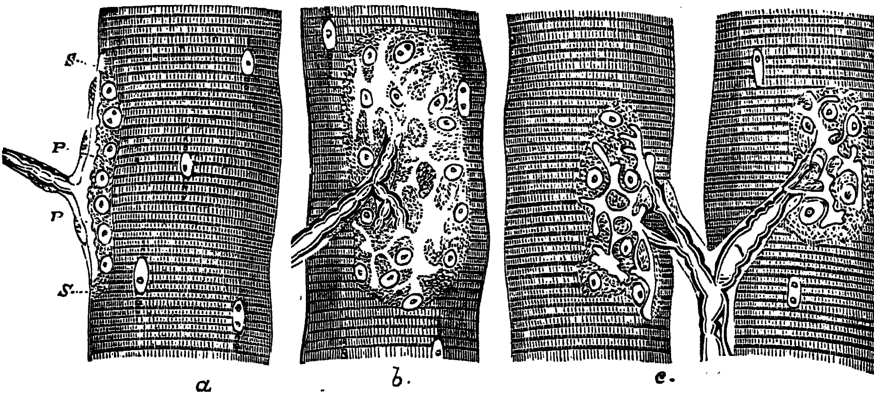
In their course, nerves subdivide into branches, and these frequently communicate with branches of neighbouring nerves; such communications form what is called a *nerve-plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as, for example, the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become intricately interlaced; so that each branch leaving a plexus may contain filaments from all the primary nerve-trunks entering the plexus. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of funiculi and fibres. In each case, however, the individual fibres remain separate and distinct.

Through this interchange of fibres, every nerve leaving a plexus gains a more extensive connexion with the spinal cord than if it had proceeded direct to its distribution without joining other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means also, groups of muscles may be associated for combined action.

Origins of nerves.—The origin of a nerve is in some cases single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots. The point where the nerve-root

or roots emerge from the surface of the nervous centre is named the *superficial*, or *apparent*, origin, but the fibres of the nerve can be traced to groups of nerve-cells in the grey matter of the nervous centre; these cell-groups constitute the *deep*, or *real*, origin of the nerve. The centrifugal, or efferent, nerve-fibres

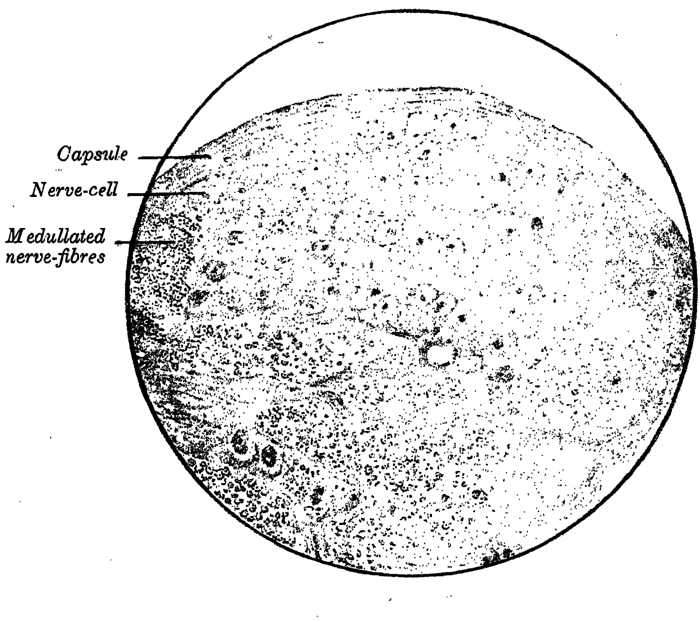
FIG. 929.—Muscular fibres of *Lacerta viridis* with the terminations of nerves.



a. Seen in profile. P.P. The motor end-plate. S.S. The base of the plate, consisting of a granular mass with nuclei. *b*. The same as seen in looking at a perfectly fresh fibre, the nerve-ends being probably still excitable. *c*. The same as seen two hours after death from poisoning by curare.

are the axons of nerve-cells situated in the grey matter of the central nervous system. The centripetal, or afferent, nerve-fibres spring from nerve-cells in the organs of special sense (e.g. the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre they branch and send their ultimate twigs among its cells, without, however, uniting with them.

FIG. 930.—A transverse section through a human spinal ganglion. Stained with methylene blue. Note the brown pigment in some of the ganglion cells. × 60.

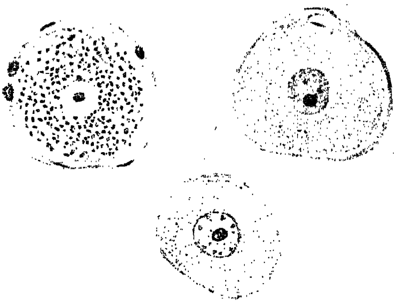


Peripheral terminations of nerves.—Nerve-fibres terminate peripherally in various ways. The terminations of the sensory nerves are dealt with on pp. 1216-1219.

Motor nerves ending in *striped*, or *voluntary*, *muscle* enter the sheath of the muscle, break up into fibres, or bundles of fibres, which form plexuses, and

gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre; if the muscular fibre is long, more than one nerve-fibre may enter it. Within the muscular fibre the nerve ends in a special expansion, called by Kühne, who first described it accurately, a *motor end-plate* (fig. 929). The nerve-fibre, on approaching the muscular fibre, suddenly loses its medullary sheath, the neurolemma becomes continuous with the sarcolemma of the muscle, and only the axis-cylinder with a thin covering of protoplasm enters the muscular fibre. There it ramifies immediately beneath the sarcolemma, and becomes imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting a motor end-plate, from which the contractile wave of the muscular fibre is said to start (see also p. 34). It should be noted that, whereas the motor nerve-endings in muscle are situated under the sarcolemma, the sensory nerve-endings lie outside that layer.

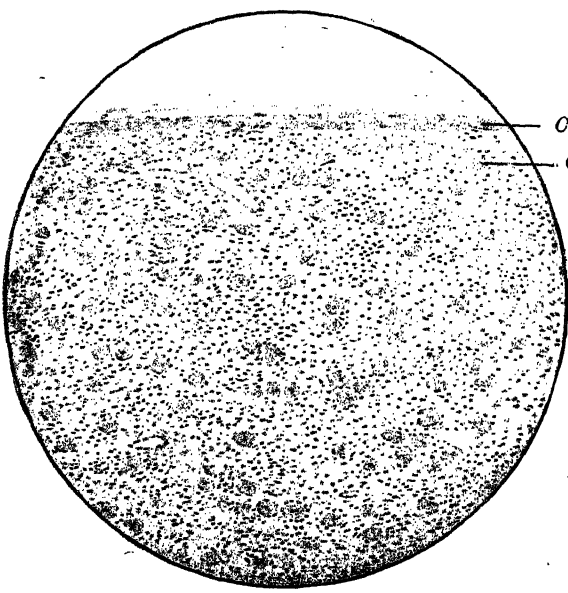
Fig. 931.—Three types of nerve-cells from a spinal ganglion of a cat. Stained with hæmatoxylin and eosin. ×350. (The nuclei of the cells lining the capsule are shown in the left-hand figure only.)



Non-medullated fibres also have been traced to muscle fibres, where they end in an elongated motor plate with numerous minute terminal grape-like enlargements, which are situated on the surface of the sarcolemma. They are believed to be sympathetic in character. (Kulchitsky, *Journ. of Anat.*, Jan. 1924.)

Ganglia are small aggregations of nerve-cells. They are found on the posterior roots of the spinal nerves; on the sensory roots of the trigeminal,

Fig. 932.—A section through a human sympathetic ganglion. Stained with hæmatoxylin and eosin. ×60.



facial, glossopharyngeal, and vagus nerves and on the auditory nerves. They are also found in connexion with the sympathetic nerves. They consist of a reddish-grey substance, traversed by numerous white nerve-fibres, and vary considerably in form and size. Each ganglion is invested by a smooth, firm, membranous envelope, consisting of dense areolar tissue; this envelope is

continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion.

Ganglia consist of nerve-cells and nerve-fibres. Each nerve-cell has a nucleated capsule which is continuous with the neurolemma of the nerve-fibre connected with the cell. The typical larger nerve-cells in the ganglia of the spinal nerves (figs. 930, 931) are irregularly spherical in shape, and each gives off a single fibre which runs towards the centre of the ganglion, and divides in a T-shaped manner; one limb of the cross-bar enters the spinal cord, the other passes outwards to the periphery. Near its origin the stem of the axon is coiled on itself, forming a *glomerulus*. As it straightens out it acquires a medullary sheath, and it usually divides at its first node of Ranvier. The typical smaller cells, which are very numerous, give off fine unmedullated fibres. These axons do not form such complicated glomeruli and they may be practically straight. The presence of plexuses of finely medullated or unmedullated fibres around the cell-bodies has been described by Dogiel, who regards them as being sympathetic in origin. The same authority has described several additional varieties of cells in the spinal ganglia. In one type, the peripheral division of the axon breaks up within the ganglion into sensory nerve-endings; in another, the cell is multipolar and, while the medullated axon passes centrally into the spinal cord, the dendrites, which are peculiar in that they may be partly medullated, break up into sensory endings within the ganglion.

Structurally the peripheral division of the axon of an unipolar ganglion cell resembles an axon in every respect, but it functions as a greatly elongated dendrite.

THE CRANIAL NERVES

There are twelve pairs of cranial (cerebral) nerves, which are named from before backwards as follows:

1st. Olfactory.	5th. Trigeminal.	9th. Glossopharyngeal.
2nd. Optic.	6th. Abducent.	10th. Vagus.
3rd. Oculomotor.	7th. Facial.	11th. Accessory.
4th. Trochlear.	8th. Auditory.	12th. Hypoglossal.

These nerves are attached to the brain, and are transmitted through openings in the base of the cranium. The **motor**, or efferent, cranial nerves arise within the brain from groups of nerve-cells which constitute their *nuclei of origin*. They are brought into relationship with the cerebral cortex by the geniculate fibres of the internal capsule; these fibres arise from the cells of the motor area of the cortex, cross the median plane and end by arborising round the cells of the nuclei of origin of the motor cranial nerves. The **sensory**, or afferent, cranial nerves arise from nerve-cells outside the brain; these nerve-cells may be grouped to form ganglia on the trunks of the nerves, or may be situated in peripheral sensory organs such as the nose, eye and ear. The centrally directed processes of the cells run into the brain and there end by arborising around nerve-cells which are grouped to form the *nuclei of termination* of the ordinary sensory nerves. Fibres arise from the cells of these nuclei and, after crossing to the opposite side, join the lemnisci, and thus connect the nuclei indirectly with the cerebral cortex.

The fibres of most of the cranial nerves begin to acquire their myelin sheaths about the fourteenth week of intra-uterine life. The process is delayed until the twenty-second week in the cases of the sensory part of the trigeminal nerve and the cochlear division of the auditory nerve. In the case of the optic nerve myelination does not commence until shortly before birth, and it is not completed until the second week after birth.*

The Olfactory Nerves (fig. 933)

The **olfactory nerves**, or nerves of smell, are distributed to the mucous membrane of the olfactory region of the nasal cavity; this region comprises the

* M. F. Lucas Keene and E. E. Hewer, *Journal of Anatomy*, vol. lxvi. 1931.

superior nasal concha, and the opposed part of the nasal septum. The nerve-fibres originate from the central, or deep, processes of the olfactory cells of the nasal mucous membrane, and are collected into bundles which cross one

FIG. 933.—The nerves of the septum of the nose. Right side.

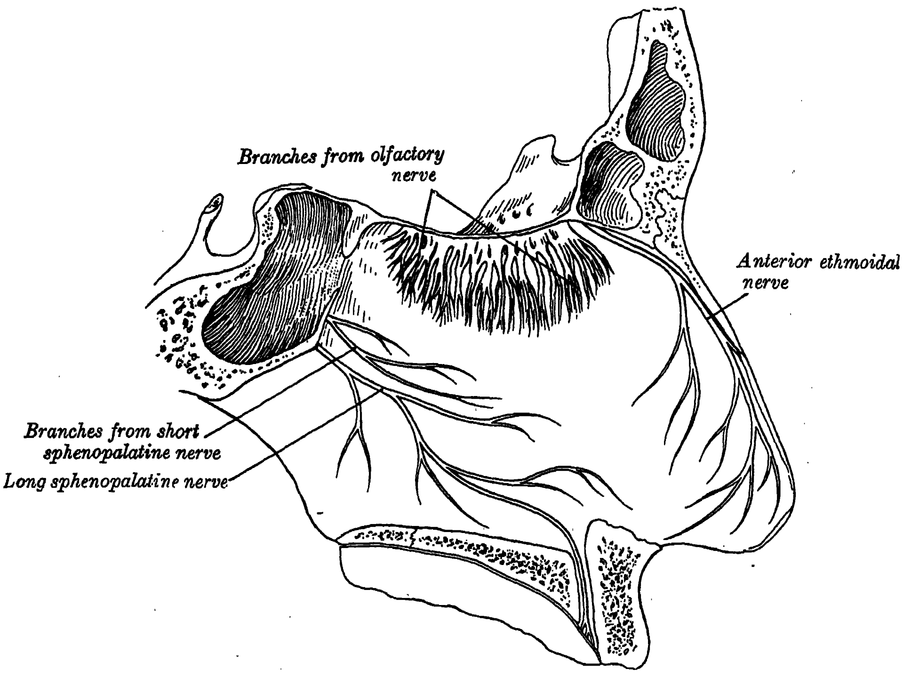


FIG. 934.—A plan of the olfactory neurons.

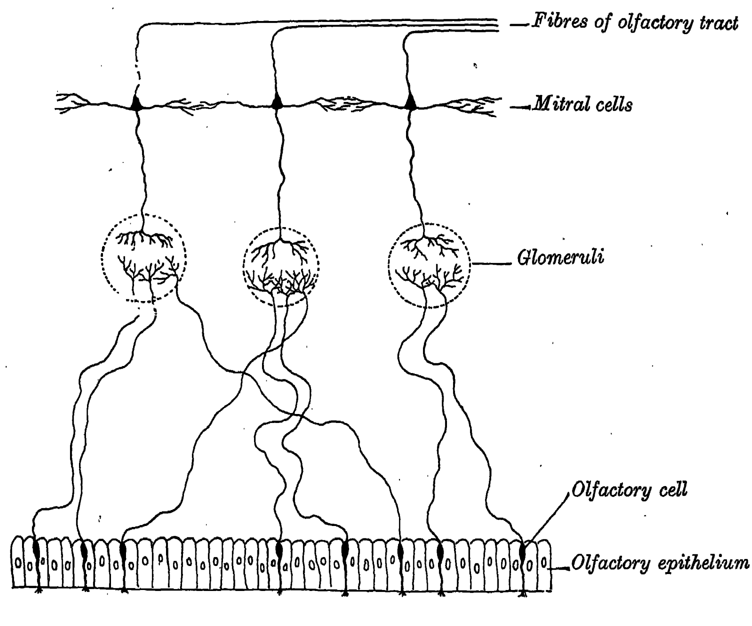


another in various directions, and thus give rise to the appearance of a plexiform network in the mucous membrane. They are then collected into about twenty branches, which pierce the cribriform plate of the ethmoid bone in lateral and medial groups, and end in the glomeruli of the olfactory bulb (fig. 934). Each branch receives tubular sheaths from the dura mater and pia-arachnoid,

the former being continued into the periosteum of the nose, the latter into the neurolemma of the nerve.

The olfactory nerves are non-medullated, and consist of axis-cylinders surrounded by nucleated sheaths, in which, however, there are fewer nuclei than in the sheaths of ordinary non-medullated nerve-fibres.

The olfactory nerves are unique in that their cells of origin develop in the ectoderm and retain this position throughout life in all forms.

Closely associated with the olfactory nerves is a pair of small nerves named the *nervi terminales*.

These nerves were first seen in the lower vertebrates, but their presence has been demonstrated in the human embryo and adult. They consist chiefly of non-medullated nerve-fibres, and on them there are small groups of bipolar and multipolar nerve-cells. Each nerve runs along the medial side of the corresponding olfactory tract, and its branches traverse the cribriform plate of the ethmoid bone, and are distributed to the nasal mucous membrane. Centrally the nerve is connected to the brain at the olfactory trigone; in some animals its fibres have been traced to the lamina terminalis: in others to the hypothalamic region. Its function is unknown; some are inclined to view it as a forward extension of the cephalic part of the sympathetic which is distributed to the blood-vessels and glands of the nasal cavity.

The central connexions of the olfactory bulb are described on pp. 984-988.

Applied Anatomy.—In severe injuries to the head involving the anterior cranial fossa, the olfactory bulb may become separated from the olfactory nerves, or the nerves may be torn, thus producing loss of smell (*anosmia*).

Anosmia sometimes occurs after acute infections of the nose.

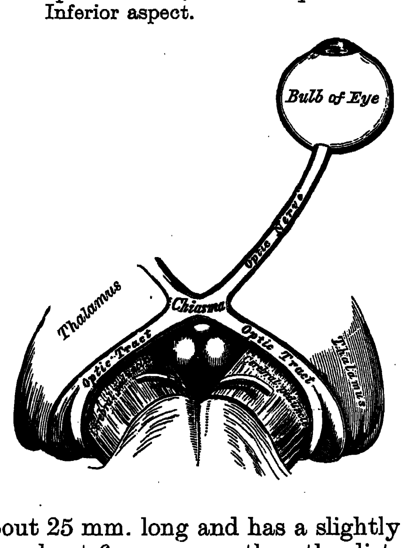
THE OPTIC NERVE (fig. 935)

The **optic nerve**, or nerve of sight, is distributed to the eyeball. Most of its fibres are afferent and originate in the nerve-cells of the ganglionic layer of the retina (p. 1174), but a few are efferent and spring from nerve-cells in the lower visual centres of the brain (p. 968). Developmentally, the optic nerves and the retinæ are parts of the brain (p. 125).

The fibres of the optic nerve form the innermost layer (stratum opticum) of the retina; they converge to the optic disc, and there pierce the outer layers of the retina, the choroid coat, and the lamina cribrosa of the sclera at the posterior part of the eyeball, about 3 or 4 mm. to the nasal side of its centre. As the nerve-fibres traverse the lamina cribrosa they receive their medullary sheaths, and run in bundles which are collected to form the optic nerve.

The optic nerve, about 4 cm. long, is directed backwards and medially through the posterior part of the orbital cavity. It then runs through the optic foramen into the cranial cavity and joins the optic chiasma.

FIG. 935.—The left optic nerve, the optic chiasma, and the optic tract. Inferior aspect.

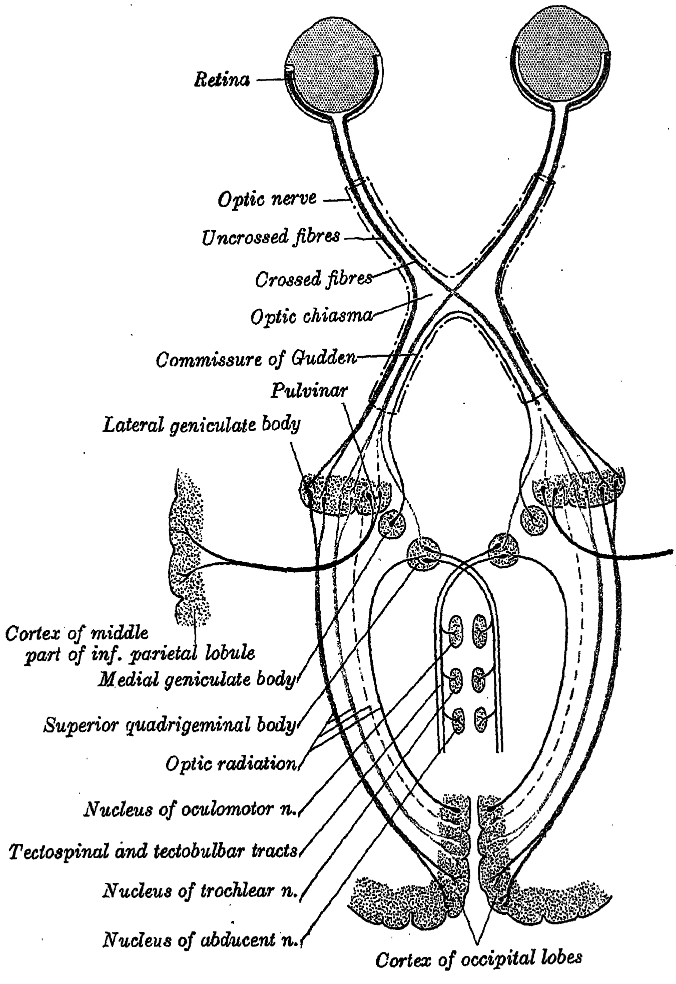


The intra-orbital part of the nerve is about 25 mm. long and has a slightly sinuous course, the length of the nerve being about 6 mm. more than the distance between the optic foramen and the eyeball. Posteriorly it is closely surrounded by the recti muscles, but anteriorly is separated from them by a quantity of fat, in which the ciliary vessels and nerves are lodged. The ciliary ganglion lies between the nerve and the rectus lateralis muscle. The inferomedial surface of the nerve is pierced, at a distance of about 12 mm. behind the eyeball, by the central artery and vein of the retina, which are then directed forwards in the centre of the nerve to the optic disc. In the optic foramen

the nerve lies above and medial to the ophthalmic artery, and is separated medially from the sphenoidal and posterior ethmoidal sinuses by a thin lamina of bone; in front of the foramen the nasociliary nerve and the ophthalmic artery run forwards and medially, crossing above the nerve.

The intracranial part of the optic nerve, about 10 mm. long, runs backwards and medially from the optic foramen to the optic chiasma. The posterior parts

FIG. 936.—A scheme showing the connexions of the optic nerves and optic tracts.



The interrupted lines indicate connexions, the existence of which is uncertain.

N.B.—*The dividing line between the decussating and the non-decussating fibres of the optic nerve passes vertically through the centre of the macula.*

of the olfactory tract and gyrus rectus, and, near the chiasma, the anterior cerebral artery lie above it. The internal carotid artery is on its lateral side.

The optic nerve consists mainly of fine medullated fibres, and is enclosed in three sheaths which are continuous with the membranes of the brain, and are prolonged as far as the back of the eyeball. The *outer sheath*, derived from the dura mater, is thick and fibrous, and blends anteriorly with the sclera. The *intermediate sheath*, derived from the arachnoid mater, is thin and delicate. It is separated from the outer sheath by the subdural space, and from the inner sheath by the subarachnoid space. The *inner sheath*, derived from the pia mater, is vascular and closely invests the nerve. From its deep surface septa pass into the nerve and subdivide and reunite to enclose what appear, in

transverse sections of the nerve, as polygonal areas, which are occupied by the bundles of nerve-fibres. From the inner sheath also, an investment is carried on the central vessels of the retina as far as the optic disc.

Close to the eyeball the macular fibres occupy the lateral part of the nerve, but, as they are traced backwards, they gradually come to lie centrally.

The **optic chiasma** (p. 967), formed by the union of the two optic nerves, is somewhat quadrilateral in shape; it lies above the tuberculum sellæ and the anterior part of the diaphragma sellæ, some distance behind the optic groove of the sphenoid bone. It forms the anterior part of the floor of the third ventricle and is in relation: above with the lamina terminalis: below with the anterior part of the interpeduncular cisterna, which separates it from the anterior part of the diaphragma sellæ: in front with the anterior cerebral and anterior communicating arteries: behind with the tuber cinereum: and laterally with the anterior perforated substance and the internal carotid artery.

The fibres of the optic nerves undergo a partial decussation in the optic chiasma (fig. 936). The fibres from the medial (nasal) half of each retina, including the medial half of the macula, cross the median plane in the anterior part of the chiasma and enter the optic tract of the opposite side. The fibres from the lateral (temporal) half of each retina, including the lateral half of the macula, do not cross, but are continued backwards, through the lateral part of the chiasma, into the optic tract of the same side. The posterior part of the chiasma consists of fibres which cross the median plane, but do not form parts of the optic nerves; these fibres connect the medial geniculate body of one side with the medial geniculate body and, possibly, the inferior quadrigeminal body of the opposite side, and constitute what is known as the *commissure of Gudden*.

The **optic tract** (fig. 876) is a cylindrical bundle of nerve-fibres which runs backwards and laterally from the optic chiasma. It passes between the anterior perforated substance and the tuber cinereum and reaches the under surface of the cerebral peduncle, where it becomes flattened. It then winds round and adheres to the cerebral peduncle, and divides into a medial and a lateral root. The fibres of the medial root form the commissure of Gudden, already referred to; the lateral, and larger, root ends in the lateral geniculate body and the superior quadrigeminal body, which together with the pulvinar of the thalamus constitute the *lower visual centres* (p. 960). From the cells of the lateral geniculate body fibres, termed the *optic radiation*, take origin, and pass through the retrolentiform part of the internal capsule to the *higher*, or *cortical*, *visual centre*, which is situated in the cuneus and in the neighbourhood of the postcalcarine and calcarine sulci. These connexions are dealt with fully on pp. 993 and 1010.

Applied Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and as a rule the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connexion with the anatomy of this nerve which tend to throw light upon the frequent association of its affections with intracranial disease. (1) From its mode of development, and from its structure, the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cranial nerve. (2) It receives sheaths from the three cerebral membranes, and these sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost sheath sends a process around the arteria centralis retinæ into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend along these spaces, or along the interstitial connective tissue in the nerve.

The optic neuritis or papillœdema (' choked disc ') that is often seen in cases of intracranial new growth with increased intracranial tension is probably caused by increased pressure in the sheath of the optic nerve, due to excess of fluid in the general subarchnoid space with which this sheath is in direct communication. If, as is the case, for example in the internal hydrocephalus seen as a complication of cerebrospinal fever, there is no increase in the amount of fluid in the subarachnoid space, then there will be no optic neuritis although the intracranial tension may rise until it brings about the patient's death.

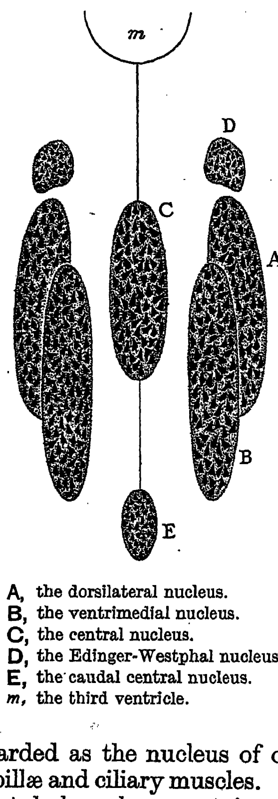
The course of the fibres in the optic chiasma has an important pathological bearing. An anteroposterior section through the chiasma would divide the decussating fibres, and would therefore produce blindness of the medial half of each eye; while a section at the margin of the side of the optic chiasma would produce blindness of the lateral half of the retina of the same side. An early symptom of tumour-growth in the hypophysis is pressure on the chiasma.

THE OCULOMOTOR NERVE (figs. 937 to 939)

The **oculomotor nerve** supplies all the ocular muscles, except the obliquus superior and rectus lateralis; it also supplies, through its connexion with the ciliary ganglion, the sphincter pupillæ and the ciliaris muscles.

The fibres of the oculomotor nerve arise from a **nucleus** which lies in the grey matter of the upper part of the floor of the aqueduct of the mid-brain and extends in front of the aqueduct for a short distance into the floor of the third ventricle, occupying the position of the somatic efferent column (p. 112). From this nucleus the fibres pass forwards through the tegmentum, the red nucleus and the medial part of the substantia nigra, forming a series of curves with a lateral convexity, and emerge from the sulcus on the medial side of the cerebral peduncle (fig. 866).

FIG. 937.—A scheme of the various groups of cells which together constitute the nucleus of the oculomotor nerve. (After le Gros Clark.)



A, the dorsilateral nucleus.
B, the ventrimedial nucleus.
C, the central nucleus.
D, the Edinger-Westphal nucleus.
E, the caudal central nucleus.
m, the third ventricle.

The nucleus of the oculomotor nerve does not consist of a continuous column of cells, but is broken up into a number of smaller nuclei: (1) the dorsilateral nucleus; (2) the ventrimedial nucleus; (3) the central nucleus; (4) the Edinger-Westphal nucleus; (5) the caudal central nucleus. The dorsilateral nucleus extends further in a headward direction than the ventrimedial nucleus, but does not extend so far caudally. The central nucleus is continuous across the median plane with the corresponding nucleus of the opposite side. These three nuclei all contain large multipolar nerve-cells, and it is believed that they supply all the striped muscle innervated by the oculomotor nerve. The evidence at present available is not conclusive, but it suggests that the dorsilateral nucleus is concerned with upward movements (superior rectus and inferior oblique muscles), the ventrimedial nucleus, which is in direct line with the nucleus of the trochlear nerve, with downward movements (inferior rectus) and the central nucleus with movements of convergence (medial rectus). The Edinger-Westphal nucleus is placed more dorsally in the central grey matter of the mid-brain and extends further in a headward direction than the other nuclei. It is generally regarded as the nucleus of origin of the fibres which innervate the sphincter pupillæ and ciliary muscles. The caudal central nucleus, which like the Edinger-Westphal nucleus contains small, stellate nerve-cells, lies in line with it and is probably similar in function.*

The whole nucleus is intimately related to the medial longitudinal bundle, which lies on its ventrilateral aspect.

Connexions.—The oculomotor nucleus receives fibres from: (1) the pyramidal tract of the opposite side; (2) the medial longitudinal bundle, by which it is connected to the nuclei of fourth, sixth and eighth cranial nerves (p. 949); and (3) the tectobulbar tract, by which it is connected to the visual cortex through the medium of the superior quadrigeminal body.

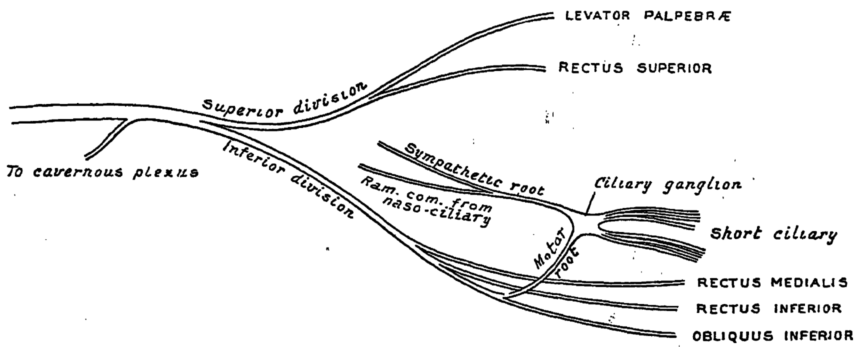
On emerging from the brain, the nerve is invested with a sheath of pia mater, and lies in the subarachnoid space. It passes between the superior cerebellar and posterior cerebral arteries, and runs forward in the interpeduncular cisterna on the lateral side of the posterior communicating artery. It

* See an article by W. E. le Gros Clark on "The Mammalian Oculomotor Nucleus," *Journal of Anatomy*, vol. lx. 1926

then perforates the arachnoid mater and lies in the triangular interval between the free and attached borders of the tentorium cerebelli. Piercing the inner layer of the dura mater on the lateral side of the posterior clinoid process the nerve traverses the lateral wall of the cavernous sinus, where it lies above the trochlear nerve. In this situation it receives one or two filaments from the internal carotid (cavernous) plexus of the sympathetic, and communicates with the ophthalmic division of the trigeminal. It then divides into a superior and an inferior ramus, which enter the orbit through the superior orbital fissure, within the annulus tendineus which gives origin to the recti muscles; here the nasociliary nerve is placed between the two rami.

The *superior ramus*, the smaller, ascends on the lateral side of the optic nerve, and supplies the rectus superior and levator palpebræ superioris. The *inferior ramus* divides into three branches (fig. 938). One passes below the

FIG. 938.—A plan of the oculomotor nerve.



optic nerve to the rectus medialis; another goes to the rectus inferior; the third and longest runs forwards between the rectus inferior and rectus lateralis, to the obliquus inferior. From the nerve to the obliquus inferior a short thick branch is given to the lower part of the ciliary ganglion, and forms its *short* or *parasympathetic root* (p. 1046). The branches enter the muscles on their ocular surfaces, with the exception of that to the obliquus inferior, which enters the posterior border of the muscle.

Applied Anatomy.—Paralysis of the oculomotor nerve leads, when complete, to (1) ptosis, or drooping of the upper eyelid, in consequence of the levator palpebræ superioris being paralysed; (2) external strabismus, on account of the unopposed action of the rectus lateralis and obliquus superior, which are not supplied by the oculomotor nerve and are therefore not paralysed; (3) dilatation of the pupil, because the sphincter pupillæ is paralysed; (4) loss of power of accommodation and of contraction on exposure to light, as the sphincter pupillæ and the ciliaris are paralysed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed; and (6) diplopia, or double vision, the false image being higher than the true. Occasionally paralysis may affect only a part of the nerve—for example, there may be a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the rectus medialis; accommodation for near objects only, from spasm of the ciliaris; or miosis (contraction of the pupil) from irritation of the sphincter pupillæ.

The oculomotor nerve is particularly liable to become involved in a syphilitic peri-arteritis, as it passes between the posterior cerebral and superior cerebellar arteries at the base of the brain.

THE TROCHLEAR NERVE (fig. 939)

The **trochlear nerve**, the slenderest of the cranial nerves, supplies the superior oblique muscle of the eyeball.

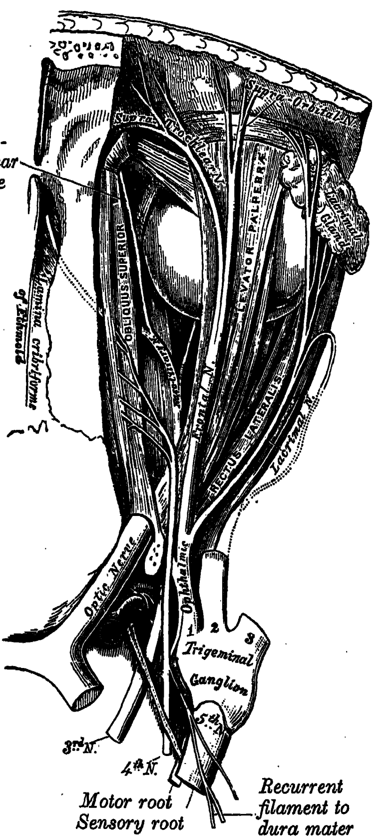
It arises from a **nucleus** situated in the floor of the aqueduct of the mid-brain, opposite the upper part of the inferior quadrigeminal body. This nucleus lies in line with the ventrimedial part of the oculomotor nucleus, and occupies the

position of the somatic efferent column. It bears an intimate relationship to the medial longitudinal bundle, which lies on its ventral aspect.

Connexions.—The nucleus of the trochlear nerve receives fibres from: (1) the pyramidal tract of the opposite side; (2) the medial longitudinal bundle, by which it is connected with the nuclei of the third, sixth and eighth cranial nerves (p. 949); and (3) with the tectobulbar tract, by which it is connected with the visual cortex through the medium of the superior quadrigeminal body (p. 952).

After leaving the nucleus the fibres of the trochlear nerve pursue a very unusual course. They first run downwards and laterally through the tegmentum and then turn backwards round the central grey matter into the upper part of the superior medullary velum. Here they decussate with the corresponding fibres of the opposite side, and, having crossed the median plane, emerge from the surface of the velum at the side of the frenulum veli, immediately behind the inferior quadrigeminal body (fig. 864).

FIG. 939.—The nerves of the right orbit. Superior aspect.



The nerve is directed across the superior cerebellar peduncle, and then winds forwards round the cerebral peduncle immediately above the pons, and between the posterior cerebral and superior cerebellar arteries. It appears between the border of the pons and the temporal lobe, and pierces the inner layer of the dura mater immediately below the free border of the tentorium cerebelli, a little behind the posterior clinoid process. It then passes forwards in the lateral wall of the cavernous sinus, below the oculomotor nerve and above the ophthalmic division of the trigeminal nerve. Near the front of the sinus it crosses the oculomotor nerve, and enters the orbit through the superior orbital fissure, above the ocular muscles, and medial to the frontal nerve. In the orbit it passes medially, above the origin of the levator palpebræ superioris, and finally enters the orbital surface of the obliquus superior.

In the lateral wall of the cavernous sinus the trochlear nerve communicates with the ophthalmic division of the trigeminal nerve, and with the internal carotid (cavernous) plexus of the sympathetic. In the superior orbital fissure it occasionally gives off a branch to the lacrimal nerve.

Applied Anatomy.—When the trochlear nerve is paralysed there is loss of function in the obliquus superior, so that the patient is unable to turn his eye downwards and laterally. Should the patient attempt to do this, the eye of the affected side is rotated medially, producing diplopia or double vision. Single vision exists in the whole of the field so long as the eyes look above the horizontal plane, diplopia occurs on looking downwards. To counteract this the patient holds his head forwards, and also inclines it to the sound side.

The Trigeminal Nerve

The **trigeminal nerve** is the largest cranial nerve. It is the sensory nerve of the face, the greater part of the scalp, the teeth, the mouth and the nasal

cavity, and the motor nerve of the muscles of mastication. It divides into three branches, viz. the ophthalmic, the maxillary, and the mandibular.

It is attached to the anterior, or ventral, surface of the pons, near its upper border, by a large sensory, and a small motor, root—the latter being placed medial and anterior to the former.

The fibres of the *sensory root* arise from the cells of the *trigeminal* (*semilunar*) *ganglion*. This ganglion (figs. 939, 940) occupies a cavity (cavum trigeminale) in the dura mater covering the trigeminal impression near the apex of the petrous part of the temporal bone (p. 1024). The ganglion is crescentic in shape, with its convexity directed forwards and laterally; its surface is obscured by a number of interlacing nerve fibres. Medially it is in relation with the internal carotid artery and the posterior part of the cavernous sinus; inferiorly, with the motor root of the nerve, the greater superficial petrosal nerve and the foramen lacerum. It receives filaments from the internal carotid plexus of the sympathetic, and gives twigs to the tentorium cerebelli.

The axis-cylinders of the cells of the trigeminal ganglion divide into peripheral and central branches. The former are grouped to form the *ophthalmic* and *maxillary* nerves, and the sensory part of the *mandibular* nerve. The central branches constitute the fibres of the sensory root of the nerve, which leaves the concave margin of the ganglion, runs backwards and medially below the superior petrosal sinus and the tentorium cerebelli, and enters the pons. In the pons these fibres divide into ascending and descending branches. The ascending branches end in the *upper sensory nucleus* of the trigeminal nerve, which is situated in the pons, lateral to, and somewhat deeper than, the motor nucleus (p. 925). It receives fibres conveying discriminative sensibility from the whole trigeminal area and probably some, if not all, of the proprioceptive fibres. The descending branches form what is named the *spinal tract* of the trigeminal nerve. This tract runs downwards through the pons into the medulla oblongata superficial to a nucleus of grey substance which is named the *nucleus of the spinal tract* of the trigeminal nerve. It is continuous inferiorly with the gelatinous substance of the spinal cord, with which it is identical in structure. As the tract descends, a succession of fibres leaves it and enters the nucleus, and the tract gradually diminishes in size, and finally ends in the upper part of the cervical portion of the spinal cord. This nucleus receives fibres conveying crude painful and thermal sensibility from the whole trigeminal area. Clinical evidence tends to show that the fibres of the ophthalmic nerve enter the lower part, those of the maxillary nerve the intermediate part, and those of the mandibular nerve the upper part of the nucleus.*

The mesencephalic nucleus of the trigeminal nerve consists of a strand of cells occupying nearly the whole length of the lateral portion of the central grey matter of the mid-brain. It was originally regarded as an additional motor nucleus, but, on the grounds of its histological characters and its developmental position in the alar lamina, J. B. Johnston has claimed it as a sensory nucleus. Kappers believes that it receives proprioceptive fibres from the muscles of mastication (p. 945). It apparently constitutes a nucleus of origin, as the fibres of the mesencephalic root of the trigeminal nerve, which runs up on its lateral side, pass through the trigeminal ganglion without interruption.

Connexions.—The new fibres which arise in these sensory nuclei cross the median plane and ascend to the lateral nucleus of the thalamus in the trigeminal lemniscus. From the thalamus they are relayed to the cortex of the postcentral gyrus.

The *motor nucleus* of the trigeminal nerve lies in the upper part of the pons, close to its dorsal surface, and along the lateral margin of the floor of the fourth ventricle. It is further from the median plane than the nuclei of the oculomotor and trochlear nerves, and it occupies the position of the branchial (special visceral) efferent column (fig. 840). It receives fibres from the pyramidal tract of the opposite side, and its outgoing fibres form the motor root.

Four small ganglia are associated with the three divisions of the trigeminal nerve, viz.—the *ciliary ganglion* with the ophthalmic nerve; the *sphenopalatine ganglion* with the maxillary nerve; and the *otic* and *submandibular* (*submaxillary*) *ganglia* with the mandibular nerve.

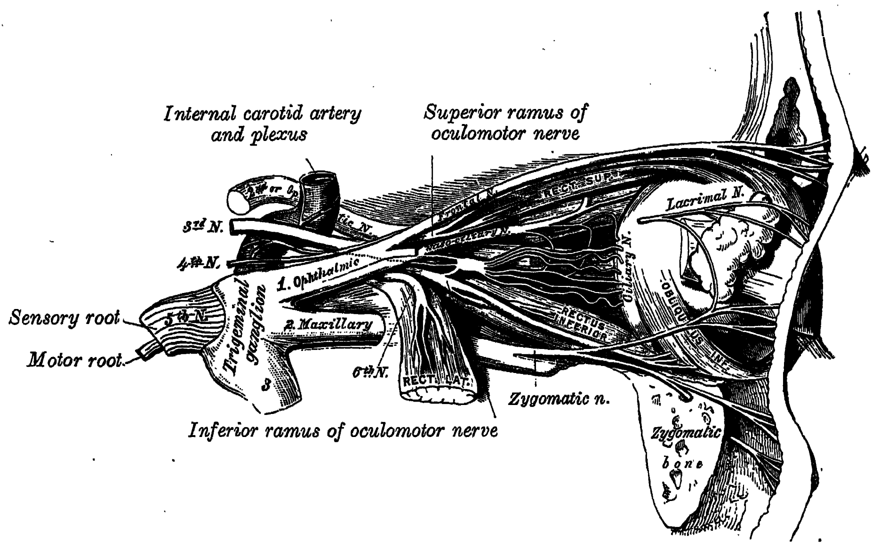
* See an article by J. S. B. Stopford, *Journal of Anatomy*, vol. lix.

The Ophthalmic Nerve (figs. 939, 940)

The **ophthalmic nerve**, the first division of the trigeminal nerve, is a sensory nerve. It supplies branches to the eyeball, the lacrimal gland and the conjunctiva, to a part of the mucous membrane of the nasal cavity, and to the skin of the nose, eyelids, forehead and scalp. It is the smallest division of the trigeminal nerve, and arises from the anteromedial part of the trigeminal ganglion as a flattened band, about 2·5 cm. long, which passes forwards along the lateral wall of the cavernous sinus below the oculomotor and trochlear nerves ; just before entering the orbit through the superior orbital fissure, it divides into three branches, viz. *lacrimal*, *frontal* and *nasociliary*.

The ophthalmic nerve is joined by filaments from the internal carotid plexus of the sympathetic, and communicates with the oculomotor, trochlear and abducent nerves ; it supplies a recurrent branch (n. tentorii), which crosses and adheres to the trochlear nerve, and is distributed to the tentorium cerebelli.

Fig. 940.—The nerves of the right orbit, and the ciliary ganglion. Lateral aspect.



The **lacrimal nerve** (fig. 939) is the smallest branch of the ophthalmic nerve. It sometimes receives a filament from the trochlear nerve, but possibly this filament consists of fibres which have previously passed from the ophthalmic to the trochlear nerve. The lacrimal nerve enters the orbit through the lateral part of the superior orbital fissure, runs along the upper border of the rectus lateralis with the lacrimal artery, and receives a twig from the zygomatic branch of the maxillary nerve, conveying some secretomotor fibres for the lacrimal gland. It enters the lacrimal gland and gives off several filaments to the gland and the conjunctiva. Finally it pierces the orbital septum, and ends in the skin of the upper eyelid, joining with filaments of the facial nerve.

The lacrimal nerve is occasionally absent, and its place is then taken by the zygomaticotemporal branch of the maxillary nerve. Sometimes the latter branch is absent and a continuation of the lacrimal is substituted for it.

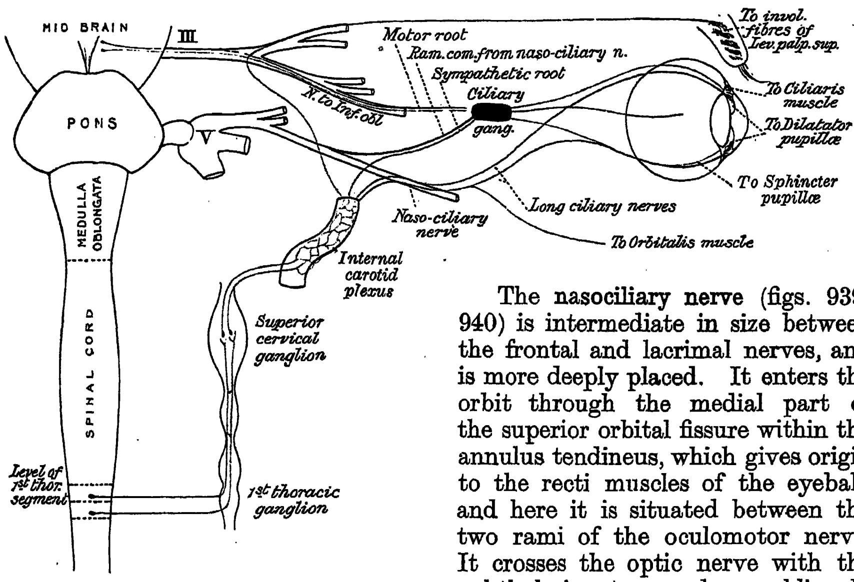
The **frontal nerve** (figs. 939, 940) is the largest branch of the ophthalmic nerve. It enters the orbit through the superior orbital fissure above the muscles, and runs forwards between the levator palpebræ superioris and the periosteum. About midway between the apex and base of the orbit it divides into a small supratrochlear and a large supra-orbital branch.

The *supratrochlear nerve* runs medially and forwards, passes above the pulley of the obliquus superior, and gives off a descending filament to join the infratrochlear branch of the nasociliary nerve. The nerve then emerges

from the orbit between the pulley of the obliquus superior and the supra-orbital foramen, curves upwards on the forehead close to the bone in company with the supratrochlear branch of the ophthalmic artery, and sends filaments to the conjunctiva and skin of the upper eyelid; it then ascends under cover of the corrugator and the frontal belly of the occipitofrontalis, and divides into branches which pierce these muscles and supply the skin of the lower part of the forehead close to the median plane.

The *supra-orbital nerve* runs forwards between the levator palpebræ superioris and the roof of the orbit, passes through the supra-orbital notch or foramen, and gives off palpebral filaments to the upper eyelid and conjunctiva. It then ascends upon the forehead with the supra-orbital artery, and divides into a smaller medial and a larger lateral, branch, which supply the skin of the scalp, reaching nearly as far back as the lambdoid suture. These two branches are at first situated deep to the frontal belly of the occipitofrontalis; the medial branch perforates this muscle, the lateral branch pierces the epicranial aponeurosis. Both branches supply small twigs to the mucous membrane of the frontal sinus and to the pericranium.

FIG. 941.—A scheme showing the roots and the branches of distribution of the ciliary ganglion.



The **nasociliary nerve** (figs. 939, 940) is intermediate in size between the frontal and lacrimal nerves, and is more deeply placed. It enters the orbit through the medial part of the superior orbital fissure within the annulus tendineus, which gives origin to the recti muscles of the eyeball, and here it is situated between the two rami of the oculomotor nerve. It crosses the optic nerve with the ophthalmic artery, and runs obliquely below the rectus superior and obliquus superior, to the medial wall of the orbital cavity. Here, under the name of the *anterior ethmoidal nerve*, it passes through the anterior ethmoidal foramen and canal and, entering the cavity of the cranium, traverses a shallow groove on the lateral margin of the front part of the cribriform plate of the ethmoid bone, beneath the dura mater; it then descends through a slit at the side of the crista galli into the nasal cavity, and lies in a groove on the inner surface of the nasal bone. It supplies two *internal nasal branches*—a medial to the mucous membrane of the front part of the nasal septum, and a lateral to the anterior part of the lateral wall of the nasal cavity. Finally it emerges, as the *external nasal branch*, between the lower border of the nasal bone and the upper nasal cartilage, and, passing down under cover of the compressor naris muscle, supplies the skin of the ala, the apex and the vestibule of the nose.

The nasociliary nerve gives off a communicating branch to the ciliary ganglion, the long ciliary, the infratrochlear and the posterior ethmoidal nerves.

The *ramus communicans to the ciliary ganglion* usually arises from the nasociliary nerve as the latter enters the orbital cavity. It passes forwards on the lateral side of the optic nerve, and enters the posterosuperior angle of the

ciliary ganglion ; it is sometimes joined by a filament from the internal carotid plexus of the sympathetic, or from the superior ramus of the oculomotor nerve.

The *long ciliary nerves*, two or three in number, are given off from the nasociliary nerve, as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the sclera near the attachment of the optic nerve, and, running forwards between the sclera and the choroid, are distributed to the ciliary body, iris and cornea; they usually contain the sympathetic fibres for the dilatator pupillæ.

The *infratrochlear nerve* is given off from the nasociliary nerve near the anterior ethmoidal foramen. It runs forwards along the medial wall of the orbit above the upper border of the rectus medialis, and is joined, near the pulley of the obliquus superior, by a filament from the supratrochlear nerve. It then escapes from the orbit below the pulley of the obliquus superior ; it supplies branches to the skin of the eyelids and side of the nose above the medial angle of the eye, the conjunctiva, lacrimal sac and caruncula lacrimalis.

The *posterior ethmoidal nerve* leaves the orbital cavity through the posterior ethmoidal foramen and gives twigs to the ethmoidal and sphenoidal sinuses. This nerve is absent in about thirty per cent. of subjects.

The **ciliary ganglion** (figs. 938, 940, 941) is a small, flattened ganglion, of a reddish-grey colour, and about the size of a pin's head; it is situated near the apex of the orbit, in some loose fat between the optic nerve and the rectus lateralis muscle, lying generally on the lateral side of the ophthalmic artery.

Its *connexions* (fig. 941) are three in number, and enter it posteriorly. A ramus communicans is derived from the nasociliary nerve. The motor root which is a thick nerve (occasionally divided into two parts) is derived from the branch of the oculomotor nerve to the obliquus inferior. The third, the sympathetic root, is a slender filament from the internal carotid plexus of the sympathetic ; it is frequently blended with the ramus communicans from the nasociliary nerve.

Its *branches* are the short ciliary nerves. These are delicate filaments, from six to ten in number, which arise from the front of the ganglion in two bundles, of which the lower bundle is the larger. They run forwards with the ciliary arteries in a wavy course, one set above the optic nerve, the other below, and are related to the long ciliary nerves. They subdivide into about fifteen or twenty branches, which pierce the sclera around the entrance of the optic nerve, pass forwards in delicate grooves on the inner surface of the sclera, and are distributed to the ciliary muscle, iris and cornea.

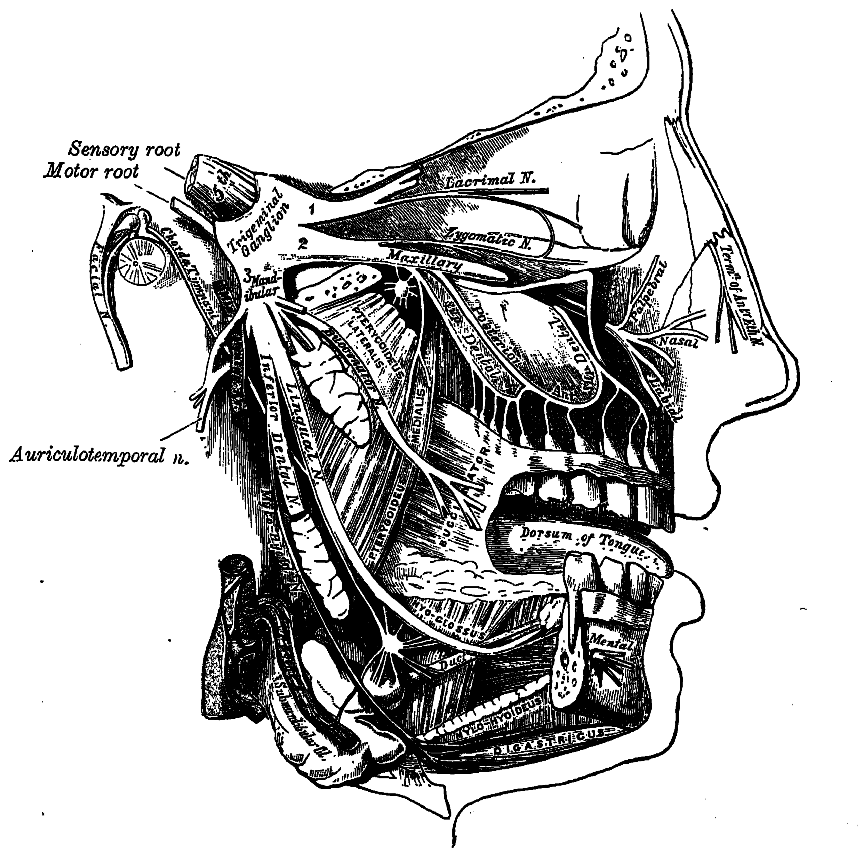
The Maxillary Nerve (fig. 942)

The **maxillary nerve**, or second division of the trigeminal nerve, is a sensory nerve, and is intermediate in position and size between the ophthalmic and mandibular nerves. It begins at the middle of the trigeminal ganglion as a flattened plexiform band, and, passing horizontally forwards along the lower part of the lateral wall of the cavernous sinus, leaves the skull through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the upper part of the pterygopalatine fossa, inclines laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla, and enters the orbit through the inferior orbital fissure. It is now named the **infra-orbital nerve** and, having traversed the infra-orbital groove and canal in the floor of the orbit, it appears on the face through the infra-orbital foramen. At its termination the nerve lies under cover of the levator labii superioris, and divides into branches which are distributed to the side of the nose, the lower eyelid, the skin and mucous membrane of the cheek and upper lip, and join with filaments of the facial nerve.

In view of the fact that the mouth is generally regarded as representing a pair of fused visceral clefts, the maxillary nerve can be described as the pretrematic

and the mandibular nerve as the post-trematic branch of the trigeminal nerve. The maxillary nerve supplies the structures derived from the maxillary process, but it extends on to structures which are developed from the median nasal process and its fused globular processes (p. 94).

FIG. 942.—The right maxillary and mandibular nerves, and the submandibular ganglion.



The *branches* of the maxillary nerve may be divided into four groups, according as they are given off in the cranium, in the pterygopalatine fossa, in the infra-orbital canal, or on the face.

In the cranium . . .	Meningeal.
In the pterygopalatine fossa .	Zygomatic. Ganglionic. Posterior superior dental.
In the infra-orbital canal .	Middle superior dental. Anterior superior dental.
On the face	Palpebral. Nasal. Labial.

The **meningeal nerve** is given off from the maxillary nerve near the trigeminal ganglion; it accompanies the anterior branch of the middle meningeal artery and supplies the dura mater of the middle cranial fossa.

The **zygomatic nerve** (fig. 940) arises in the pterygopalatine fossa, enters the orbit by the inferior orbital fissure, courses along the lateral wall of the orbit, and divides into two branches, zygomaticotemporal and zygomatico-facial.

The *zygomaticotemporal branch* runs along the lateral wall of the orbit, sends a branch to join the lacrimal nerve (p. 1044), and, passing through a canal in the zygomatic bone, enters the temporal fossa. It ascends between the bone and the temporalis muscle, pierces the temporal fascia about 2 cm. above the zygomatic arch, and is distributed to the skin of the temple. It communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve. As it pierces the temporal fascia, it sends a slender twig between the two layers of the fascia towards the lateral angle of the eye.

The *zygomaticofacial branch* passes along the inferolateral angle of the orbit, emerges upon the face through a foramen in the zygomatic bone, and, perforating the orbicularis oculi, supplies the skin on the prominence of the cheek. It joins the zygomatic branches of the facial nerve and the palpebral branches of the maxillary nerve.

The **ganglionic branches** (sphenopalatine nerves), two in number, descend towards the sphenopalatine ganglion, but only a few of their fibres enter the ganglion.

The **posterior superior dental (alveolar) branches** (fig. 942) arise from the maxillary nerve just before it enters the infra-orbital groove; they are generally two in number, but sometimes they arise by a single trunk. They descend on the posterior surface of the maxilla and give off twigs to the gums and adjoining parts of the mucous membrane of the cheek. They then enter the posterior dental canals on the posterior surface of the maxilla, and, passing forwards in the substance of the bone, communicate with the middle superior dental nerve, and give off branches to the lining membrane of the maxillary sinus and twigs to each molar tooth; these twigs enter the foramina at the apices of the roots of the teeth.

The **middle superior dental (alveolar) branch** is given off from the infra-orbital nerve in the posterior part of the infra-orbital canal, and runs downwards and forwards in a canal in the lateral wall of the maxillary sinus to supply the two premolar teeth. It forms a superior dental plexus with the anterior and posterior superior dental branches.

The **anterior superior dental (alveolar) branch** (fig. 942) leaves the lateral side of the infra-orbital nerve in the front part of the infra-orbital canal, and runs in a canal in the anterior wall of the maxillary sinus. At first it curves beneath the infra-orbital foramen and passes medially towards the nose; it then turns downwards and divides into branches which supply the incisor and canine teeth. It communicates with the middle superior dental branch, and gives off a *nasal branch*, which passes through a minute canal in the lateral wall of the inferior meatus, and supplies the mucous membrane of the anterior part of the inferior meatus and the floor of the nasal cavity, communicating with the nasal branches from the sphenopalatine ganglion.

The **palpebral branches** ascend behind the orbicularis oculi. They supply the skin and conjunctiva of the lower eyelid, and join with the facial and zygomaticofacial nerves near the lateral angle of the eye.

The **nasal branches** supply the skin of the side of the nose and of the movable part of the nasal septum, and join with the external nasal branch of the anterior ethmoidal nerve.

The **labial branches** are large and numerous; they descend behind the levator labii superioris, and supply the skin of the anterior part of the cheek, the skin of the upper lip, the mucous membrane of the mouth, and the labial glands. They are joined by branches from the facial nerve, and form with them the *infra-orbital plexus*.

The **sphenopalatine ganglion** (fig. 943) is the largest of the ganglia associated with the branches of the trigeminal nerve, and is deeply placed in the pterygopalatine fossa, close to the sphenopalatine foramen and in front of the pterygoid canal. It is somewhat flattened, of a reddish-grey colour, and is situated just below the maxillary nerve as it crosses the fossa. It receives ganglionic branches from the maxillary nerve, and sympathetic and, probably, parasympathetic branches from the nerve of the pterygoid canal (fig. 943).

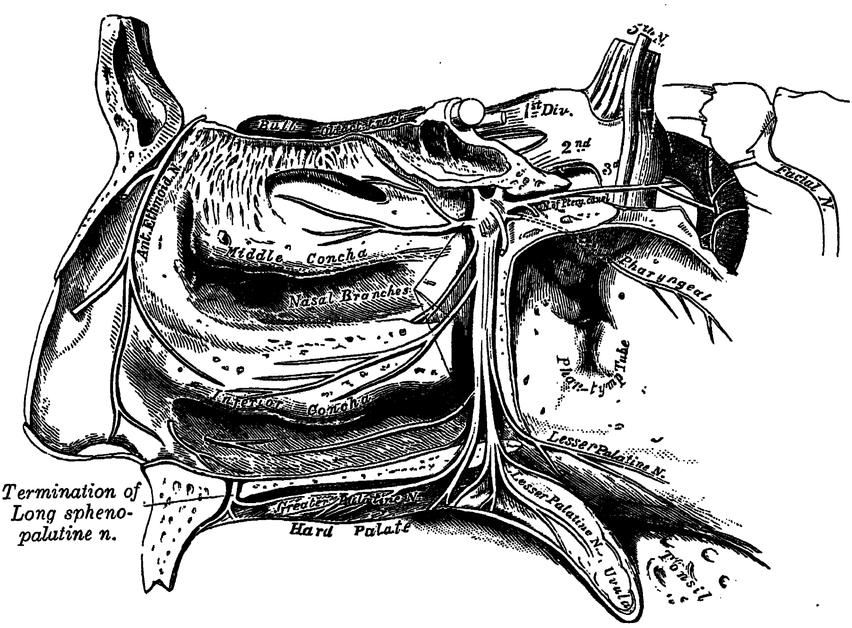
Most of the fibres conveyed by the *ganglionic branches* are not relayed in the ganglion but pass directly into the palatine and nasal nerves which spring from the ganglion.

The *nerve of the pterygoid canal* is formed by the union of the greater superficial petrosal and the deep petrosal nerve.

The *greater superficial petrosal nerve* is given off from the (genicular) ganglion of the facial nerve; it receives a branch from the tympanic plexus, passes through the hiatus on the anterior surface of the petrous part of the temporal bone, and runs forwards beneath the dura mater in a groove on the bone. It traverses the fibrocartilage which fills the foramen lacerum, and there unites with the deep petrosal nerve to form the *nerve of the pterygoid canal.*

The *deep petrosal nerve* is given off from the carotid sympathetic plexus, and runs through the carotid canal lateral to the internal carotid artery. It then enters the fibrocartilage which fills the foramen lacerum, and joins with the greater superficial petrosal nerve to form the nerve of the pterygoid canal.

FIG. 943.—The right sphenopalatine ganglion and its branches.



The *nerve of the pterygoid canal* runs forward through the pterygoid canal, where it is accompanied by the corresponding artery, and is joined by a small ascending branch from the otic ganglion. Finally, it enters the pterygopalatine fossa and joins the sphenopalatine ganglion.

The *branches* of the sphenopalatine ganglion are divisible into four groups, viz. orbital, palatine, nasal, and pharyngeal.

The *orbital branches* are two or three delicate filaments which enter the orbit by the inferior orbital fissure, and are distributed to the periosteum and the orbitalis muscle; some twigs pass through the posterior ethmoidal foramen to the sphenoidal and ethmoidal sinuses, and others are said to convey some of the secretomotor fibres to the lacrimal gland.

The *palatine nerves* (fig. 943) are distributed to the roof of the mouth, the soft palate, the tonsil, and the lining membrane of the nasal cavity. Most of their fibres are derived from the ganglionic branches of the maxillary nerve.

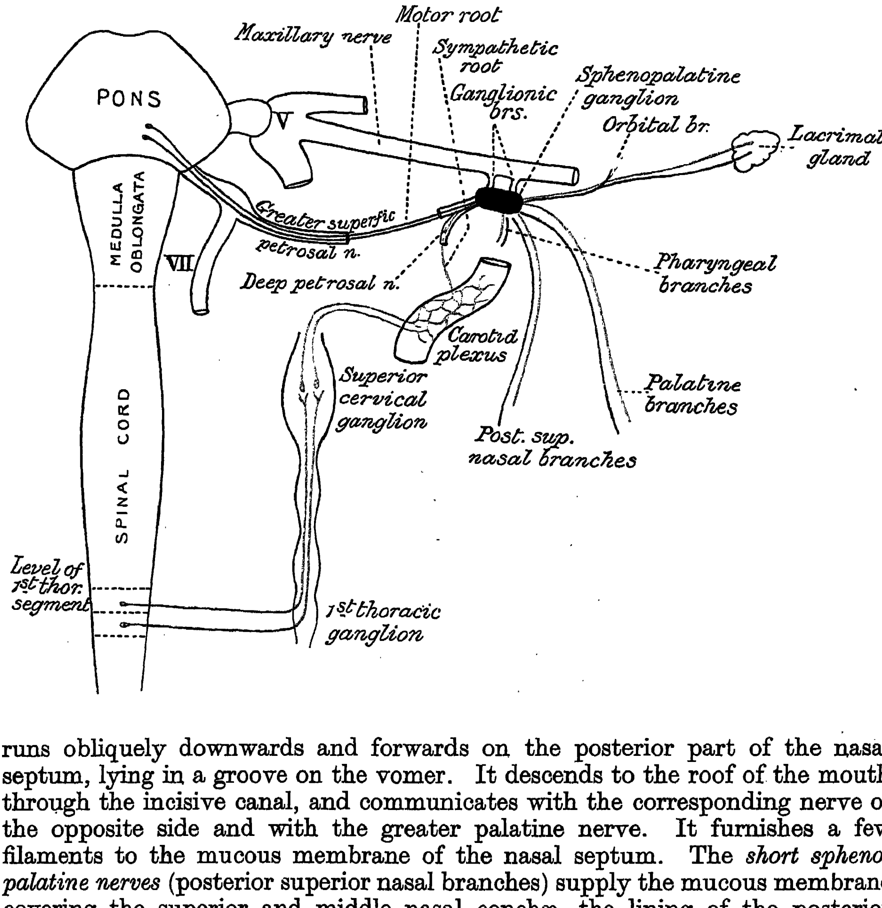
The *greater palatine nerve* (anterior palatine nerve) descends through the greater palatine canal (pterygopalatine canal), emerges upon the hard palate through the greater palatine foramen, and runs forwards in a groove on the inferior surface of the bony palate, nearly as far as the incisor teeth. It supplies the gums, and the mucous membrane and glands of the hard palate, and communicates in front with terminal filaments of the long sphenopalatine (naso-

palatine) nerve. While in the greater palatine canal, it gives off *nasal branches*, which emerge through openings in the perpendicular plate of the palatine bone, and ramify over the inferior nasal concha and the walls of the middle and inferior meatuses ; at its exit from the canal, palatine branches are distributed to both surfaces of the soft palate.

The *lesser palatine nerves* (middle and posterior palatine nerves) descend through the greater palatine canal, emerge through the lesser palatine foramina and supply branches to the uvula, tonsil and soft palate.

The long and short sphenopalatine nerves enter the nasal cavity through the sphenopalatine foramen. The *long sphenopalatine* (nasopalatine) *nerve* crosses the roof of the nasal cavity below the orifice of the sphenoidal sinus, and then

Fig. 944.—A scheme showing the roots and the branches of distribution of the sphenopalatine ganglion.



runs obliquely downwards and forwards on the posterior part of the nasal septum, lying in a groove on the vomer. It descends to the roof of the mouth through the incisive canal, and communicates with the corresponding nerve of the opposite side and with the greater palatine nerve. It furnishes a few filaments to the mucous membrane of the nasal septum. The *short sphenopalatine nerves* (posterior superior nasal branches) supply the mucous membrane covering the superior and middle nasal conchæ, the lining of the posterior ethmoidal sinuses and the posterior part of the nasal septum.

The *pharyngeal nerve*, a small branch, arises from the posterior part of the ganglion, passes through the palatinovaginal (pharyngeal) canal with the pharyngeal branch of the maxillary artery, and is distributed to the mucous membrane of the nasal part of the pharynx, behind the pharyngotympanic (auditory) tube.

The Mandibular Nerve (figs. 942, 945)

The **mandibular nerve** supplies the teeth and gums of the mandible, the skin of the temporal region, part of the auricle, the lower lip, the lower part of the face, and the muscles of mastication ; it also supplies the mucous membrane

of the anterior two-thirds of the tongue and the floor of the mouth. It is the largest division of the trigeminal nerve, and is made up of two roots : a large, sensory root, which proceeds from the lateral part of the trigeminal (semilunar) ganglion and emerges almost immediately through the foramen ovale of the sphenoid bone ; and a small motor root (the motor part of the trigeminal) which passes below the ganglion, and unites with the sensory root, just outside the foramen ovale, where the nerve lies between the tensor palati muscle medially and the lateral pterygoid laterally. Immediately beyond the junction of the two roots the nerve sends off from its medial side the nervus spinosus and the nerve to the medial pterygoid muscle, and then divides into a small anterior and a large posterior trunk.

The **nervus spinosus** enters the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater ; the posterior branch also supplies a twig to the mucous lining of the mastoid air-cells ; the anterior communicates with the meningeal branch of the maxillary nerve.

The **nerve to the medial pterygoid muscle** is a slender branch which enters the deep surface of the muscle; it gives one or two filaments to the otic ganglion.

The small anterior trunk gives off (*a*) a sensory branch named the buccal (buccinator) nerve, and (*b*) motor branches, viz. the masseteric, deep temporal and lateral pterygoid nerves.

The **buccal nerve** (buccinator nerve) (fig. 945) passes forwards between the two heads of the lateral pterygoid, and downwards beneath or through the lower part of the temporal muscle ; it emerges from under the anterior border of the masseter, and unites with the buccal branches of the facial nerve. It furnishes a branch to the lateral pterygoid during its passage through that muscle, and may give off the anterior deep temporal nerve. The buccal nerve supplies the skin over the anterior part of the buccinator muscle, and the mucous membrane lining its inner surface and the posterior part of the buccal surface of the gum.

The **masseteric nerve** (fig. 945) passes laterally, above the lateral pterygoid, in front of the mandibular articulation, and behind the tendon of the temporal muscle ; it crosses the posterior part of the mandibular notch with the masseteric artery, ramifies in the deep surface of the masseter, and gives a filament to the mandibular joint.

The **deep temporal nerves** are usually two in number, anterior and posterior. They pass above the upper border of the lateral pterygoid and enter the deep surface of the temporal muscle. The *posterior branch*, of small size, is placed at the posterior part of the temporal fossa, and sometimes arises in common with the masseteric nerve. The *anterior branch* is frequently given off from the buccal nerve, and then ascends over the upper head of the lateral pterygoid. A third, or intermediate, branch is often present.

The **nerve to the lateral pterygoid** enters the deep surface of the muscle. It may arise separately from the anterior division of the mandibular nerve, or in conjunction with the buccal nerve.

The large posterior trunk of the mandibular nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into auriculotemporal, lingual and inferior dental (inferior alveolar) nerves.

The **auriculotemporal nerve** generally arises by two roots, which encircle the middle meningeal artery (fig. 942). It runs backwards under cover of the lateral pterygoid on the surface of the tensor palati and passes between the sphenomandibular ligament and the neck of the mandible. It then passes laterally behind the mandibular joint in relationship with the upper part of the parotid gland. Finally it ascends, posterior to the superficial temporal vessels, over the zygomatic arch, and divides into superficial temporal branches.

The auriculotemporal nerve communicates with the facial nerve and the otic ganglion. The branches to the facial nerve, usually two in number, pass forwards and laterally behind the neck of the mandible and join the facial nerve at the posterior border of the masseter. The filaments to the otic ganglion are derived from the roots of the auriculotemporal nerve close to their origin.

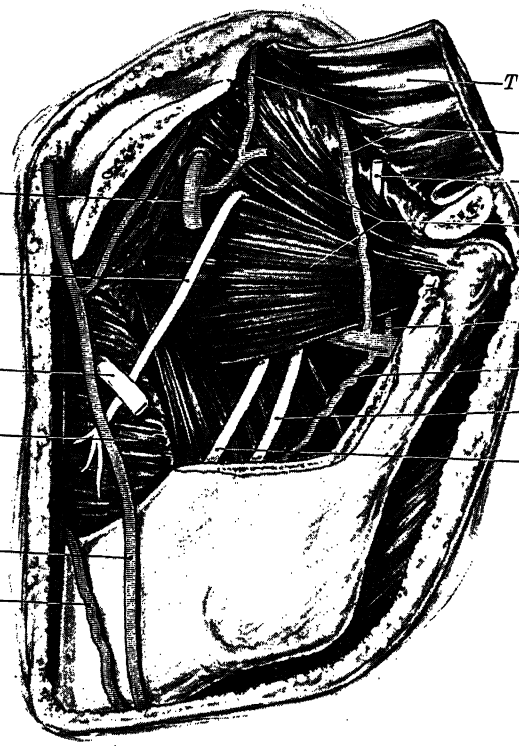
The *branches* of the auriculotemporal nerve are the anterior auricular, branches to the external auditory meatus, articular, parotid and superficial temporal.

The *auricular branches* are usually two in number: they supply the front of the upper part of the auricle, being distributed principally to the skin covering the front of the helix and tragus.

The *branches to the external auditory meatus*, two in number, pass between the bony and cartilaginous parts of the meatus, and supply the skin of the meatus; the upper one sends a twig to the tympanic membrane.

The *articular branches* consist of one or two twigs which enter the posterior part of the mandibular joint.

Fig. 945.—A dissection of the left pterygoid region, showing some of the branches of the mandibular nerve and the internal maxillary artery.



The *parotid branches* convey secretomotor fibres to the parotid gland. These are originally derived from the glossopharyngeal nerve and travel by the lesser superficial petrosal nerve and the otic ganglion to reach the auriculotemporal nerve.

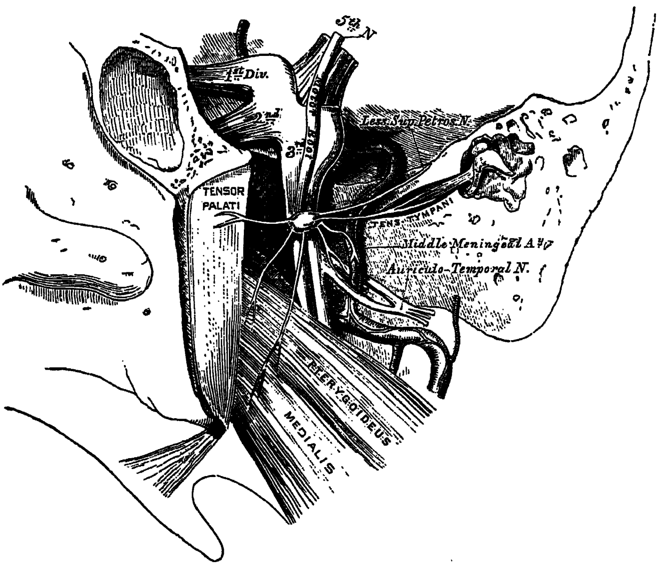
The *superficial temporal branches* accompany the superficial temporal artery and its terminal branches; they supply the skin of the temporal region and communicate with the facial and zygomaticotemporal nerves.

The **lingual nerve** (fig. 942) is sensory to the mucous membrane of the anterior two-thirds of the tongue, and to the floor of the mouth and the mandibular gums.

It arises from the posterior division of the mandibular nerve, and lies at first in relation with the deep surface of the lateral pterygoid muscle, where it is joined by the chorda tympani branch of the facial nerve, and frequently by a branch of the inferior dental nerve. Emerging from under cover of the lateral pterygoid muscle the lingual nerve proceeds downwards and forwards between the ramus of the mandible and the medial pterygoid muscle, lying anterior to, and slightly deeper than the inferior dental nerve. It then

passes below the mandibular origin of the superior constrictor of the pharynx, and lies against the deep surface of the mandible on the medial side of the roots of the third molar tooth, where it is covered only by the mucous membrane of the mouth. It next crosses the styloglossus, and runs on the lateral surface of the hyoglossus and deep to the mylohyoid muscle ; here it is placed above the deep part of the submandibular (submaxillary) gland and its duct. It then proceeds forwards on the side of the tongue, lying lateral to the hyoglossus and genioglossus, and divides into its terminal branches, which lie directly under cover of the mucous membrane of the tongue. In the latter part of its course the nerve is in close relation with the submandibular duct ; it passes from above downwards and forwards on the lateral side of the duct, and, then winding below it, runs upwards and forwards on its medial side.

FIG. 946.—The right otic ganglion and its branches displayed from the medial side.



In addition to receiving the chorda tympani and the branch from the inferior dental nerve, already referred to, the lingual nerve sends two or three branches to the submandibular (submaxillary) ganglion, and, at the anterior margin of the hyoglossus muscle, forms loops of communication with twigs of the hypoglossal nerve.

The *branches* of the lingual nerve supply the sublingual gland, the mucous membrane of the mouth, the lingual surface of the gums, and the mucous membrane of the anterior two-thirds of the tongue ; the terminal filaments join, at the tip of the tongue, with those of the hypoglossal nerve.

The **inferior dental nerve** descends with the inferior dental artery, at first under cover of the lateral pterygoid muscle, and then between the sphenomandibular ligament and the ramus of the mandible to the mandibular foramen. Here it enters the mandibular canal, and runs below the teeth as far as the mental foramen, where it divides into an incisive and a mental branch.

The inferior dental nerve gives off the mylohyoid nerve, branches to the molar and premolar teeth of the mandible, the incisive and the mental nerves.

The *mylohyoid nerve* is derived from the inferior dental nerve just before the latter enters the mandibular foramen. It pierces the sphenomandibular ligament, descends in a groove on the medial surface of the ramus of the mandible, and reaching the under surface of the mylohyoid supplies this muscle and the anterior belly of the digastric.

The branches to the molar and premolar teeth supply the adjoining gum also. Before they enter the roots of the teeth they communicate with one another and form an inferior dental plexus.

The *incisive branch* is continued onwards within the bone and supplies the canine and incisor teeth.*

The *mental nerve* emerges at the mental foramen, and divides beneath the depressor anguli oris muscle into three branches; one descends to the skin of the chin, and two ascend to the skin and mucous membrane of the lower lip; these branches communicate freely with the facial nerve (mandibular branch).

Two small ganglia, named the otic and the submandibular, are connected with the mandibular nerve.

The **otic ganglion** (figs. 946, 947) is a small, oval-shaped, flattened ganglion of a reddish-grey colour, situated immediately below the foramen ovale; it lies on the medial surface of the mandibular nerve, and surrounds the origin of the nerve to the medial pterygoid muscle. It is in relation *laterally* with the trunk of the mandibular nerve at the point where the motor and sensory roots join; *medially*, with the tensor palati, by which it is separated from the cartilaginous part of the pharyngotympanic (auditory) tube; *posteriorly*, with the middle meningeal artery.

It is connected by two or three short filaments with the nerve to the medial pterygoid muscle (fig. 947). It communicates with the glossopharyngeal and facial nerves, through the lesser superficial petrosal nerve continued from the tympanic plexus, and through this nerve receives parasympathetic roots from the glossopharyngeal nerve; its sympathetic roots are from the sympathetic plexus on the middle meningeal artery.

Branches.—A twig ascends from the otic ganglion to join the nerve of the pterygoid canal, and another connects the ganglion with the chorda tympani nerve. Two or more branches run backwards and join the roots of the auriculotemporal nerve; these branches probably carry secretomotor fibres from the glossopharyngeal nerve to the parotid gland. A filament is supplied to the tensor tympani muscle, and another to the tensor palati muscle. The former passes backwards, lateral to the pharyngotympanic tube; the latter arises from the ganglion, near the origin of the nerve to the medial pterygoid and is directed forwards. The fibres of the nerves to the tensor tympani and tensor palati are mainly derived from the nerve to the medial pterygoid muscle.

The **submandibular ganglion** (submaxillary ganglion) (figs. 942, 948) is small, and somewhat fusiform in shape. It is situated on the upper part of the hyoglossus, and deep to the posterior fibres of the mylohyoid muscle. Here it is placed above the deep part of the submandibular gland and below the lingual nerve, and is suspended from the latter by an anterior and a posterior filament. Through the posterior filament it receives fibres from the lingual and chorda tympani nerves. Sympathetic fibres are conveyed to the ganglion from the plexus on the cervical part of the facial artery (fig. 942).

Five or six branches arise from the ganglion, and supply the mucous membrane of the mouth, and the submandibular gland and its duct. Fibres pass through the filament connecting the fore part of the ganglion to the lingual nerve, and are conveyed to the sublingual gland and the tongue.

The mandibular nerve is distributed to the structures derived from the mandibular arch, and represents the post-trematic branch of the trigeminal nerve. The connexion of the nerve with the arch is indicated by: (1) its close relationship to the sphenomandibular ligament and the mandible; (2) its distribution to the anterior portion of the tongue; (3) its distribution to the anterosuperior part of the auricle; and (4) its union with the pretrematic nerve of the hyomandibular cleft, viz. the chorda tympani branch of the facial nerve.

Applied Anatomy.—A lesion of the whole trigeminal nerve causes anaesthesia of the corresponding anterior half of the scalp, of the face (excepting a small area near the angle of the mandible supplied by the great auricular nerve), of the cornea and conjunctiva, and of the mucous membranes of the nose, mouth and tongue. Paralysis and atrophy occur in the muscles supplied by the nerve and, when the mouth is opened the mandible is thrust

* According to C. Starkie and D. Stewart (*Journal of Anatomy*, vol. lxv. 1931), the nerves which supply the incisor teeth form an elaborate plexus on the external aspect of the mandible, after emerging from the mental foramen and before they enter the bone. The canine tooth may be supplied either from the incisor plexus or from the plexus which innervates the premolars.

FIG. 947.—A scheme showing the connexions and branches of the otic ganglion.

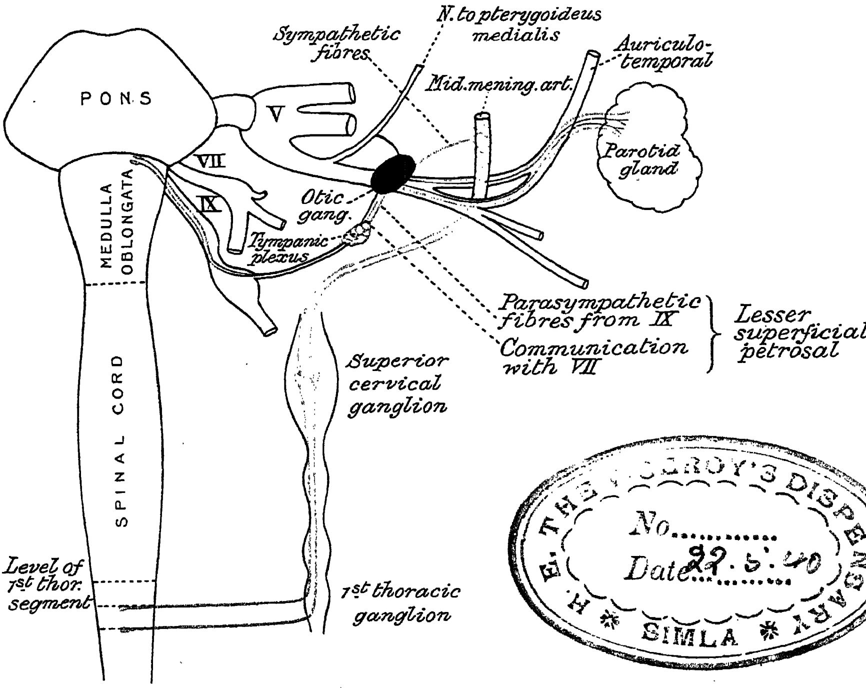


FIG. 948.—A scheme showing the connexions and branches of the submandibular ganglion.

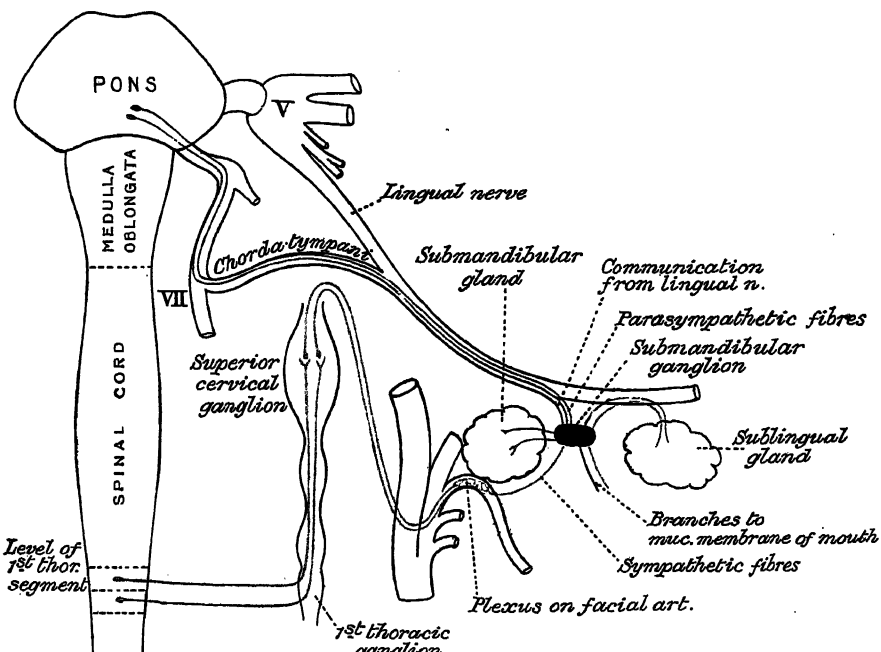
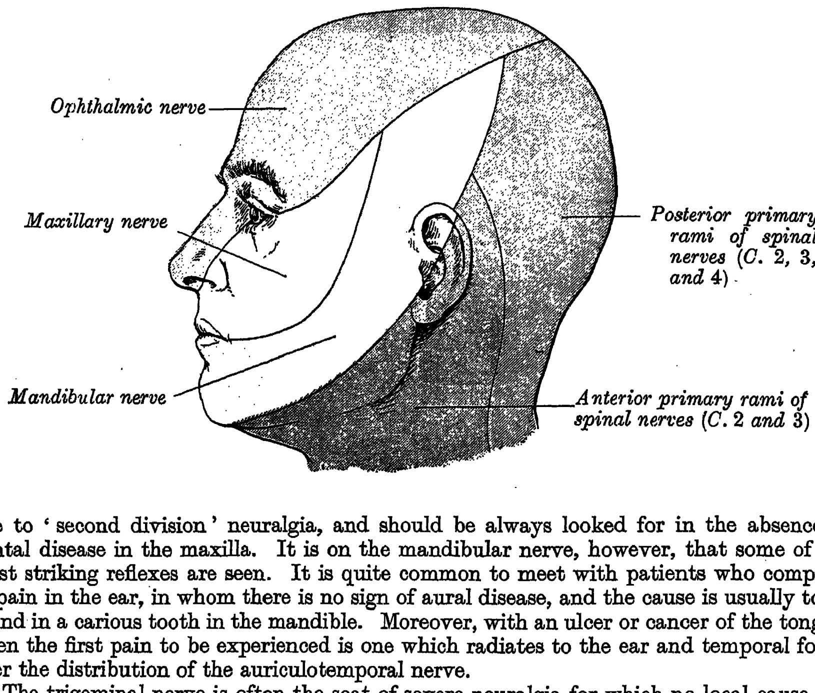


over to the paralysed side. Lesions of the divisions of the nerve give a more limited sensory loss and, if affecting the lingual nerve below the point at which it is joined by the chorda tympani, will be accompanied by loss of taste in the corresponding half of the anterior part of the tongue.

Trigeminal nerve reflexes.—Pains referred to various branches of the trigeminal nerve are of very frequent occurrence. As a general rule the diffusion of pain over the various branches of the nerve is at first confined to one only of the main divisions, although in severe cases pain may radiate over the branches of the other main divisions. The commonest example of this condition is the neuralgia which is so often associated with dental caries —here, although the tooth itself may not appear to be painful, the most distressing referred pains may be experienced, and these are at once relieved by treatment directed to the affected tooth.

Many other examples of trigeminal reflexes could be quoted, but it will be sufficient to mention the more common ones. In the area of the ophthalmic nerve, severe supra-orbital pain is commonly associated with acute glaucoma or with disease of the frontal or ethmoidal sinuses. Malignant growths or empyema of the maxillary sinus, or unhealthy conditions about the inferior conchæ or the septum of the nose, are often found giving

FIG. 949.—A diagram showing the cutaneous nerve-areas of the face and scalp.



rise to ' second division ' neuralgia, and should be always looked for in the absence of dental disease in the maxilla. It is on the mandibular nerve, however, that some of the most striking reflexes are seen. It is quite common to meet with patients who complain of pain in the ear, in whom there is no sign of aural disease, and the cause is usually to be found in a carious tooth in the mandible. Moreover, with an ulcer or cancer of the tongue, often the first pain to be experienced is one which radiates to the ear and temporal fossa, over the distribution of the auriculotemporal nerve.

The trigeminal nerve is often the seat of severe neuralgia for which no local cause can be discovered; each of the three divisions has been divided, or a portion of nerve excised for this affection, usually, however, with only temporary relief.

The lingual nerve is occasionally divided with a view to relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line be drawn from the middle of the crown of the last molar tooth to the angle of the mandible it will cross the nerve, which lies about 1·25 cm. behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone.

In severe cases of neuralgia of the trigeminal nerve, the trunks of the maxillary and mandibular nerves may be injected with alcohol; if this treatment fails the trigeminal ganglion may be removed in whole or in part, or the sensory root of the nerve may be divided. Attempts at avulsion of the whole ganglion, however, frequently result in death owing to laceration of the cavernous sinus during the exposure and separation of the ophthalmic nerve from the ganglion. In cases where the neuralgia has been limited to the maxillary nerve intracranial resection of that nerve alone has been performed with great success. In other cases where the disease has not affected the ophthalmic division, resection of the lateral half of the ganglion only, with the maxillary and mandibular nerves, has been performed, thus leaving the sensory nerve supply to the cornea intact. The motor

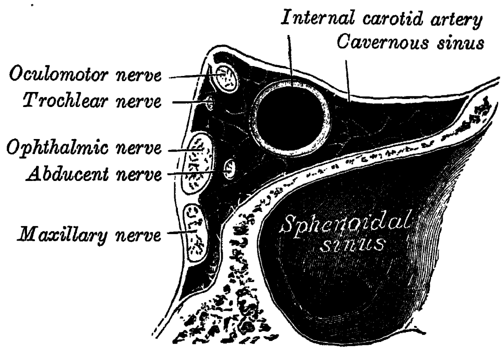
root is usually resected with the mandibular nerve, leading to complete paralysis of the muscles of mastication on that side. In the most recent operation the sensory root is divided behind the trigeminal ganglion; the motor root may in this way be left intact.

The Abducent Nerve (fig. 940)

The **abducent nerve** supplies the lateral rectus muscle of the eyeball.

Its fibres arise from a small nucleus which is situated in the upper part of the floor of the fourth ventricle, close to the median plane and beneath the colliculus facialis. They pass downwards and forwards through the pons, and emerge in the furrow between the lower border of the pons and the upper end of the pyramid of the medulla oblongata.

Fig. 950.—An oblique section through the left cavernous sinus. Posterior aspect.



The **nucleus** of the abducent nerve represents the somatic efferent column and retains its primitive position close to the median plane (p. 910).

Connexions.—The nucleus of the abducent nerve receives fibres from: (1) the pyramidal tract of the opposite side; (2) the medial longitudinal bundle, by which it is connected with the nuclei of the third, fourth and eighth cranial nerves; and (3) the tectobulbar tract, by which it is connected with the visual cortex through the medium of the superior quadrigeminal body.

After leaving the surface of the brain-stem, the abducent nerve runs upwards, forwards and laterally through the cisterna pontis, and usually dorsal to the anterior inferior cerebellar artery. It pierces the dura mater lateral to the dorsum sellæ of the sphenoid bone and then bends sharply forwards as it crosses the superior border of the petrous part of the temporal bone close to its apex. In this situation it passes below the petrosphenoidal ligament—a fibrous band which connects the lateral margin of the dorsum sellæ to the upper border of the petrous part of the temporal bone near its medial end. It next traverses the cavernous sinus, lying at first lateral and then inferolateral to the internal carotid artery, and enters the orbital cavity through the medial part of the superior orbital fissure. It passes within the common tendinous ring from which the recti muscles of the eyeball arise, lying below the oculomotor and nasociliary nerves, and finally sinks into the ocular surface of the lateral rectus.

In the cavernous sinus the abducent nerve is joined by several filaments from the internal carotid plexus, and communicates with the ophthalmic nerve.

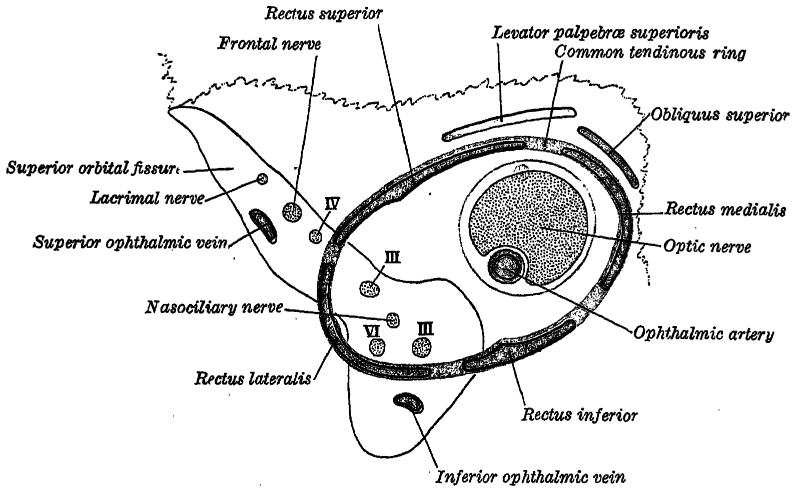
The oculomotor, trochlear, ophthalmic and abducent nerves bear certain relations to each other in the cavernous sinus, at the superior orbital fissure, and in the cavity of the orbit, as follows.

In the *cavernous sinus* (fig. 950), the oculomotor, trochlear and ophthalmic nerves are placed in the lateral wall of the sinus, in the order given, from above downwards; the abducent nerve lies at the lateral side of the internal carotid artery. As these nerves pass forwards to the superior orbital fissure, the oculomotor and ophthalmic nerves divide into branches, and the abducent nerve approaches the others; so that their relative positions are considerably changed.

In the *superior orbital fissure* (fig. 951), the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie in this order from the medial to the lateral side upon the same plane; they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit within the common tendinous ring. The superior division of the oculomotor nerve is the highest of these, and is separated from the inferior division by the nasociliary nerve (fig. 951); the abducent nerve is placed on the lateral side of the inferior division of the oculomotor nerve.

In the *orbit* (fig. 939) the trochlear, frontal and lacrimal nerves lie immediately below the periosteum; the trochlear nerve at once enters the obliquus

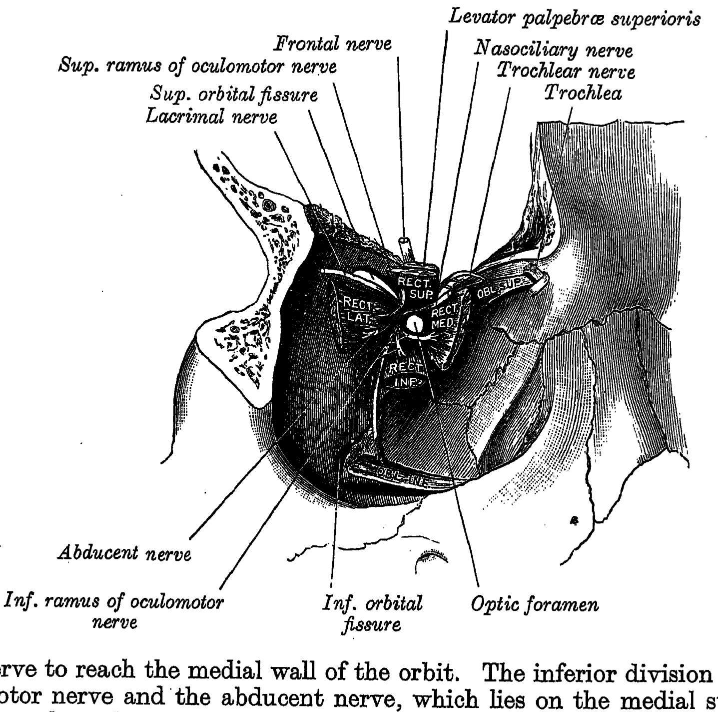
Fig. 951.—Scheme to show the common tendinous ring, the origins of the Recti, and the relative positions of the nerves entering the orbital cavity through the superior orbital fissure. (Modified from a figure in Whitnall's *Anatomy of the Human Orbit*; Oxford Medical Publications.)



The ophthalmic veins often pass through the common tendinous ring.

superior, the frontal lies on the levator palpebræ superioris, and the lacrimal on the rectus lateralis. The superior division of the oculomotor nerve lies immediately below the rectus superior, while the nasociliary nerve crosses the optic

Fig. 952.—A dissection showing the origins of the right ocular muscles, and the nerves entering the orbit through the superior orbital fissure.



nerve to reach the medial wall of the orbit. The inferior division of the oculomotor nerve and the abducent nerve, which lies on the medial surface of the rectus lateralis, lie below the optic nerve.

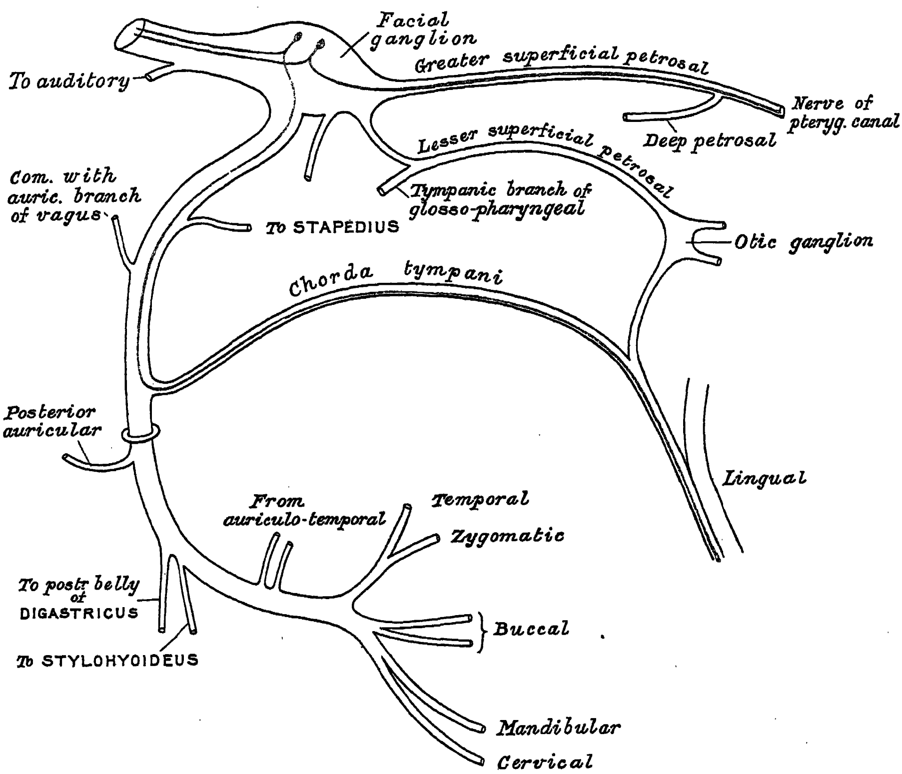
Applied Anatomy.—The abducent nerve is occasionally involved in fractures of the base of the skull. The result of paralysis of this nerve is medial or convergent squint. Diplopia

is also present. When injured so that its function is destroyed, there is, in addition to the paralysis of the rectus lateralis, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the dilatator pupillæ muscle are conveyed through this nerve.

The Facial Nerve (figs. 953 to 956)

The **facial nerve** consists of a motor and a sensory root (*nervus intermedius*) (fig. 836). The two roots appear at the lower border of the pons just lateral to the recess between the olive and the inferior cerebellar peduncle (restiform body), the motor part being the more medial; the auditory nerve lies immediately to the lateral side of the sensory.

Fig. 953.—A plan of the facial nerve. The course of the sensory fibres is represented by the blue lines.



The motor part supplies the muscles of the face, scalp, and auricle, the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric and the secretomotor fibres for the submandibular (submaxillary) and sublingual salivary glands and for the lacrimal gland; the sensory part conveys from the chorda tympani nerve the fibres of taste for the anterior two-thirds of the tongue, and from the palatine and greater superficial petrosal nerves the fibres of taste from the soft palate.

The **nucleus** from which most of the motor fibres of the facial nerve are derived lies deeply in the reticular formation of the lower part of the pons. It is situated behind the dorsal nucleus of the corpus trapezoideum (superior olivary nucleus) and ventrimedial to the nucleus of the spinal tract of the trigeminal nerve. It represents the branchial (special visceral) efferent column, but it lies much more deeply in the pons than might be expected, and its outgoing fibres pursue a very unusual course. Both these features are explicable in accordance with the principle of neurobiotaxis (p. 911). The nucleus receives fibres from the pyramidal tract of the opposite side. In addition, some of the efferent fibres of the facial nerve take origin from the *superior salivary nucleus*, which lies in the reticular formation, dorsilateral to the caudal end of the motor

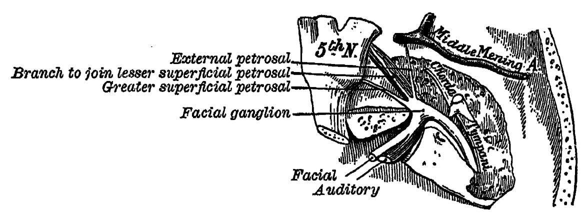
nucleus. It represents the general visceral efferent column, and it sends its fibres to join the motor root, by which they are ultimately distributed through the chorda tympani to the submandibular (submaxillary) and sublingual salivary gland.* From this double origin the fibres of the *motor root* pass backwards and medially, and, reaching the lower end of the nucleus of the abducent nerve, run upwards superficial to this nucleus beneath the colliculus facialis. At the upper end of the nucleus of the abducent nerve they make a second bend, and run downwards and forwards through the pons to their point of emergence between the olive and the inferior cerebellar peduncle (restiform body) (figs. 836, 851).

The **sensory nucleus** of the facial nerve is the upper part of the *nucleus of the tractus solitarius* of the medulla oblongata (p. 913). It receives afferent fibres from the sensory root and sends efferent fibres to the cortex, probably to the hippocampal gyrus in the neighbourhood of the uncus. Their pathway is unknown, but it is almost certain that they have a cell station in the thalamus.

The *sensory root* (nervus intermedius) consists of the central branches of the axons of the unipolar cells of the facial (geniculate) ganglion, which leave the trunk of the facial nerve in the internal auditory meatus and pass centrally, in close relation with the motor root and the auditory nerve, to enter the brain-stem at the lower border of the pons.

From their attachments to the brain, the two roots of the facial nerve pass laterally and forwards with the auditory nerve to the opening of the internal auditory meatus. In the meatus the motor root lies in a groove on the upper and anterior surface of the auditory nerve, the sensory root being placed between them.

FIG. 954.—The course and connexions of the facial nerve in the temporal bone.



At the bottom of the meatus, the facial nerve enters the facial canal. In this canal the nerve runs at first laterally above the vestibule, and reaching the medial wall of the epitympanic recess, bends suddenly backwards above the promontory, and arches downwards in the medial wall of the aditus to the tympanic antrum. Finally it descends to reach the stylomastoid foramen. The point where it bends suddenly backwards is named the *genu* ; it presents a reddish gangliform swelling, named the *ganglion of the facial nerve* (fig. 954). On emerging from the stylomastoid foramen, the facial nerve runs forwards in the substance of the parotid gland, crosses the styloid process and the external carotid artery, and divides behind the ramus of the mandible into branches which pierce the anteromedial surface of the parotid gland and diverge from one another under cover of it. They form a network (*parotid plexus*) and are distributed to the superficial muscles on the side of the head, face, and upper part of the neck.

The *branches of communication* of the facial nerve may be arranged as follows :

In the internal auditory meatus	With the auditory nerve.
At the facial ganglion .	With the sphenopalatine ganglion by the greater superficial petrosal nerve. With the otic ganglion by a branch which joins the lesser superficial petrosal nerve. With the sympathetic plexus on the middle meningeal artery.
In the facial canal . .	With the auricular branch of the vagus nerve.
At its exit from the stylomastoid foramen . .	With the glossopharyngeal, vagus, great auricular, and auriculotemporal nerves.
Behind the ear . . .	With the lesser occipital nerve.
On the face . . .	With the trigeminal nerve.
In the neck . . .	With the anterior cutaneous cervical nerve.

* The source of the secretomotor fibres to the lacrimal gland is uncertain.

In the internal auditory meatus some minute filaments pass from the facial nerve to the auditory nerve.

The *greater superficial petrosal nerve* arises from the ganglion of the facial nerve, and consists chiefly of taste fibres which are distributed to the mucous membrane of the soft palate ; but it probably contains a few parasympathetic fibres which are destined for the sphenopalatine ganglion and are there relayed through the zygomatic and lacrimal nerves (p. 1048) to the lacrimal gland. It receives a twig from the tympanic plexus, passes forwards through the hiatus on the anterior surface of the petrous portion of the temporal bone and runs in a groove on the bone. It passes beneath the trigeminal ganglion and reaches the foramen lacerum. In this foramen it is joined by the deep petrosal nerve from the sympathetic plexus on the internal carotid artery, and forms the nerve of the pterygoid canal, which passes forwards through the pterygoid canal and ends in the sphenopalatine ganglion. From the ganglion of the facial nerve a branch runs to join the lesser superficial petrosal nerve, and is conveyed through this nerve to the otic ganglion. The sympathetic plexus on the middle meningeal artery is joined to the ganglion of the facial nerve by an inconstant branch, sometimes named the *external petrosal nerve.*

Before the facial nerve emerges from the stylomastoid foramen, it receives a twig from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, the facial nerve receives a twig from the glossopharyngeal nerve, and communicates with the great auricular and auriculotemporal nerves in the parotid gland, with the lesser occipital nerve behind the ear, with the terminal branches of the trigeminal nerve on the face, and with the anterior cutaneous cervical nerve in the neck.

The *branches of distribution* (figs. 953, 955) of the facial nerve may be grouped as follows :

Within the facial canal	Nerve to the stapedius muscle. Chorda tympani.
At its exit from the stylomastoid foramen	Posterior auricular. Digastric, posterior belly. Stylohyoid.
On the face	Temporal. Zygomatic. Buccal. Mandibular. Cervical.

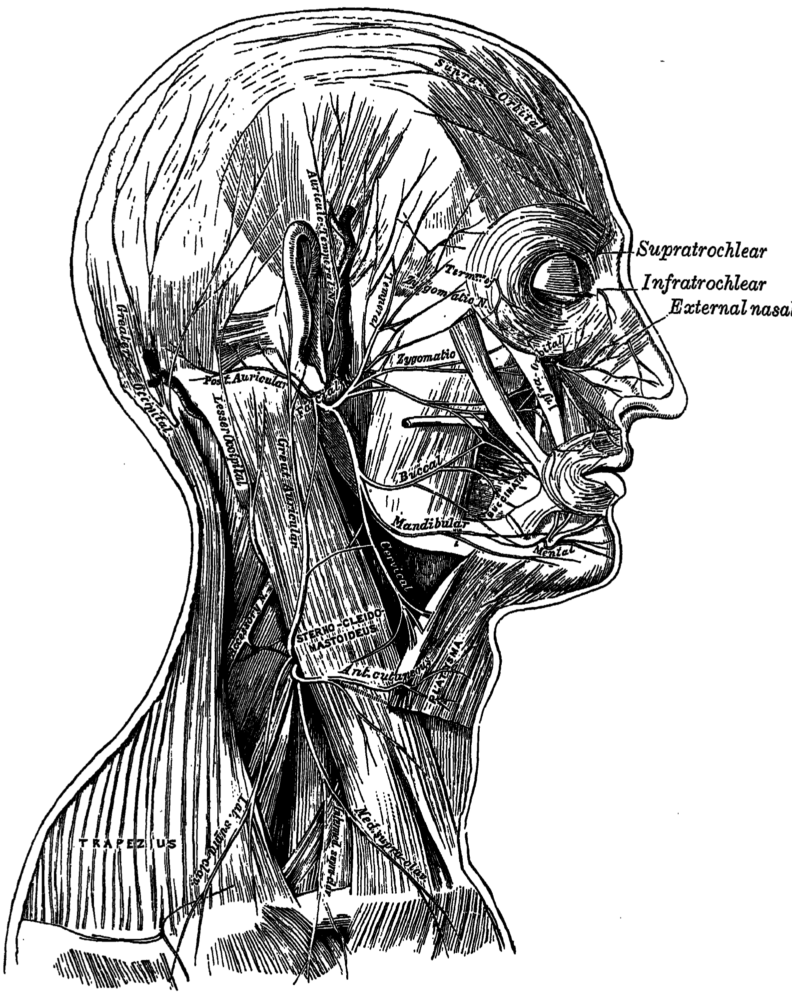
The **nerve to the stapedius** arises from the facial nerve opposite the pyramidal eminence on the posterior wall of the tympanic cavity ; it passes forwards through a small canal to reach the muscle.

The **chorda tympani nerve** (fig. 942) arises from the facial nerve about 6 mm. above the stylomastoid foramen. It runs upwards and forwards in a canal, and enters the tympanic cavity through the posterior canaliculus for the chorda tympani nerve, which is situated on its posterior wall, close to the posterior border of the medial surface of the tympanic membrane and on a level with the upper end of the manubrium of the malleus. It traverses the tympanic cavity, between the fibrous and mucous layers of the tympanic membrane, crosses the manubrium of the malleus, and leaves the cavity through the anterior canaliculus for the chorda tympani nerve, which is placed at the inner end of the petrotympanic fissure. The nerve now runs downwards and forwards on the medial surface of the spine of the sphenoid bone (which it sometimes grooves) and passes deep to the lateral pterygoid muscle. In this part of its course the nerve lies on the tensor palati and is crossed by the middle meningeal artery, the roots of the auriculotemporal nerve and the inferior dental nerve. Finally it joins the posterior border of the lingual nerve at an acute angle. It contains a few efferent secretomotor fibres which enter the submandibular (submaxillary) ganglion, which sends postganglionic fibres to the submandibular and sublingual glands ; the majority of its fibres are afferent, and are continued onwards through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds ; they constitute the nerve of taste for this portion of

the tongue. Before uniting with the lingual nerve the chorda tympani is joined by a small branch from the otic ganglion.

The **posterior auricular nerve** arises close to the stylomastoid foramen and runs upwards in front of the mastoid process ; here it is joined by a filament from the auricular branch of the vagus nerve, and communicates with the posterior branch of the great auricular nerve, and with the lesser occipital nerve. As it ascends between the external auditory meatus and the mastoid process it divides into an auricular and an occipital branch. The *auricular*

FIG. 955.—The nerves of the right side of the scalp, face, and neck.



branch supplies the auricularis posterior and the intrinsic muscles on the cranial surface of the auricle (pinna). The *occipital branch*, the larger, passes backwards along the superior nuchal line of the occipital bone, and supplies the occipital belly of the occipitofrontalis.

The **digastric branch** arises close to the stylomastoid foramen, and divides into several filaments which supply the posterior belly of the digastric ; one of these filaments joins the glossopharyngeal nerve.

The **stylohyoid branch**, long and slender, frequently arises in conjunction with the digastric branch ; it enters the middle part of the stylohyoid muscle.

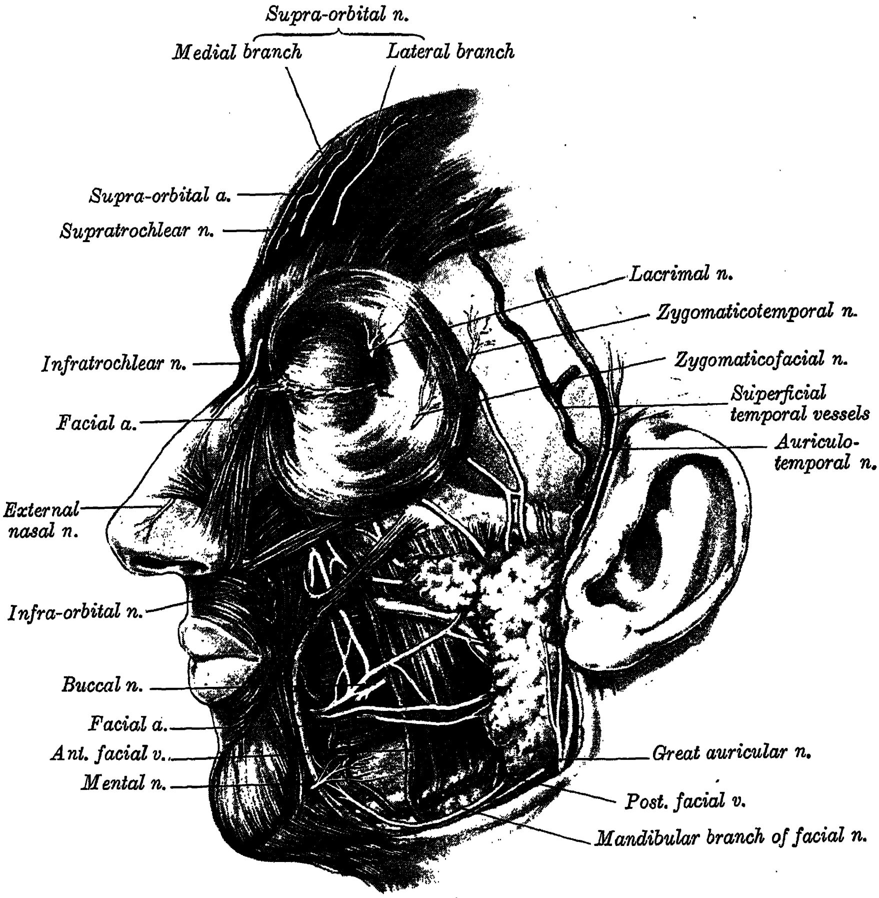
The **temporal branches** cross the zygomatic arch to the temporal region. They supply the intrinsic muscles on the lateral surface of the auricle, the anterior and superior auricular muscles, and join with the zygomaticotemporal branch of the maxillary nerve, and with the auriculotemporal branch of the

mandibular nerve. The more anterior branches supply the frontal belly of the occipitofrontalis, the orbicularis oculi and the corrugator, and join the supra-orbital and lacrimal branches of the ophthalmic nerve.

The **zygomatic branches** run across the zygomatic bone to the lateral angle of the eye; they supply the orbicularis oculi, and join with filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The **buccal branches** pass horizontally forwards to be distributed below the orbit and around the mouth. The *superficial branches* run between the skin of the face and the superficial muscles, and supply the latter; some are dis-

FIG. 956.—The cutaneous branches of the trigeminal nerve.



The branches of the facial nerve are seen emerging from the parotid gland.

tributed to the procerus, joining with the infratrochlear and external nasal nerves. The upper *deep branches* pass under cover of the zygomaticus major and the levator labii superioris, supplying them and forming an *infra-orbital plexus* with the superior labial branches of the infra-orbital nerve; they also supply the levator anguli oris, the zygomaticus minor, the levator labii superioris alæque nasi and the small muscles of the nose. These branches are sometimes described as lower zygomatic branches. The lower deep branches supply the buccinator and orbicularis oris, and join with filaments of the buccal branch of the mandibular nerve.

The **mandibular branch** runs forwards below the angle of the mandible under cover of the platysma. It lies at first superficial to the upper part of the digastric triangle and then turns upwards and forwards across the body of the mandible to lie under cover of the depressor anguli oris (triangularis) (fig. 956). It supplies the risorius and the muscles of the lower lip and chin, and joins the mental branch of the inferior dental nerve.

The **cervical branch** issues from the lower part of the parotid gland, runs forwards and downwards under cover of the platysma to the front of the neck. It supplies the platysma and communicates with the anterior cutaneous cervical nerve.

Applied Anatomy.—Facial palsy is commonly unilateral, and may be either: (1) *peripheral*, from lesion of the facial nerve; (2) *nuclear*, from destruction of the facial nucleus; or (3) *central, cerebral* or *supranuclear*, from injury in the brain to the fibres passing from the cortex through the internal capsule to the facial nucleus, or from injury to the face-area of the motor cortex itself. In supranuclear facial paralysis, which is usually part of a hemiplegia, it is the lower part of the face that is chiefly affected, while the forehead can be freely wrinkled on the palsied side, the eye can be closed fairly well and the eyeball is not rolled up under the upper lid; emotional movements of the face are executed much better than voluntary movements; and the electrical reactions of the muscles on the affected side are not altered. If the paralysis is due to lesion of the facial nucleus, the orbicularis oris escapes, as the nuclear origin of the nerve to this muscle seems to be connected with that of the tongue-nerves; otherwise the symptoms are identical with those of the common peripheral facial palsy, of which several types may be distinguished according to the point in its course at which the facial nerve is injured. If the lesion occurs (*a*) in the pons, facial paralysis is produced as in (*d*) below; taste and hearing are not affected, but the abducent nerve also will be paralysed because the fibres of the facial nerve loop round its nucleus in the pons. When the nerve is paralysed (*b*) in the petrous temporal, in addition to the paralysis of the motor nucleus, there is loss of taste in the anterior part of the tongue, and the patient is unable, from involvement of the chorda tympani, to recognise the difference between bitters and sweets, acids and salines: the sense of hearing is affected from paralysis of the stapedius. When the cause of the paralysis is (*c*) fracture of the base of the skull, the auditory and petrosal nerves are usually involved. But by far the commonest cause of facial palsy is (*d*) exposure of the nerve to cold or injury at or after its exit from the stylomastoid foramen (Bell's paralysis). In these cases the face looks asymmetrical even when at rest, and more so in the old than in the young. The affected side of the face and forehead remains motionless when voluntary or emotional movement is attempted. The lines on the forehead are smoothed out, the eye can be shut only by hand, tears fail to enter the lacrimal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent, and efforts to close the eye merely cause the eyeball to roll upwards until the cornea lies under the upper lid. The tip of the nose is drawn over towards the sound side; the nasolabial fold is partially obliterated on the affected side, and the ala nasi does not move properly on respiration. The lips remain in contact on the paralysed side, but cannot be pursed for whistling; when a smile is attempted the angle of the mouth is drawn up on the unaffected side but on the affected side the lips remain nearly closed, and the mouth assumes a characteristic triangular form. During mastication food accumulates in the cheek, from paralysis of the buccinator, and dribbles or is pushed out from between the paralysed lips. On protrusion the tongue seems to be thrust over towards the palsied side, but verification of its position by reference to the incisor teeth will show that this is not really so. The platysma and the muscles of the auricle are paralysed; in severe cases the articulation of labials is impaired. The electrical reactions of the affected muscles are altered (reaction of degeneration), and the degree to which this alteration has taken place after a week or ten days gives a valuable guide to the prognosis. Most cases of Bell's palsy recover completely.

The facial nerve is at fault in cases of so-called 'histrionic spasm,' which consists in an almost constant and uncontrollable twitching of some or all of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient, and to interfere with sleep, and for its relief the facial nerve has been stretched.

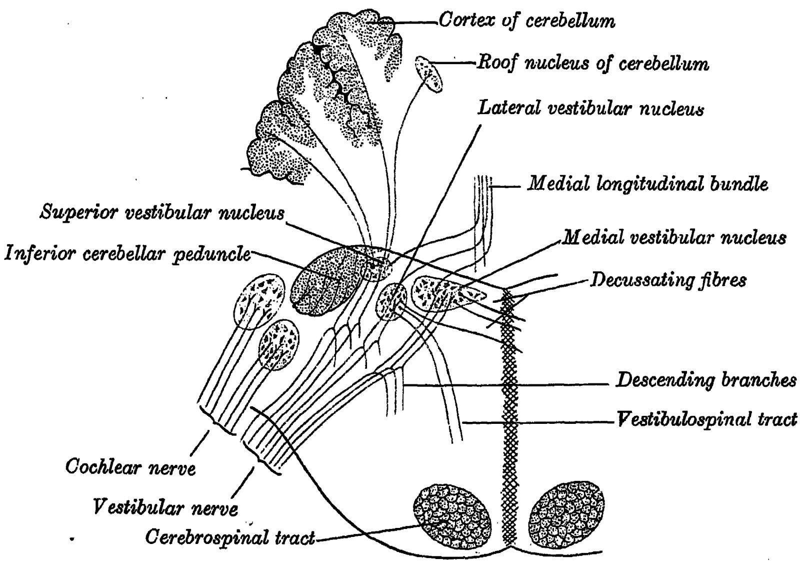
The Auditory Nerve

The **auditory nerve** (acoustic nerve) appears in the groove between the pons and medulla oblongata, behind the facial nerve and in front of the inferior cerebellar peduncle (restiform body) (fig. 836). It consists of two sets of fibres, which, although differing in their principal central connexions, are both concerned in the transmission of afferent impulses from the internal ear to the brain. One set of fibres forms the vestibular nerve, or nerve of equilibration, and arises from the cells of the vestibular ganglion situated in the bottom of the internal auditory meatus; the other set constitutes the cochlear nerve, or true nerve of hearing, and takes origin from the cells of the spiral ganglion of the cochlea. Both ganglia consist of bipolar nerve-cells, and from each cell a central fibre passes to the brain, and a peripheral fibre to the internal ear.

Vestibular nerve (fig. 957).—The fibres of the vestibular nerve enter the brain medial to those of the cochlear nerve and on a higher level. They pass backwards through the pons between the inferior cerebellar peduncle and the spinal tract of the trigeminal nerve and divide into ascending and descending branches which mostly end in the vestibular nuclei, although many proceed direct to the cerebellum along the inferior cerebellar peduncle.

The **vestibular nucleus** of termination comprises the following subdivisions: (1) The *medial vestibular nucleus* (p. 917), which lies in the vestibular area (area acustica) of the floor of the fourth ventricle, crossed dorsally by the auditory striæ (striæ medullares). It is the largest subdivision and extends upwards from the medulla oblongata into the pons. On transverse section it is triangular in outline. (2) The *inferior* (*spinal*) *vestibular nucleus* (p. 917) lies lateral to the medial nucleus and reaches to a lower level in the medulla oblongata. It is placed between the medial nucleus and the inferior cerebellar peduncle, and

FIG. 957.—The terminal nuclei and central connexions of the vestibular nerve. (Schematic.)



the descending branches of the incoming vestibular fibres are closely applied to its lateral aspect. (3) The *lateral nucleus* (p. 922) lies ventrilateral to the upper part of the medial nucleus, and it is characterised by the large size of its constituent cells. Its upper end inclines dorsally and becomes continuous with the lower end of (4) the *superior nucleus*, which extends higher into the pons than the other subdivisions and occupies the upper part of the vestibular area.

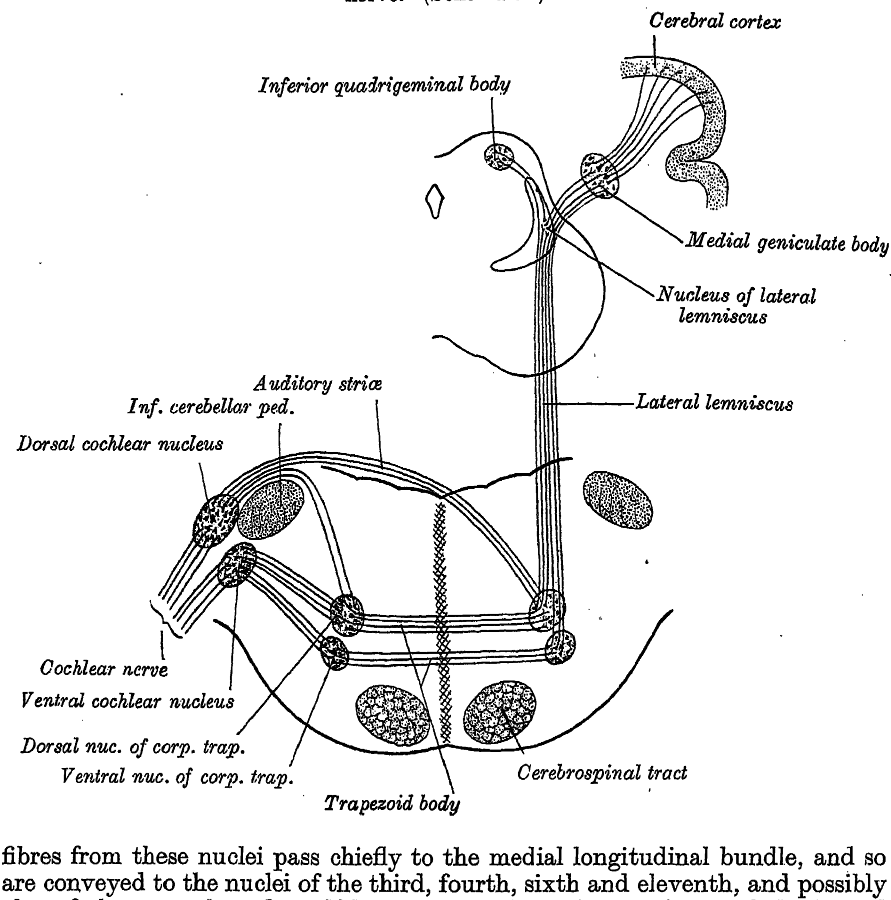
Connexions.—In addition to receiving afferent fibres from the vestibular nerve, the superior and lateral nuclei receive afferent fibres from the cerebellum, which travel by the inferior cerebellar peduncle.

The efferent fibres from the vestibular nuclei pass: (1) to the cerebellum, where they terminate in the cortex, including the flocculus; (2) to the medial longitudinal bundle (p. 949), by which they are conveyed to the nuclei of the third, fourth, sixth and eleventh cranial nerves and, by means of the anterior intersegmental tract, to the anterior grey column of the spinal cord; (3) to the vestibulospinal tract (p. 898), which arises chiefly from the large-celled lateral nucleus; and (4) to the corpus trapezoideum and the lateral lemniscus and so to the inferior quadrigeminal body.

Cochlear nerve (fig. 958).—As it reaches the brain-stem the cochlear nerve is placed on the lateral side of the vestibular nerve, but the two nerves soon become separated by the inferior cerebellar peduncle. The cochlear nerve passes round the lateral aspect of the peduncle, while the vestibular nerve penetrates the brain-stem on the medial side of that structure.

The **cochlear nuclei** are two in number. The *ventral cochlear nucleus* is placed on the ventrilateral aspect of the inferior cerebellar peduncle, and it receives the ascending branches of the cochlear nerve. The *dorsal cochlear nucleus* lies on the dorsal aspect of the peduncle in the lateral part of the vestibular area of the floor of the fourth ventricle, where it forms the auditory tubercle. It receives the descending branches of the cochlear nerve. The efferent fibres from the ventral cochlear nucleus run medially through the ventral part of the tegmentum of the pons and constitute the corpus trapezoideum. Having crossed the median plane they ascend in the lateral lemniscus (p. 922). In their course some of the trapezoidal fibres give off collaterals to, and others end in, the ventral and dorsal nuclei of the corpus trapezoideum. The efferent

FIG. 958.—The terminal nuclei and central connexions of the cochlear nerve. (Schematic.)



fibres from these nuclei pass chiefly to the medial longitudinal bundle, and so are conveyed to the nuclei of the third, fourth, sixth and eleventh, and possibly also of the seventh and twelfth cranial nerves. As the fibres of the lateral lemniscus ascend, some of them are interrupted in the nucleus of the lateral lemniscus and there relayed, many of them passing to the medial longitudinal bundle. Finally, the fibres of the lateral lemniscus terminate in the substantia nigra, the inferior quadrigeminal body and the medial geniculate body. From the last-named new fibres arise and pass through the retrolentiform part of the internal capsule to reach the auditosensory area of the cortex (p. 995).

The efferent fibres from the dorsal cochlear nucleus pass medially as the auditory striæ (striæ medullares) across the floor of the fourth ventricle. They pass forwards at the median sulcus, cross the median plane and then course forwards and laterally through the tegmentum to join the lateral lemniscus.

The auditory nerve is soft in texture, and is destitute of neurolemma in its proximal part.* After leaving the medulla oblongata it passes forwards across

* H. Alan Skinner, *British Journal of Surgery*, Jan. 1929.

the posterior border of the middle cerebellar peduncle, in company with the facial nerve, from which it is partially separated by the internal auditory artery. It then enters the internal auditory meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and splits into its *cochlear* and *vestibular* parts, the distribution of which will be described with the anatomy of the internal ear.

The cochlear and vestibular nuclei develop in the most dorsal part of the alar lamina, and the eighth nerve itself does not lie in series either with the ventral or with the dorsal cranial nerves (p. 1031). The mode of development of the cochlear and vestibular ganglia is consistent with this distinction, for their cells of origin are derived partly from the neural crest and partly from a dorsilateral ectodermal placode which is developed in association with the ectoderm of the auditory pit (p. 129). In fishes, a whole series of organs, termed lateral line organs or neuromasts, develops both in the head and in the trunk for the reception of vibration waves. These sense organs are very necessary for an aquatic life, but they disappear in terrestrial forms, leaving the auditory apparatus as their sole survivor. The auditory nerve, therefore, occupies a special position amongst the cranial nerves, and the olfactory nerve alone can be compared with it justifiably.

The vestibular and cochlear nerves, although apparently distinct, yet have much in common. The cochlear nerve, when it leaves the labyrinth and before it joins the vestibular nerve, carries with it fibres from the ampulla of the posterior semicircular duct and from the macula of the saccule. Winkler * has shown that some vestibular fibres run with the cochlear fibres on the lateral aspect of the inferior cerebellar peduncle and that some cochlear fibres terminate in the lateral vestibular nucleus. Vestibular fibres enter into the constitution of the corpus trapezoideum and may reach the inferior quadrigeminal body. The two systems, therefore, are not sharply separated from each other, and the chief distinction would appear to be that, whereas the main connexions of the cochlear nerve are ultimately established with the cerebral cortex and so enter the domain of consciousness, the main connexions of the vestibular nerve are with the spinal cord and cerebellum. Both systems can influence the motor nuclei of the brain-stem and the spinal cord, and they appear to share the subsidiary nuclei (nuclei of corpus trapezoideum and nucleus of lateral lemniscus).

Applied Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fracture of the middle fossa of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture of the skull, and deafness may arise from loud explosions, probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. Tumours in the cerebellopontine angle involve the auditory and facial nerves, as they lie in relation to the flocculus (fig. 836) at the lower border of the pons.

The Glossopharyngeal Nerve (figs. 959, 960, 961)

The **glossopharyngeal nerve** contains motor and sensory fibres. It supplies motor fibres to the stylopharyngeus, secretomotor fibres to the parotid gland, and sensory fibres to the pharynx, the tonsil, and the posterior part of the tongue; it is also the nerve of taste for this part of the tongue. It is attached by three or four filaments to the upper part of the medulla oblongata, in the groove between the olive and the inferior cerebellar peduncle (restiform body).

The **sensory nucleus** is formed by the lower part of the *nucleus of the tractus solitarius*, which lies dorsilateral to the dorsal nucleus of the vagus below and ventrilateral to it at its upper end. It receives the central fibres of the unipolar cells of the superior and inferior (petrous) ganglia, which are situated on the trunk of the glossopharyngeal nerve and will presently be described. Some of the efferent fibres from this nucleus probably pass to the thalamus, where they are relayed to the hippocampal gyrus (sense of taste, posterior third of tongue).

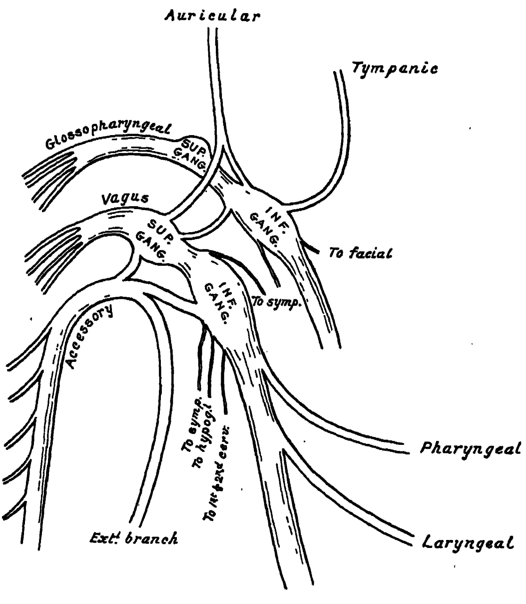
The **motor nucleus** is formed by the upper part of the *nucleus ambiguus* (p. 916), which lies deeply in the formatio reticularis of the medulla oblongata. It is connected with the pyramidal tract of the opposite side, and sends its efferent fibres to the stylopharyngeus muscle. This nucleus represents the branchial (special visceral) efferent column, but it lies more deeply in the substance of the medulla oblongata than might be expected (p. 916).

* See second footnote, p. 922.

In addition, fibres join the motor part of the glossopharyngeal nerve from a representative of the general visceral efferent column which is termed the **inferior salivary nucleus.** This nucleus lies in the reticular formation below the superior salivary nucleus, and sends its fibres *viâ* the tympanic branch to the lesser superficial petrosal nerve and the otic ganglion, whence they pass to the auriculotemporal nerve and so reach the parotid gland.

From the medulla oblongata the glossopharyngeal nerve passes forwards and laterally towards the triangular depression into which the aquæductus cochleæ opens, on the inferior surface of the petrous portion of the temporal bone. It lies at first under cover of the flocculus, and rests on the jugular tubercle of the occipital bone, which is sometimes grooved by it. It leaves the skull by bending sharply downwards through the central part of the jugular foramen, anterior and lateral to the vagus and accessory nerves, and in a separate sheath of dura mater (fig. 960). In its transit through the jugular foramen it is lodged in a deep groove leading from the triangular depression for the aquæductus cochleæ, and here it is separated by the inferior petrosal sinus from the vagus and accessory nerves. The deep groove is converted into a canal by a bridge which is usually composed of fibrous tissue, but consists of bone in about 25 per cent. of skulls.* After its exit from the skull it passes forwards between the internal jugular vein and internal carotid artery; it descends in front of the latter vessel, deep to the styloid process and the muscles connected with it, to reach the posterior border of the stylopharyngeus. It then curves forwards, lying upon the stylopharyngeus muscle, and either pierces the lower fibres of the superior constrictor of the pharynx or passes between the adjoining borders of the superior and middle constrictors (fig. 578) to be distributed to the tonsil, the mucous membrane of the pharynx and the posterior part of the tongue, and the mucous glands of the mouth.

FIG. 959.—A plan of the upper portions of the glossopharyngeal, vagus, and accessory nerves.



Two ganglia, named the superior and the inferior (petrous), are situated on that portion of the nerve which traverses the jugular foramen (fig. 959).

The **superior ganglion** is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is very small, gives off no branches, and is usually regarded as a detached portion of the inferior ganglion.

The **inferior ganglion** (petrous ganglion) is larger than the superior ganglion and is situated in a notch in the lower border of the petrous portion of the temporal bone (p. 272).

The glossopharyngeal nerve communicates with the sympathetic trunk, and with the vagus and facial nerves.

The inferior ganglion is connected by a filament with the superior cervical ganglion of the sympathetic. The branches to the vagus consist of two filaments which arise from the inferior ganglion; one joins the auricular branch, and the other the superior (jugular) ganglion, of the vagus. The branch to the facial arises from the trunk of the glossopharyngeal nerve below the inferior ganglion;

* E. Joyce Partridge, *Journal of Anatomy*, vol. lii.

it perforates the posterior belly of the digastric muscle and joins the facial nerve near the stylomastoid foramen.

The *branches of distribution* of the glossopharyngeal nerve are: tympanic, carotid, pharyngeal, muscular, tonsillar and lingual.

The **tympanic nerve** arises from the inferior ganglion of the glossopharyngeal nerve, and ascends to the tympanic cavity through the inferior tympanic canaliculus (p. 263). In the tympanic cavity it divides into branches which form the *tympanic plexus* and are contained in grooves upon the surface of the promontory. This plexus gives off: (1) the lesser superficial petrosal nerve; (2) a branch to join the greater superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which are described with the anatomy of the middle ear (p. 1203).

The **carotid branches** descend along the trunk of the internal carotid artery as far as its origin, communicating with the pharyngeal branch of the vagus, and with branches of the sympathetic trunk; they are distributed to the wall of the carotid sinus (p. 700) and to the carotid body.

The **pharyngeal branches** are three or four filaments which unite, opposite the middle constrictor muscle of the pharynx, with the pharyngeal branch of the vagus nerve and the laryngopharyngeal branches of the sympathetic trunk to form the *pharyngeal plexus*; through this plexus the glossopharyngeal nerve supplies the mucous membrane of the pharynx with sensory branches.

The **muscular branch** supplies the stylopharyngeus muscle.

The **tonsillar branches** supply the tonsil, and form around it a plexus with branches of the lesser palatine nerves; from this plexus filaments are distributed to the soft palate and the region of the oropharyngeal isthmus.

The **lingual branches** are two in number: one supplies the vallate papillæ and the mucous membrane near the sulcus terminalis of the tongue; the other supplies the mucous membrane and follicular glands of the posterior one-third of the tongue, and communicates with the lingual nerve. It is the nerve of special sense (taste) and of general sensibility to the posterior one-third of the tongue.

The glossopharyngeal nerve is the nerve of the third branchial arch, or it would be more nearly correct to describe it as the post-trematic branch of that arch. The pretrematic branch of the second (hyoid) arch is probably the tympanic branch of the glossopharyngeal nerve, but that is uncertain. Like the trigeminal and the facial nerves, the glossopharyngeal corresponds to a dorsal nerve which has acquired special visceral efferent fibres.

The Vagus Nerve (figs. 959, 960, 961)

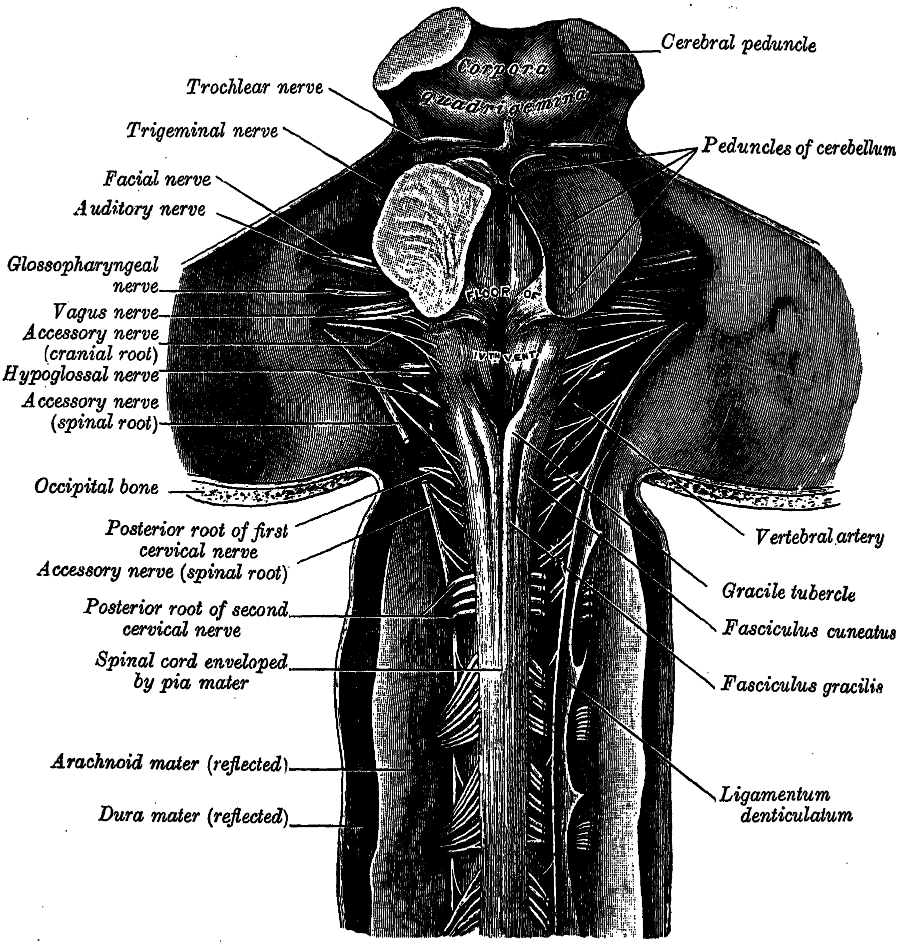
The **vagus nerve** is composed of motor and sensory fibres, and has a more extensive course and distribution than any of the other cranial nerves, since it passes through the neck and thorax to the abdomen. It is attached by eight or ten filaments to the medulla oblongata, below the glossopharyngeal nerve, in the groove between the olive and the inferior cerebellar peduncle (restiform body).

The fibres of the vagus nerve are connected to three nuclei in the medulla oblongata. (1) The **dorsal nucleus** of the vagus is a mixed nucleus and represents the fused general visceral efferent and general visceral afferent columns. It lies in the central grey matter of the lower, closed, part of the medulla oblongata, and extends upwards into the upper, open, part, where it is placed under the vagal triangle, separated from the hypoglossal nucleus by the nucleus intercalatus (p. 917). The *motor fibres* which arise from it are distributed to the involuntary muscle of the bronchi, heart, œsophagus, stomach and small intestines. The *sensory fibres* which terminate in the nucleus are derived from the larynx, pharynx, lungs, heart, œsophagus, stomach and small intestine. (2) Below the origin of the fibres which join the glossopharyngeal nerve, the **nucleus ambiguus** (pp. 916 and 1067) gives origin to those fibres of the vagus nerve which are distributed to the striped muscle of the pharynx and to the cricothyroid muscle. It represents the branchial (special visceral) efferent column, and its position in the deeper part of the medulla oblongata is attributable to neurobiotaxis (p. 911). It is uncertain whether the muscles of the soft palate are innervated by the vagal part of the nucleus ambiguus or by the

cerebral nucleus of the accessory nerve. (3) The lower end of the **nucleus of the tractus solitarius** (pp. 913 and 916) receives those fibres of the vagus which are distributed to the taste-buds of the epiglottis and the valleculæ. It represents the special visceral afferent column.

The filaments of the nerve unite, and form a flat cord which passes below the flocculus of the cerebellum to the jugular foramen, through which it leaves the cranium. In emerging through this opening, the vagus nerve is accompanied by and contained in the same sheath of dura and arachnoid mater as the

Fig. 960.—The upper part of the spinal cord, and the hind-brain and mid-brain. Exposed from behind.



accessory nerve, a fibrous septum separating them from the glossopharyngeal nerve, which lies in front (fig. 960). In this situation the vagus nerve presents a well-marked enlargement, named the *superior ganglion* (jugular ganglion). After its exit from the jugular foramen the vagus nerve enlarges into a second swelling, named the *inferior ganglion* (ganglion nodosum).

The **superior ganglion** (jugular ganglion) is of a greyish colour, spherical in form, about 4 mm. in diameter. It is joined by one or two delicate filaments with the cranial root of the accessory nerve; it is connected by a twig with the inferior ganglion of the glossopharyngeal nerve, and with the sympathetic trunk by a filament from the superior cervical ganglion; the auricular branch of the ganglion gives off an ascending twig which joins the facial nerve.

The **inferior ganglion** (ganglion nodosum) is cylindrical in form, of a reddish colour, and 2·5 cm. long. It is connected with the hypoglossal nerve, the

superior cervical ganglion of the sympathetic trunk, and the loop between the first and second cervical nerves. The cranial root of the accessory nerve passes over the ganglion, but is attached to it by fibrous tissue.

Beyond the inferior ganglion the cranial root of the accessory nerve blends with the vagus nerve ; its fibres are distributed principally to the pharyngeal and inferior laryngeal branches of the vagus nerve.

The vagus nerve passes vertically down the neck within the carotid sheath, lying between the internal jugular vein and internal carotid artery as far as the upper border of the thyroid cartilage, and then between the same vein and the common carotid artery to the root of the neck. The further course of the nerve differs on the two sides of the body.

On the *right side* the vagus nerve passes across the first part of the subclavian artery, between it and the right internal jugular vein. It enters the thorax and descends through the superior mediastinum, lying at first behind the right innominate vein, and then to the right of the trachea and posteromedial to the right innominate vein and the superior vena cava. The right pleura and lung are lateral to the nerve above, but are separated from it below by the azygos vein, which arches forward above the root of the right lung (fig. 785).

The nerve next passes behind the right bronchus to reach the posterior aspect of the root of the right lung, and there breaks up into posterior bronchial branches, which unite with filaments from the second, third and fourth thoracic sympathetic ganglia to form the *right posterior pulmonary plexus*. From the lower part of this plexus two or three branches descend on the back of the œsophagus, where, with a branch from the left vagus, they form the posterior part of the *œsophageal plexus* ; from this plexus the nerve is continued behind the œsophagus, and enters the abdomen through the œsophageal opening in the diaphragm. In the remainder of its course the nerve trunk contains fibres from both vagus nerves.

In the abdomen the posterior vagal trunk divides into a small gastric and a large cœliac branch. The gastric branch supplies the postero-inferior surface of the stomach with the exception of the pyloric canal. The cœliac branch ends chiefly in the cœliac ganglia, but sends twigs to the splenic, hepatic, renal, suprarenal and superior mesenteric plexuses.

On the *left side* the vagus nerve enters the thorax between the left common carotid and left subclavian arteries, and behind the left innominate vein. It descends through the superior mediastinum, crosses the aortic arch and passes behind the root of the left lung. Just above the aortic arch the nerve is crossed superficially by the left phrenic nerve, and on the arch by the left superior intercostal vein (fig. 998).

Behind the root of the left lung it divides into posterior bronchial branches, which unite with filaments of the second, third and fourth thoracic sympathetic ganglia and form the *left posterior pulmonary plexus*. From this plexus two branches descend on the front of the œsophagus where, with a twig from the right vagus, they form the anterior part of the *œsophageal plexus* ; from this plexus the nerve is continued in front of the œsophagus, and enters the abdomen through the œsophageal opening of the diaphragm. The nerve trunk now contains fibres from both vagus nerves.

In the abdomen the anterior vagal trunk nerve supplies twigs to the cardiac antrum, and then divides into right and left groups of branches. The fibres of the left group follow the lesser curvature of the stomach and supply the antero-superior surface of this viscus. The right group consists of three main branches. The first, which may be duplicated, runs between the layers of the lesser omentum towards the porta hepatis, and divides into (*a*) upper branches which enter the porta hepatis, and (*b*) lower branches which supply chiefly the pyloric canal, the pylorus, the first and second parts of the duodenum, and the head of the pancreas. The second branch is distributed to the antero-superior surface of the body of the stomach ; the third branch follows the lesser curvature of the stomach as far as the incisura angularis.*

* For further details, consult an article on "The Abdominal Distribution of the Vagus," by E. D'Arcy M'Crea, *Journal of Anatomy*, vol. lix. p. 18.

The *branches* of the vagus nerve are :

In the jugular fossa . .	Meningeal. Auricular.
In the neck	Pharyngeal. Branches to Carotid body. Superior laryngeal. Recurrent laryngeal (right). Cardiac.
In the thorax	Cardiac. Recurrent laryngeal (left). Pulmonary. Œsophageal.
In the abdomen	Gastric. Cœliac. Hepatic.

The **meningeal branch** springs from the jugular ganglion of the vagus nerve, and is distributed to the dura mater in the posterior fossa of the skull.

The **auricular branch** arises from the superior ganglion of the vagus nerve, and is joined soon after its origin by a filament from the inferior ganglion of the glossopharyngeal ; it passes behind the internal jugular vein, and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the canal for the facial nerve about 4 mm. above the stylomastoid foramen, and here it gives off an ascending branch which joins the facial nerve. It then passes through the tympano-mastoid fissure, and divides into two branches ; one joins the posterior auricular nerve, the other is distributed to the skin of part of the cranial surface of the auricle and to the posterior part of the external auditory meatus.

The **pharyngeal branch,** which is the principal motor nerve of the pharynx, arises from the upper part of the inferior ganglion of the vagus nerve, and consists principally of filaments from the cranial root of the accessory nerve. It passes between the external and internal carotid arteries to the upper border of the middle constrictor muscle of the pharynx, where it divides into numerous filaments which join with branches from the sympathetic trunk, the glossopharyngeal and external laryngeal nerves, to form the *pharyngeal plexus.* Through this plexus vagal fibres are distributed to the muscles of the pharynx, and the muscles of the soft palate, except the tensor palati. A minute filament joins the hypoglossal nerve as the latter winds round the occipital artery, and is termed the *ramus lingualis vagi.*

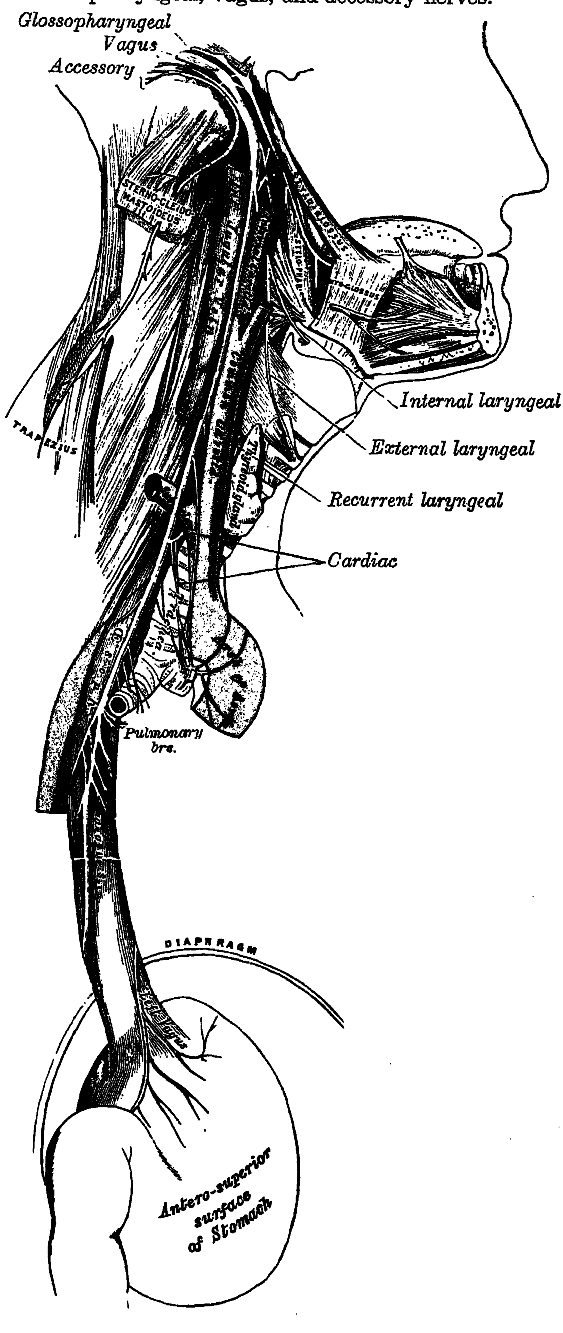
The *branches to the carotid body* are minute and variable in number. They may spring from the inferior ganglion or they may travel either in the pharyngeal branch or the superior laryngeal nerve.

The **superior laryngeal nerve,** which is larger than the preceding, arises from the middle of the inferior ganglion of the vagus nerve, and in its course receives a branch from the superior cervical ganglion of the sympathetic trunk. It descends, by the side of the pharynx, behind the internal carotid artery and divides into the internal and external laryngeal nerves.

The *internal laryngeal nerve* is sensory to the mucous membrane of the larynx as far down as the level of the vocal folds. It descends to the thyrohyoid membrane, pierces this membrane at a higher level than the superior laryngeal artery, and divides into an upper and a lower branch. The upper branch is directed horizontally, and supplies twigs to the mucous membrane of the pharynx, the epiglottis, the vallecula and the vestibule of the larynx. The lower branch descends in the medial wall of the piriform fossa, and gives branches to the aryepiglottic fold, and to the mucous membrane on the back of the arytenoid cartilage. It also supplies one or two branches to the arytænoideus muscle, and these branches unite with twigs from the recurrent laryngeal nerve to the same muscle ; the arytenoideus has there-

fore a double nerve-supply. The internal laryngeal nerve ends by piercing the inferior constrictor muscle of the pharynx, and joining with an ascending branch from the recurrent laryngeal nerve.*

FIG. 961.—The course and distribution of the glossopharyngeal, vagus, and accessory nerves.



The *external laryngeal nerve*, which is the smaller of the two, descends under cover of the sternothyroid muscle in company with the superior thyroid artery but on a deeper plane; it lies at first on the inferior constrictor muscle of the pharynx, and then, piercing that muscle, winds closely round the inferior thyroid tubercle and enters the cricothyroid muscle. It gives branches to the pharyngeal plexus and to the inferior constrictor; behind the common carotid artery it communicates with the superior cardiac nerve.

The **recurrent laryngeal nerve** (recurrent nerve) differs, as to its origin and course, on the two sides of the body. On the *right* side it arises from the vagus nerve in front of the first part of the subclavian artery; it winds from before backwards round that vessel, and ascends obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the lobe of the thyroid gland the nerve is always intimately related to the inferior thyroid artery; it may cross either in front of or behind the vessel, or may pass between its branches. On the *left* side, it arises from the vagus nerve on the left of the arch of the aorta, and winds below the arch immediately behind the attachment of the ligamentum arteriosum to the concavity of the arch, and then ascends to the side of the trachea. The nerve on each side ascends in the groove between the trachea and œsophagus, and is intimately related to the medial surface of the thyroid gland,† before it passes under the lower border of the inferior con-

* Consult an article on "The Nerves of the Human Larynx," by T. F. M. Dilworth, *Journal of Anatomy*, vol. lvi.

† F. G. Parsons (*Journal of Anatomy*, vol. liv.) pointed out that the right nerve may lie at some little distance from the groove between the trachea and the œsophagus.

strictor muscle and enters the larynx behind the articulation of the inferior cornu of the thyroid with the cricoid cartilage ; it gives branches to all the muscles of the larynx, excepting the cricothyroid. It communicates with the internal laryngeal nerve, and supplies sensory filaments to the mucous membrane of the larynx below the level of the vocal folds.

As the recurrent laryngeal nerve hooks round the subclavian artery, or the arch of the aorta, it gives several cardiac filaments to the deep part of the cardiac plexus. As it ascends in the neck it gives branches, more numerous on the left than on the right side, to the mucous membrane and muscular coat of the œsophagus ; branches to the mucous membrane and muscular fibres of the trachea ; and some filaments to the inferior constrictor muscle.

The **cardiac branches**, two or three in number, arise from the vagus nerve at the upper and lower parts of the neck. The *upper branches* are small, and join with the cardiac branches of the sympathetic trunk. They can be traced to the deep part of the cardiac plexus.

The *lower branches* arise at the root of the neck. That from the right vagus passes in front or by the side of the innominate artery, and proceeds to the deep part of the cardiac plexus ; that from the left runs down across the arch of the aorta, and joins the superficial part of the cardiac plexus.

Additional cardiac branches arise from the trunk of the right vagus nerve as it lies by the side of the trachea, and from both recurrent laryngeal nerves. They end in the deep part of the cardiac plexus. The cardiac plexus is described on p. 1149.

The **anterior pulmonary branches**, two or three in number and of small size, are distributed on the anterior surface of the root of the lung. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The **posterior pulmonary branches**, more numerous and larger than the anterior, are distributed on the posterior surface of the root of the lung ; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic trunk, and form the *posterior pulmonary plexus*. Branches from this plexus accompany the ramifications of the bronchi and supply their constrictor muscles.

The **œsophageal branches** are given off both above and below the pulmonary branches ; the lower are more numerous and larger than the upper. They form, as already described (p. 1071), the *œsophageal plexus*. From this plexus filaments are distributed to the œsophagus and to the back of the pericardium.

The **gastric branches** are distributed to the stomach, the anterosuperior surface of which is mainly supplied by the left vagus, and the postero-inferior surface mainly by the right. The gastric branches sometimes form *anterior* and *posterior gastric plexuses*. " The pyloric canal, sphincter, and first stage of the duodenum receive their nerve-supply from above, receiving twigs from the vagal branches to the liver " (M'Crea).

The **cœliac branches** are derived from the right vagus : they join the cœliac ganglia.

The **hepatic branches** arise from both vagus nerves (p. 1071) : they join the hepatic plexus and through it are conveyed to the liver.

The vagus is a composite nerve and has been formed by the fusion of a number of dorsal nerves. It innervates the fourth, fifth and sixth branchial arches, but, in view of the presence of the large intestinal ramus in the vagus nerves of all fishes, it is impossible to speak with confidence as to the original number of its constituents.

It is interesting to observe that although the seventh and ninth cranial nerves have lost their somatic afferent constituent, it still persists in connexion with the tenth nerve, as its auricular branch. There is, however, some good grounds for supposing that its afferent fibres terminate in the nucleus of the spinal tract of the trigeminal nerve. However that may be, it is certain that irritation of the terminal twigs of the auricular branch in the external auditory meatus is capable of producing an efferent vagal response.

Applied Anatomy.—The trunk of the vagus is rarely injured, but the functions of the nerve may be interfered with by damage to its nucleus of origin in the medulla ; by thickening or growth from the meninges or bones, or aneurysm of the basilar artery, before its exit from the skull ; injuries such as gunshot or punctured wounds in the neck or

injuries during such operations as ligature of the carotid artery, removal of tuberculous glands or other deep-seated tumours. The vagus may also be compressed by aneurysms of the carotid artery, and its deep origin becomes affected in bulbar paralysis. The symptoms produced by paralysis of the nerve are palpitation, with increased frequency of the pulse, constant vomiting, slowing of the respiration, and a sensation of suffocation.

'Reflexes' in connexion with the branches of the vagus are not infrequent. The 'ear cough' is perhaps one of the commonest, where a plug of wax in the auditory meatus may, by irritating the filaments of the auricular nerve, be responsible for a persistent cough. Syringing the external auditory meatus frequently produces cough, and, in children, vomiting is not uncommon as the result of such a procedure; moreover, in people with weak hearts, syringing the ear has been responsible for a sudden fatal syncope, by reflex irritation of the cardiac branches. Another very common example is the persistent cough which is frequently due to enlarged bronchial glands in children, the irritation of which is referred to the superior laryngeal filaments.

The anatomy of the laryngeal nerves is of importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them reflex spasm of the glottis is the result. When its trunk is pressed upon by, for instance, a goitre or an aneurysm of the upper part of the carotid, there is a peculiar dry, brassy cough. When the nerve is paralysed, there is anæsthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, as the nerve also supplies the crico-thyroid muscle, the vocal folds cannot be made tense, and the voice is deep and hoarse. Paralysis may be the result of bulbar paralysis; may be a sequel to diphtheria, when both nerves are usually involved; or it may, though less commonly, be caused by the pressure of tumours or aneurysms, when the paralysis is generally unilateral. Irritation of the recurrent laryngeal nerves produces spasm of the muscles of the larynx. When both recurrent laryngeal nerves are paralysed, the vocal folds are motionless, in the so-called 'cadaveric position'—that is to say, in the position in which they are found in ordinary tranquil respiration; neither closed as in phonation, nor widely open as in deep inspiratory efforts. When one recurrent laryngeal nerve is paralysed, the vocal fold of the same side is motionless, while the opposite one crosses the median plane to accommodate itself to the affected one; hence phonation is possible, but the voice is altered and weak in timbre. Paralysis of the adductor muscles of the larynx on both sides is quite common, and is usually functional in nature. The voice is reduced to a whisper, but the power of coughing is preserved.

The Accessory Nerve (figs. 959, 960, 961)

The **accessory nerve** is formed by the union of a cranial and a spinal root. It represents the separated caudal rootlets of the vagus, but the separation is only partial, for its constituent parts are associated with each other only for a very short part of their course before the cranial part joins the vagus to be distributed through its branches. It is, however, both customary and convenient to describe it as a separate cranial nerve.

The **cranial root** is the smaller; its fibres arise from the cells of an elongated nucleus which is continuous above with the lower end of the **nucleus ambiguus** (p. 916) and emerge as four or five delicate rootlets from the side of the medulla oblongata, below the roots of the vagus. It runs laterally to the jugular foramen, where it interchanges fibres with the spinal root or becomes united to it for a short distance; here it is also connected by one or two filaments with the superior ganglion of the vagus. It passes through the jugular foramen, separates from the spinal portion, and is continued over the inferior ganglion of the vagus, to the surface of which it is adherent, and is distributed principally to the pharyngeal and recurrent laryngeal branches of the vagus. It is probably the source of the motor fibres which run in the pharyngeal branch of the vagus to supply the muscles of the soft palate, with the exception of the tensor palati. Some filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves.

The **spinal root** is firm in texture, and its fibres arise from an elongated nucleus of motor cells which is situated in the lateral part of the anterior grey column of the spinal cord, and extends downwards as low as the level of the fifth cervical nerve. Passing through the lateral white column of the spinal cord, they emerge on its surface and unite to form a trunk, which ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, and enters the skull through the foramen magnum, behind the vertebral

artery. It is then directed upwards and laterally to the jugular foramen, through which it passes in the same sheath of dura mater as the vagus nerve, but separated from that nerve by a fold of the arachnoid mater. In the jugular foramen, it receives one or two filaments from the cranial root, or else joins it for a short distance and then parts from it again. At its exit from the jugular foramen, it runs backwards over the internal jugular vein in about 66 per cent. of subjects, and deep to it in about 33 per cent. (Tandler). In this situation the accessory nerve crosses the transverse process of the atlas and is itself crossed by the occipital artery. The nerve then descends obliquely, passing deep to the styloid process, the stylohyoid muscle and the posterior belly of the digastric. Accompanied by the upper sternomastoid branch of the occipital artery, it reaches the upper part of the sternomastoid and pierces its deep surface (fig. 702), supplying it and joining with branches from the second cervical nerve. Emerging above the middle of the posterior border of the sternomastoid, the nerve crosses the posterior triangle of the neck lying on the levator scapulæ muscle, from which it is separated by the prevertebral layer of the deep cervical fascia and the fatty tissue which occupies the triangle. Here it is comparatively superficial, being related to the superficial cervical lymph glands and receiving communications from the second and third cervical nerves. Finally, about 5 cm. above the clavicle, the accessory nerve disappears under the anterior border of the trapezius and, together with branches from the third and fourth cervical nerves, forms a plexus on the deep surface of the muscle. From this plexus the trapezius receives its innervation.

The nucleus of the spinal root of the accessory nerve represents the branchial (special visceral) efferent column, and the muscles which it innervates must be regarded as greatly modified branchial muscles. It is not possible to identify the particular branchial arch which is concerned, but it must be caudal to the six arches which can be identified in the human embryo.

Applied Anatomy.—The functions of the accessory nerve may be interfered with either by central changes; or at its exit from the skull, by fractures running across the jugular foramen; or in the neck, by inflamed lymph glands, etc. The acute wry-neck in children is most commonly due to inflamed or suppurating glands, and rapidly subsides with appropriate treatment. Central irritation causes clonic spasm of the sternomastoid and trapezius muscles, or, as it is termed, spasmodic torticollis. In cases of this affection in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the accessory nerve has been resorted to.

In cases where extensive dissections are undertaken for enlarged glands in the neck, it is essential that this nerve should be sought at once and isolated from the mass of inflamed glands so as to maintain its continuity.

The Hypoglossal Nerve (figs. 960, 962, 963)

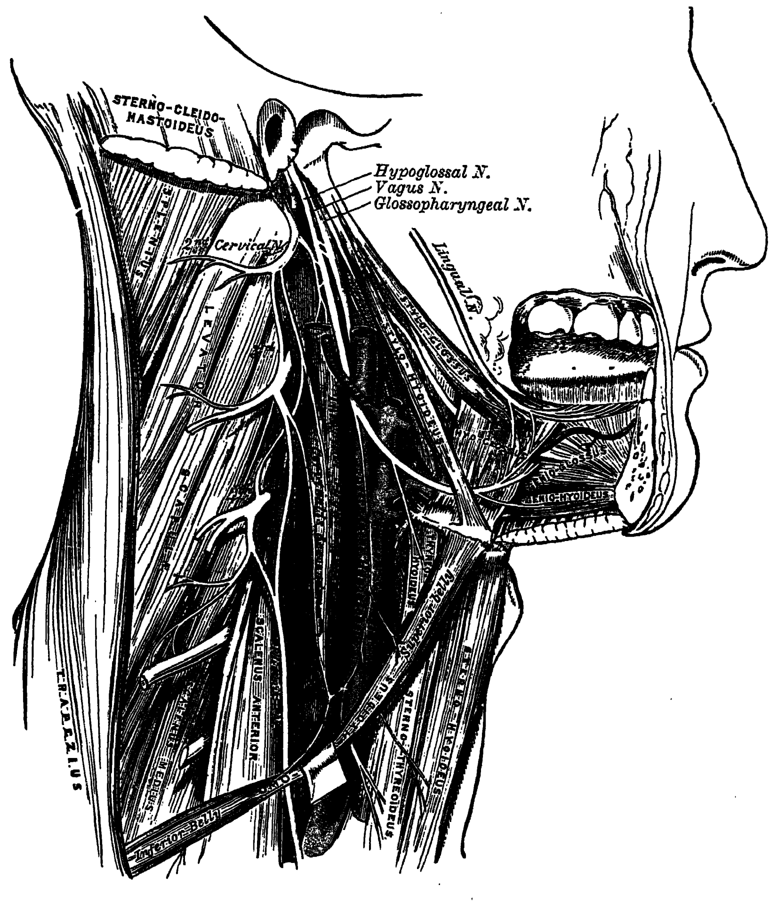
The **hypoglossal nerve** is the motor nerve of the tongue. It is in series with the third, fourth and sixth cranial nerves and the anterior nerve-roots of the spinal nerves, and represents the fused anterior roots of, probably, four precervical or spino-occipital nerves, the posterior roots of which have disappeared entirely.

The **nucleus** from which its fibres arise is in line with the base of the anterior grey column of the spinal cord. This nucleus is about 2 cm. long, and its upper part corresponds with the hypoglossal triangle of the floor of the fourth ventricle (p. 941). The lower part of the nucleus extends downwards into the closed part of the medulla oblongata, and there lies in relation to the ventrilateral aspect of the central canal (p. 910). It occupies the position of the somatic efferent column and therefore lies ventrimedial to the dorsal nucleus of the vagus (fig. 846). The fibres run forwards through the medulla oblongata, and emerge in the anterolateral sulcus between the pyramid and the olive (fig. 836).

The rootlets of the hypoglossal nerve run laterally behind the vertebral artery, and are collected into two bundles, which perforate the dura mater separately, opposite the anterior condylar (hypoglossal) canal in the occipital bone, and unite together after their passage through it; in some cases the canal is divided into two by a small bony spicule. The fact that each bundle acquires a separate sheath from the dura mater is confirmatory evidence of the

composite character of the nerve. On emerging from its canal the nerve lies on a deeper plane than the internal jugular vein, the internal carotid artery, the ninth, tenth and eleventh cranial nerves. It passes laterally, with a downward inclination, behind the internal carotid artery and the glossopharyngeal and vagus nerves to gain the interval between the artery and the internal jugular vein. In this part of its course it makes a half-spiral turn round the inferior ganglion of the vagus, to which it is united by a mass of connective tissue. It then descends almost vertically, lying between the vessels and in front of the vagus nerve, to a point corresponding with the angle of the mandible, and becomes superficial below the posterior belly of the digastric muscle. The nerve

FIG. 962.—The right hypoglossal nerve and cervical plexus.



then loops round the lower sternomastoid branch of the occipital artery (p. 710) and crosses the occipital and the external carotid arteries and the loop of the lingual artery (fig. 701), being itself crossed by the common facial vein. It inclines upwards as it runs forwards on the hyoglossus muscle, passing deep to the tendon of the digastric, the stylohyoid and the posterior border of the mylohyoid muscle. In the interval between the hyoglossus and mylohyoid muscles the nerve is related above to the deep part of the submandibular (submaxillary) gland, the submandibular duct and the lingual nerve. It passes next on to the lateral aspect of the genioglossus and is continued forwards in its substance as far as the tip of the tongue, distributing branches to its muscular substance. It communicates with the sympathetic trunk, and with the vagus, first and second cervical, and lingual nerves.

Opposite the atlas the nerve receives branches from the superior cervical ganglion of the sympathetic trunk, and at the same level is joined by a filament from the loop connecting the first and second cervical nerves.

The communications with the vagus nerve take place close to the skull, numerous filaments passing between the hypoglossal nerve and the inferior ganglion of the vagus nerve through the mass of connective tissue which unites them. As the nerve winds round the occipital artery it receives a filament from the pharyngeal plexus, which is termed the *ramus lingualis vagi*.

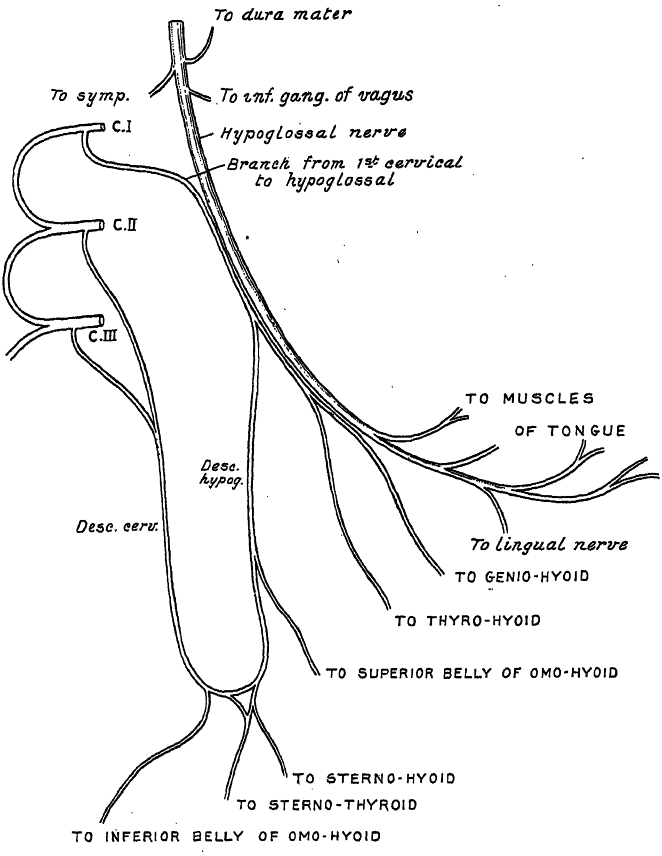
Near the anterior border of the hyoglossus it is united to the lingual nerve by numerous filaments which ascend upon the muscle.

The *branches of distribution* of the hypoglossal nerve are :

Meningeal.	Thyrohyoid.
Descending.	Muscular.

Of these branches the meningeal, descending, thyrohyoid, and that to the geniohyoid muscle, are probably derived mainly from the branch which passes

FIG. 963.—A plan of the hypoglossal nerve.



from the loop between the first and second cervical nerves to join the hypoglossal (fig. 963).

Meningeal branches.—As the hypoglossal nerve passes through the anterior condylar canal it supplies several filaments to the dura mater in the posterior fossa of the skull.

The **descending branch**, long and slender, leaves the hypoglossal nerve where the latter turns round the occipital artery, and descends in front of or within the sheath of the carotid vessels ; it gives a branch to the superior belly of the omohyoid muscle, and, just below the middle of the neck, joins the nervus descendens cervicalis from the second and third cervical nerves to form a loop, termed the *ansa hypoglossi*. From the convexity of this loop branches pass to supply the sternohyoid, the sternothyroid and the inferior belly of the

omohyoid muscle. According to Arnold, another filament descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The **nerve to the thyrohyoid** arises from the hypoglossal nerve near the posterior border of the hyoglossus; it runs obliquely across the greater cornu of the hyoid bone, and supplies the thyrohyoid muscle.

The **muscular branches** are distributed to the styloglossus, hyoglossus, geniohyoid and genioglossus muscles. Numerous slender branches pass upwards into the substance of the tongue to supply its intrinsic muscles.

Applied Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery. It runs forwards on the hyoglossus just above the greater cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought by cutting through the fibres of the hyoglossus. In cases where the nerve is involved by gumma or new growth of the base of the skull, or where it has been injured on one side of the neck, or in some cases of bulbar paralysis, unilateral paralysis, together with hemiatrophy of the tongue, results; the tongue, when protruded, being directed to the paralysed side owing to the unopposed action of the genioglossus of the opposite side. On retraction, the wasted and paralysed side of the tongue rises up higher than the other. The larynx may deviate towards the sound side on swallowing, from the unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, e.g. the result of a bullet wound of the infrahyoid region, the tongue lies motionless in the mouth, taste and tactile sensibility of the organ are perfect, articulation is slow and sticky; swallowing is very difficult, and the patient has to throw his head backwards and push the bolus of food back into the pharynx with his finger before he can swallow it.

THE MORPHOLOGICAL RELATIONSHIPS OF THE CRANIAL NERVES *

It is now possible to group the cranial nerves in a manner which conforms better with their phylogenetic history and with their individual components. At least three, probably four, and possibly five groups are necessary.

Group I includes the third, fourth, sixth and twelfth cranial nerves. These all arise from the cells of the somatic efferent column, and they are distributed to the musculature derived from the cranial myotomes. They correspond, therefore, to the anterior nerve-roots of the spinal nerves, and with the exception of the fourth, they emerge from the brain-stem, in line with them. The identification of the individual segments with which each nerve is associated is a matter of considerable difficulty and is not susceptible of proof in the present state of our knowledge, for the precise number of segments represented by the head is still uncertain (p. 103).

Group II includes the fifth, seventh, ninth, tenth and eleventh cranial nerves. These nerves were concerned with the innervation of the branchial arches, and they are placed in series with the posterior nerve-roots of the spinal nerves. They differ from the latter in possessing motor roots which are distributed to the musculature derived from the lateral mesodermic plates of the branchial region. Some of these cranial nerves (the fifth, tenth and eleventh), are compound nerves and have been formed by the fusion of two or more dorsal nerves (p. 1031). In the process cutaneous branches originally connected with the seventh, ninth and tenth nerves, have been taken over by the fifth, so that these nerves in man bear but little resemblance to their homologues in the lower forms of vertebrates and still less to the posterior nerve-roots of the spinal nerves.

On account of the complexity of their components, each nerve may possess more than one nucleus of origin and more than one nucleus of termination. It is noteworthy that the cells of the ganglion of the seventh, the inferior ganglion of the ninth and the inferior ganglion of the tenth nerve, though derived to a large extent from the neural crest, owe their origin in part to ectodermal epibranchial placodes which develop at the dorsal ends of the first three branchial clefts in close relation to the ganglia.

* For Analysis of the Cranial Nerves, see pp. 1080-81.

ANALYSIS OF THE CRANIAL NERVES.

NERVE	COMPONENTS	FUNCTION	CELLS OF ORIGIN	PRINCIPAL CENTRAL CONNEXIONS
Olfactory	Special somatic (? and visceral) afferent	Smell	In nasal mucous membrane	(*a*) Olfactory bulb (*b*) Olfactory pyramid and piriform area (*c*) Hippocampal formation

	General somatic afferent	General cutaneous sensibility of part of auricle and external auditory meatus	Superior ganglion	(*a*) ? Nucleus of spinal tract of V. (*b*) Thalamus (*c*) Postcentral gyrus
Accessory (spinal part)	Branchial (special visceral) efferent	Movements of head and shoulder (sternomastoid and trapezius)	Lateral part of anterior grey column of spinal cord (C. 1-C. 5)	Precentral gyrus
Hypoglossal	Somatic efferent	Movements of tongue	XII. nucleus	Precentral gyrus
	General somatic afferent	Proprioceptive (muscles of tongue)	?	(*a*) Thalamus (*b*) Postcentral gyrus

Although there are certain difficulties in the way, the homologies of the nerves in Groups I and II are generally accepted, but the allocation of the three remaining cranial nerves is entirely uncertain. On account of its mode of development, the optic nerve is usually regarded as having nothing in common with any of the other cranial nerves except its function as a special somatic afferent. The cells of the retina from which its fibres are derived really constitute an outlying part of the brain, although it may be urged that they are derivatives of the forerunners of the neural crest cells.

The olfactory and auditory nerves may be grouped together or separately, or the auditory nerve may be regarded as being homologous with a dorsal nerve. Both nerves arise, in part at least, from ectodermal cells outside the area of the neural tube and crest, but whereas the olfactory cells remain intercalated amongst the epithelial cells of the nasal mucous membrane, the auditory cells migrate a short distance away from the otic vesicle. It must be explained, however, that many authorities believe that the contribution made by the neural crest is responsible for the formation of the whole of the auditory ganglion, and on this account they prefer to regard the auditory as a modified dorsal nerve. In comparing the olfactory and auditory nerves it must be remembered that the olfactory nerves are restricted in all forms to the region of the head, whereas the auditory nerve in man is the sole survivor of a whole series of nerves of the organs of the lateral line, which in lower forms are distributed not only to the head but also to the whole length of the trunk. There is, therefore, considerable justification for the allocation of the olfactory and auditory nerves to separate groups.

THE SPINAL NERVES

The **spinal nerves** arise in series from the sides of the spinal cord and emerge through the intervertebral foramina. Each nerve is formed by the union of an anterior (motor) and a posterior (sensory) nerve-root, but these roots perforate the spinal dura mater independently before they unite (fig. 927), an indication that the two nerve-roots originally remain separate throughout their course (p. 1031). As they emerge from the intervertebral foramina the spinal nerves obviously possess a segmental character, but this feature is much less conspicuous in the connexions of the nerve-roots with the spinal cord. The anterior nerve-roots are the axons of the large motor cells of the anterior grey column, and are derivatives of the cells of the basal lamina of the neural tube. On the other hand, the posterior nerve-roots are the central branches of the axons of the unipolar cells of the spinal ganglia, and are therefore derivatives of the neural crest (p. 108).

The spinal nerves number thirty-one pairs, which are grouped as follows: cervical, 8; thoracic, 12; lumbar, 5; sacral, 5; coccygeal, 1.

The first cervical nerve emerges from the vertebral canal between the occipital bone and the atlas vertebra, and is therefore called the *suboccipital nerve*; the eighth issues between the seventh cervical and first thoracic vertebræ.

Nerve-roots.—Each nerve is attached to the spinal cord by an anterior and a posterior root (p. 903), the latter being characterised by the presence of a ganglion, which is termed the *spinal ganglion*.

The **anterior root** emerges from the anterior surface of the spinal cord as a number of rootlets or filaments, which coalesce to form two bundles near the intervertebral foramen.

The **posterior root** (except that of the first cervical nerve) is larger than the anterior; its rootlets are attached along the posterolateral furrow of the spinal cord and unite to form two bundles which join the spinal ganglion.

The **spinal ganglia** are collections of nerve-cells on the posterior roots of the spinal nerves. Each ganglion is oval in shape, reddish in colour, and its size bears a proportion to that of the nerve-root on which it is situated; it is bifid medially where it is joined by the two bundles of the posterior nerve-root. The ganglia are usually placed in the intervertebral foramina, immediately outside the points where the nerve-roots perforate the dura mater (fig. 965), but the

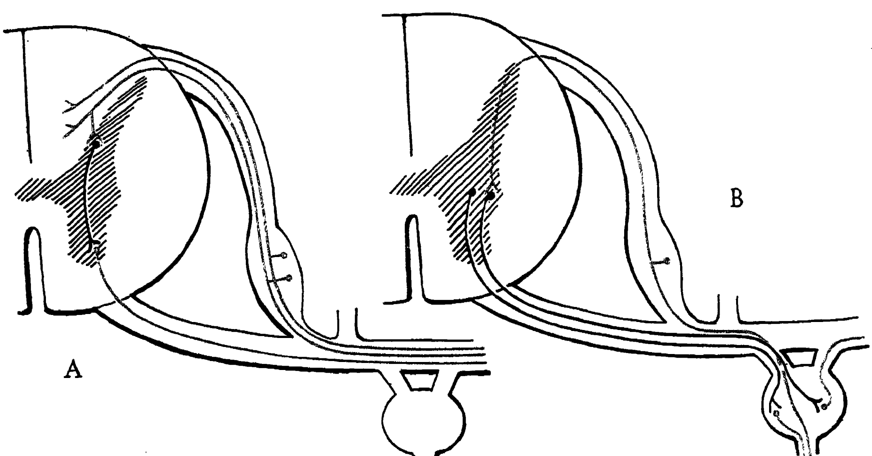
ganglia of the first and second cervical nerves lie on the vertebral arches of the atlas and axis, and those of the sacral nerves are inside the vertebral canal, and that of the coccygeal nerve is within the sheath of dura mater.

The ganglia of the first pair of cervical nerves may be absent, while small *aberrant ganglia* consisting of groups of nerve-cells are sometimes found on the posterior roots of the upper cervical nerves between the spinal ganglia and the spinal cord.

Each nerve-root receives a covering from the pia mater, and is loosely invested by the arachnoid mater, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane (fig. 927); where the roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

Size and direction.—The roots of the upper four *cervical* nerves are small; those of the lower four are large. The posterior roots of the cervical nerves bear a proportion to the anterior of three to one, which is greater than in the

FIG. 964.—Diagrams of the central connexions of the somatic fibres (A) and sympathetic fibres (B) of a typical spinal nerve. Afferent fibres, *blue*; connector neurons, *black*; and efferent fibres, *red*.



other regions; their individual filaments are also larger than those of the anterior roots. The posterior root of the first cervical is an exception to this, being smaller than the anterior root; in about eight per cent. of cases it is wanting. The roots of the first and second cervical nerves are short, and run nearly horizontally to their points of exit from the vertebral canal. From the third to the eighth cervical they are directed obliquely downwards, the obliquity and length of the roots successively increasing; the distance, however, between the level of attachment of any of these roots to the spinal cord and the points of exit of the corresponding nerves never exceeds the height of one vertebra.

The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the posterior roots only slightly exceed the anterior in thickness. They increase successively in length, from above downwards, and, in the lower part of the thoracic region, descend in contact with the spinal cord for a distance equal to the height of at least two vertebræ before they emerge from the vertebral canal.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral, and coccygeal nerves run vertically downwards to their respective exits, and as the spinal cord ends near the lower border of the first lumbar vertebra it follows that the lengths of the successive

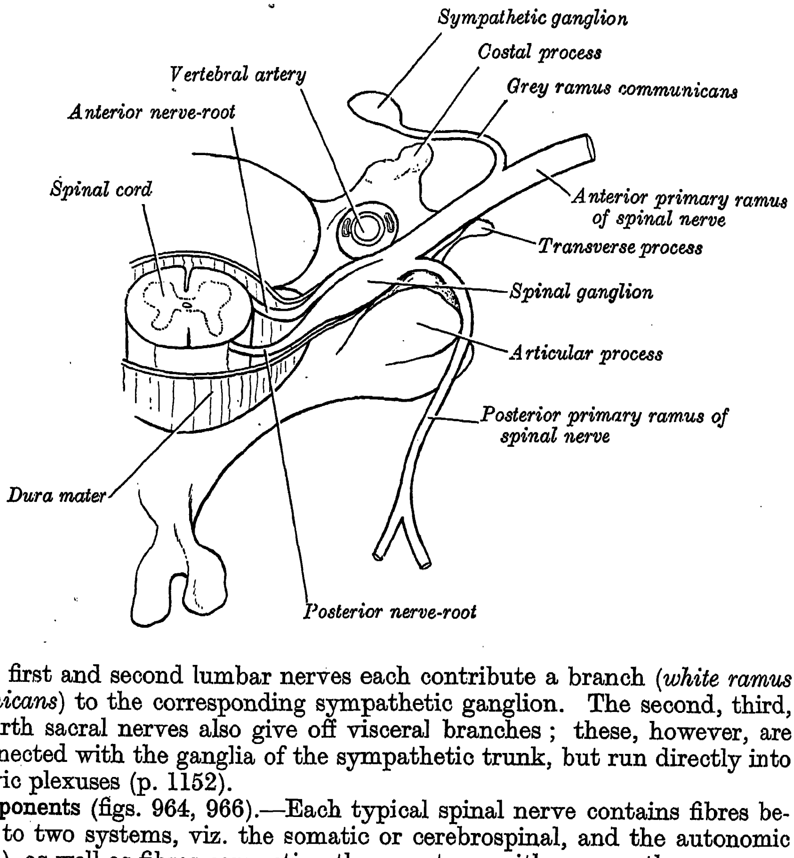
roots must rapidly increase. As already mentioned (p. 888), the term *cauda equina* is applied to this collection of nerve-roots.

From the description given it will be seen that the largest nerve-roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the spinal cord; these nerves are distributed to the upper and lower limbs.

Immediately beyond the spinal ganglion, the anterior and posterior nerve-roots unite to form the *spinal nerve*, which emerges through the intervertebral foramen.

Connexions with the sympathetic trunks.—After emerging from the intervertebral foramen each spinal nerve receives a branch (*grey ramus communicans*) from the corresponding ganglion of the sympathetic trunk, while the thoracic,

FIG. 965.—Scheme showing the relations of a cervical nerve and its ganglion to a cervical vertebra.



and the first and second lumbar nerves each contribute a branch (*white ramus communicans*) to the corresponding sympathetic ganglion. The second, third, and fourth sacral nerves also give off visceral branches; these, however, are not connected with the ganglia of the sympathetic trunk, but run directly into the pelvic plexuses (p. 1152).

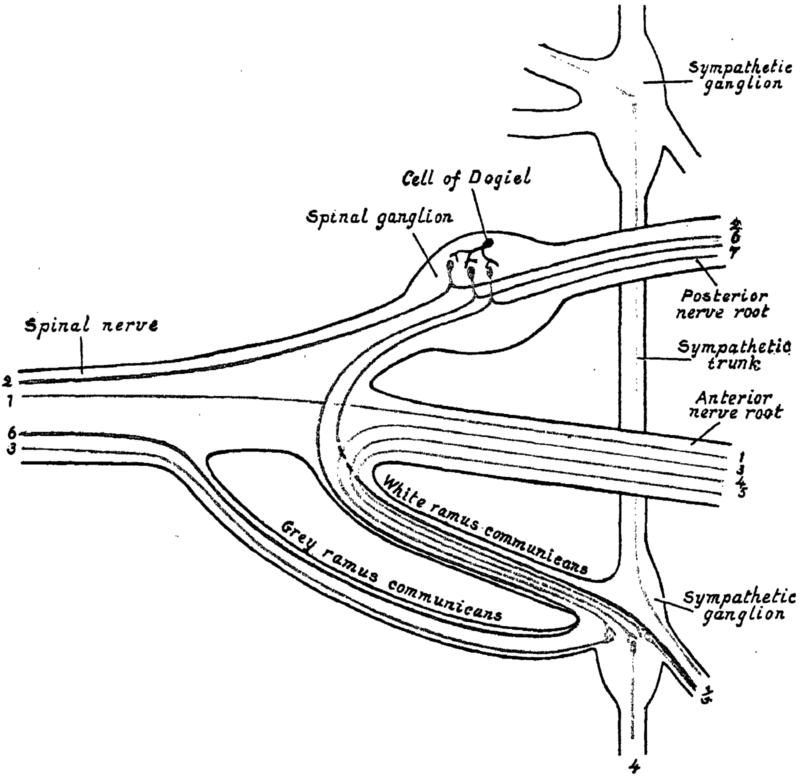
Components (figs. 964, 966).—Each typical spinal nerve contains fibres belonging to two systems, viz. the somatic or cerebrospinal, and the autonomic (fig. 966), as well as fibres connecting these systems with one another.

1. The *somatic efferent* fibres originate in the cells of the anterior grey column of the spinal cord, and run outwards through the anterior nerve-roots to the spinal nerve. They convey impulses to the voluntary muscles, and are continuous from their origin to their peripheral distribution. The *somatic afferent* fibres convey impressions inwards from the skin, etc., and originate in the unipolar nerve-cells of the spinal ganglia. The single processes of these cells divide into peripheral and central fibres, and the latter enter the spinal cord through the posterior nerve-roots.

2. The *autonomic* fibres are also efferent and afferent. The *efferent* fibres originate in the lateral column of the spinal cord, and are conveyed through the anterior nerve-roots and the white rami communicantes. Those issuing from the thoracic and lumbar regions of the spinal cord pass to the corresponding ganglia of the sympathetic trunk; here they may end by forming synapses around the cells of the ganglia, or they may run through one ganglion

to end in another on the sympathetic trunk, or in a more distally placed ganglion in one of the sympathetic plexuses. In all cases they end by forming synapses around other nerve-cells. From the cells of the ganglia of the sympathetic trunk other fibres (*postganglionic*) take origin ; some of these run through the grey rami communicantes to join the spinal nerves and are distributed to the blood-vessels, sweat glands, etc. ; others pass to the viscera. The fibres issuing from the sacral region of the spinal cord are *parasympathetic* ; they do not join the sympathetic ganglia but pass as the *pelvic splanchnic nerves* to the pelvic plexuses. The *afferent* fibres are derived from the cells of the spinal

FIG. 966.—A scheme showing the structure of a typical spinal nerve.



1. Somatic efferent. 2. Somatic afferent. 3, 4, 5. Autonomic efferent. 6, 7. Autonomic afferent.

ganglia. Their peripheral processes are carried through the white rami communicantes, and after passing without interruption through one or more sympathetic ganglia end in the tissues of the viscera. The central processes of the unipolar cells enter the spinal cord through the posterior nerve-roots and form synapses around either somatic or sympathetic efferent neurons, thus completing reflex arcs. Some authorities believe that the cells of Dogiel in the spinal ganglia (p. 1035) bring the autonomic afferent neurons into relationship with those of the somatic system, and so render possible the transference of an impulse from the former to the brain.

Rami or Divisions.—After emerging from the intervertebral foramen, each spinal nerve supplies a small *meningeal branch*, which re-enters the vertebral canal through the intervertebral foramen and is distributed to the vertebræ and their ligaments, and the blood-vessels of the spinal cord and its membranes. The spinal nerve then splits into a *posterior* and an *anterior primary ramus*, each receiving fibres from both nerve-roots.

THE POSTERIOR PRIMARY RAMI OF THE SPINAL NERVES

The **posterior primary rami** of the spinal nerves are as a rule smaller than the anterior. They are directed backwards, and, with the exceptions of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into medial and lateral branches for the supply of the muscles and skin (fig. 967) of the posterior part of the trunk.

The Posterior Primary Rami of the Cervical Nerves

The posterior primary ramus of each cervical nerve, with the exception of the first, divides into a medial and a lateral branch. All these branches innervate muscles but, as a rule, only the medial branches of the second, third, fourth and, usually, the fifth, supply cutaneous areas. With the exception of the first and second, each posterior ramus passes backwards medial to the posterior intertransverse muscle and winds round the articular process to gain the interval between the semispinalis capitis and the semispinalis cervicis muscles.

The **posterior primary ramus of the first cervical or suboccipital nerve** (fig. 591) is larger than the anterior ramus, and emerges above the posterior arch of the atlas and below the vertebral artery. It enters the suboccipital triangle and supplies the muscles which bound this triangle, viz. the rectus capitis posterior major, and the superior and inferior oblique muscles ; it gives branches also to the rectus capitis posterior minor and the semispinalis capitis. A filament from the branch to the inferior oblique muscle joins the posterior primary ramus of the second cervical nerve (fig. 591).

The nerve occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the greater and lesser occipital nerves.

The **posterior primary ramus of the second cervical nerve** is much larger than the anterior, and is the greatest of all the cervical posterior primary rami. It emerges between the posterior arch of the atlas and the lamina of the axis, below the inferior oblique muscle. It supplies a twig to this muscle, receives a communicating filament from the posterior primary ramus of the first cervical, and then divides into a large medial and a small lateral branch.

The *medial* branch, called from its size and distribution the *greater occipital nerve*, ascends obliquely between the inferior oblique and the semispinalis capitis, and pierces the latter muscle and the trapezius near their attachments to the occipital bone. It is then joined by a filament from the medial branch of the posterior primary ramus of the third cervical, and, ascending on the back of the head with the occipital artery, divides into branches which communicate with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives muscular branches to the semispinalis capitis, and occasionally a twig to the back of the auricle. The *lateral* branch supplies filaments to the splenius, longissimus capitis and semispinalis capitis, and is often joined by the corresponding branch of the third cervical.

The **posterior primary ramus of the third cervical nerve** is intermediate in size between those of the second and fourth. Its *medial* branch runs between the semispinalis capitis and semispinalis cervicis, and, piercing the splenius and trapezius, ends in the skin. While under the trapezius it gives a branch, called the *third occipital nerve*, which pierces the trapezius and ends in the skin of the lower part of the back of the head (fig. 967). It lies medial to the greater occipital nerve, and communicates with it. The *lateral* branch often joins that of the second cervical.

The posterior primary ramus of the suboccipital, and the medial branches of the posterior primary rami of the second and third cervical nerves are sometimes joined by communicating loops to form the *posterior cervical plexus* (Cruveilhier).

The posterior primary rami of the lower five cervical nerves divide into medial and lateral branches. The *medial* branches of the fourth and fifth run between

the semispinalis cervicis and semispinalis capitis, and, having reached the spines of the vertebræ, pierce the splenius and trapezius to end in the skin (fig. 967). Sometimes the medial branch of the fifth fails to reach the skin. The medial branches of the lowest three nerves are small, and end in the semispinalis cervicis, semispinalis capitis, multifidus and interspinales. The *lateral* branches of the lower five nerves supply the costocervicalis (iliocostalis cervicis), longissimus cervicis, and longissimus capitis.

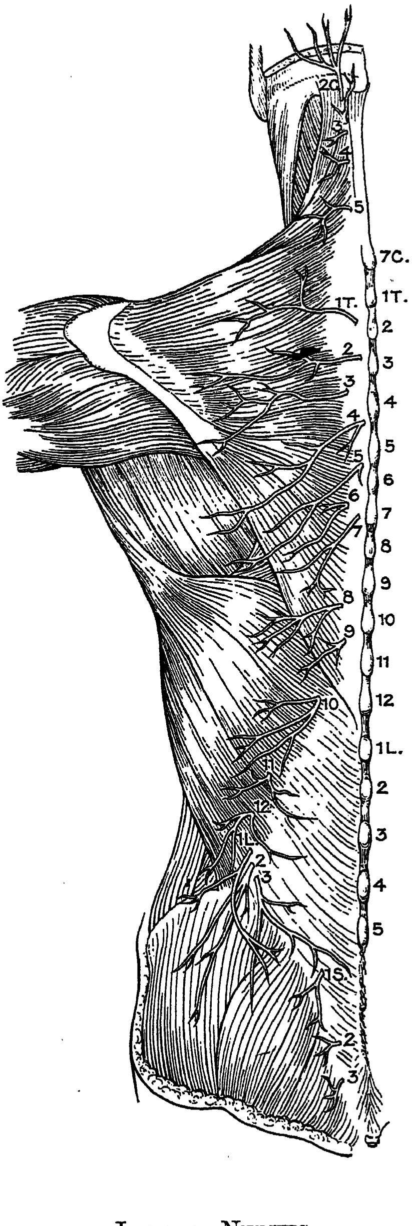


FIG. 967.—A diagram showing the distribution of the cutaneous branches of the posterior primary rami of the spinal nerves.

THE POSTERIOR PRIMARY RAMI OF THE THORACIC NERVES

The *medial* branches of the posterior primary rami of the upper six thoracic nerves run between the semispinalis thoracis and multifidus, which they supply; they then pierce the rhomboids and trapezius, and reach the skin by the sides of the spines (fig. 967). The medial branches of the lower six thoracic nerves are distributed chiefly to the multifidus and longissimus thoracis; occasionally they give filaments to the skin near the median plane.

The *lateral* branches increase in size from above downwards. They run through or deep to the longissimus thoracis to the interval between it and the iliocostocervicalis (iliocostalis), and supply these muscles; the lower five or six also give off cutaneous branches, which pierce the serratus posterior inferior and latissimus dorsi in a line with the angles or the ribs (fig. 967). The lateral branches of a variable number of the upper thoracic nerves also give filaments to the skin. The lateral branch of the twelfth thoracic, after sending a filament medially along the iliac crest, passes downwards to the skin of the anterior part of the buttock.

The medial cutaneous branches of the posterior primary rami of the thoracic nerves descend for some distance close to the spines before reaching the skin, while the lateral branches travel downwards for a considerable distance—it may be as much as the breadth of four ribs—before they become superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.*

THE POSTERIOR PRIMARY RAMI OF THE LUMBAR NERVES

The *medial* branches of the posterior primary rami of the lumbar nerves run close to the articular processes of the vertebræ and end in the multifidus.

The *lateral* branches supply the sacrospinalis. The upper three give off cutaneous nerves which pierce the aponeurosis of the latissimus dorsi at the lateral border of the sacrospinalis and cross the posterior part of the iliac crest

* H. M. Johnston, *Journal of Anatomy and Physiology*, vol. xliii.

to reach the skin of the buttock (fig. 967), some of their twigs running as far as the level of the greater trochanter.

The Posterior Primary Rami of the Sacral Nerves

The **posterior primary rami of the sacral nerves** are small, and diminish in size from above downwards; they emerge, except the last, through the posterior sacral foramina. The *upper three* are covered at their points of exit by the multifidus, and divide into medial and lateral branches.

The *medial* branches are small, and end in the multifidus.

The *lateral* branches join with one another and with the lateral branches of the posterior primary rami of the last lumbar and fourth sacral to form loops on the dorsal surface of the sacrum. From these loops branches run to the dorsal surface of the sacrotuberous ligament and form a second series of loops under the gluteus maximus. From this second series of loops the *gluteal branches*, two or three in number, arise and at once pierce the gluteus maximus along a line drawn from the posterior superior iliac spine to the tip of the coccyx; they supply the skin over the posterior part of the buttock (fig. 967).

The posterior primary rami of the *lower two* sacral nerves are small and lie below the multifidus. They do not divide into medial and lateral branches, but unite with each other and with the posterior primary ramus of the coccygeal nerve to form loops on the back of the sacrum; filaments from these loops supply the skin over the coccyx.

The Posterior Primary Ramus of the Coccygeal Nerve

The **posterior primary ramus of the coccygeal nerve** does not divide into a medial and a lateral branch, but receives, as already stated, a communicating branch from the last sacral; it is distributed to the skin over the back of the coccyx.

THE ANTERIOR PRIMARY RAMI OF THE SPINAL NERVES

The **anterior primary rami of the spinal nerves** supply the limbs and the anterior and lateral aspects of the trunk; they are for the most part larger than the posterior primary rami. In the thoracic region they run independently of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form plexuses.

THE ANTERIOR PRIMARY RAMI OF THE CERVICAL NERVES

The **anterior primary rami of the cervical nerves**, with the exception of the first, appear between the corresponding anterior and posterior intertransverse muscles. The anterior primary rami of the *upper four* nerves unite to form the *cervical plexus*; those of the *lower four*, together with the greater part of the anterior primary ramus of the first thoracic nerve, join to form the *brachial plexus*.

Each nerve receives a grey ramus communicans, the upper four from the superior cervical ganglion, the fifth and sixth from the middle cervical ganglion, and the seventh and eighth from the inferior cervical ganglion, of the sympathetic trunk (see p. 1145).

The anterior primary ramus of the *first cervical* (*suboccipital*) *nerve* appears above the posterior arch of the atlas vertebra, and passes forwards round the lateral side of its lateral mass, medial to the vertebral artery. It supplies a branch to the rectus lateralis, and, emerging on the medial side of that muscle, descends in front of the transverse process of the atlas and behind the internal jugular vein, and joins with the ascending branch of the second nerve.

The anterior primary ramus of the *second cervical nerve* issues between the vertebral arches of the atlas and axis and runs forwards between the transverse processes of these two vertebræ; passing in front of the first posterior inter-transverse muscle and on the lateral side of the vertebral artery it emerges between the longus capitis and levator scapulæ muscles, but when the scalenus medius takes origin from the transverse process of the atlas, it intervenes between the nerve and the levator scapulæ. It divides into an ascending branch which joins with the first cervical nerve, and a descending branch which unites with the ascending branch of the third cervical nerve.

The anterior primary ramus of the *third cervical nerve* appears between the longus capitis and scalenus medius. The anterior primary rami of the remaining cervical nerves emerge between the scalenus anterior and scalenus medius.

The Cervical Plexus

The **cervical plexus** (fig. 968) is formed by the anterior primary rami of the upper four cervical nerves; each nerve, except the first, divides into an upper and a lower branch, and these unite to form three loops. The plexus is situated opposite the upper four cervical vertebræ, in front of the levator scapulæ and scalenus medius, and under cover of the internal jugular vein and the sternomastoid muscle.

Its branches are divided into two groups, *superficial* and *deep*, and are here given in tabular form; the figures following the names indicate the spinal nerves from which the different branches take origin:

Superficial			Lesser occipital	2 C.
			Great auricular	2, 3 C.
			Anterior cutaneous	2, 3 C.
			Supraclavicular	3, 4 C.
Deep	Medial	Communicating	With hypoglossal	1, 2 C.
			,, vagus	1, 2 C.
			,, sympathetic	1, 2, 3, 4 C.
		Muscular	Rectus capitis lateralis	1 C.
			Rectus capitis anterior	1, 2 C.
			Longus capitis	1, 2, 3 C.
			Longus cervicis	2, 3, 4 C.
			Descendens cervicalis	2, 3 C.
			Phrenic	3, 4, 5 C.
	Lateral	Communicating with accessory		2, 3, 4 C.
		Muscular	Sternomastoid	2 C.
			Trapezius	3, 4 C.
			Levator scapulæ	3, 4 C.
			Scalenus medius	3, 4 C.

The Superficial Branches of the Cervical Plexus (figs 968, 969)

The **lesser occipital nerve** (figs. 968, 969) arises from the second cervical nerve, sometimes also from the third; it hooks around the accessory nerve and ascends along the posterior border of the sternomastoid muscle. Near the cranium it perforates the deep fascia, and is continued upwards on the side of the head behind the auricle, supplying the skin and communicating with the great auricular and greater occipital nerves, and with the posterior auricular branch of the facial nerve. The lesser occipital nerve varies in size, and is sometimes duplicated.

It sends off an *auricular branch* which supplies the skin of the upper third of the cranial surface of the auricle, and communicates with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve.

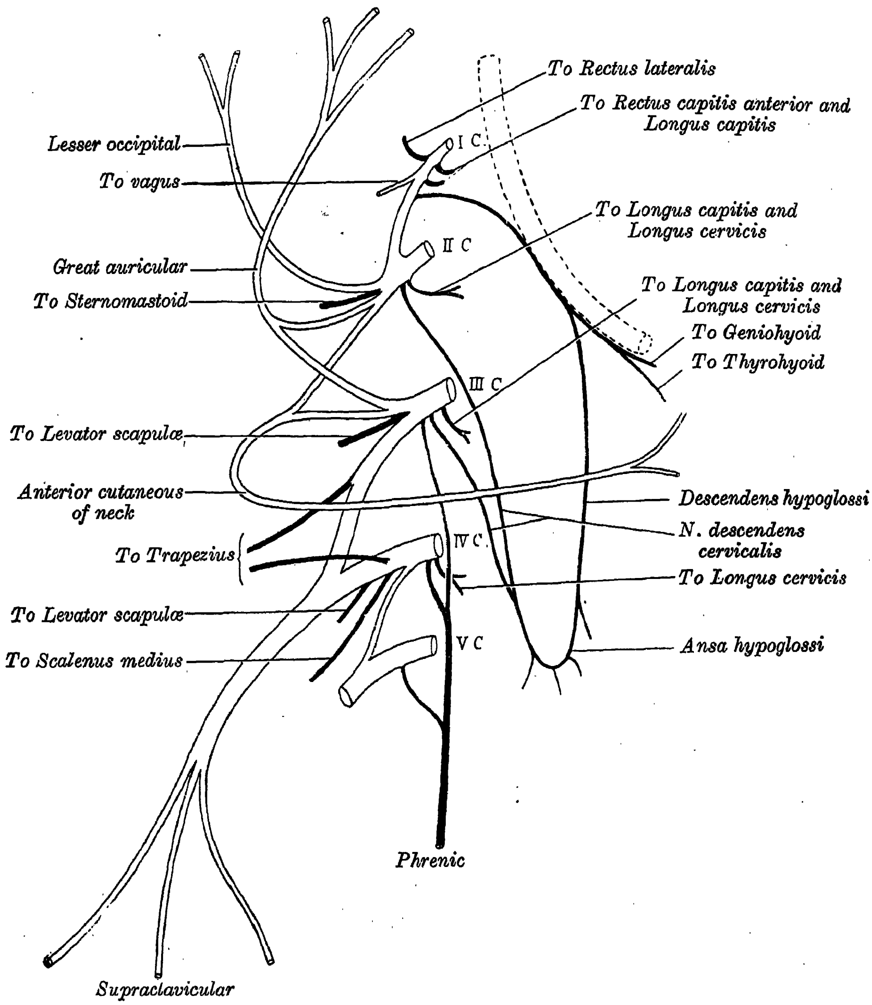
The **great auricular nerve** (figs. 968, 969) is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the sternomastoid muscle, and, after perforating the deep fascia, ascends upon that muscle beneath the platysma in company with the

external jugular vein. It passes on to the parotid gland, where it divides into an anterior and a posterior branch.

The *anterior branch* is distributed to the skin of the face over the parotid gland, and communicates in the substance of the gland with the facial nerve.

The *posterior branch* supplies the skin over the mastoid process and on the back of the auricle, except at its upper part; a filament pierces the auricle to reach its lateral surface, where it is distributed to the lobule and lower part

Fig. 968.—A plan of the cervical plexus.



of the concha. The posterior branch communicates with the lesser occipital nerve, the auricular branch of the vagus nerve, and the posterior auricular branch of the facial nerve.

The **anterior cutaneous nerve of the neck** (n. cutaneus colli) (figs. 968, 969) arises from the second and third cervical nerves, turns round the posterior border of the sternomastoid about its middle, and runs obliquely forwards, deep to the external jugular vein, to the anterior border of the muscle. It perforates the deep cervical fascia, and divides beneath the platysma into ascending and descending branches, which are distributed to the anterolateral parts of the neck.

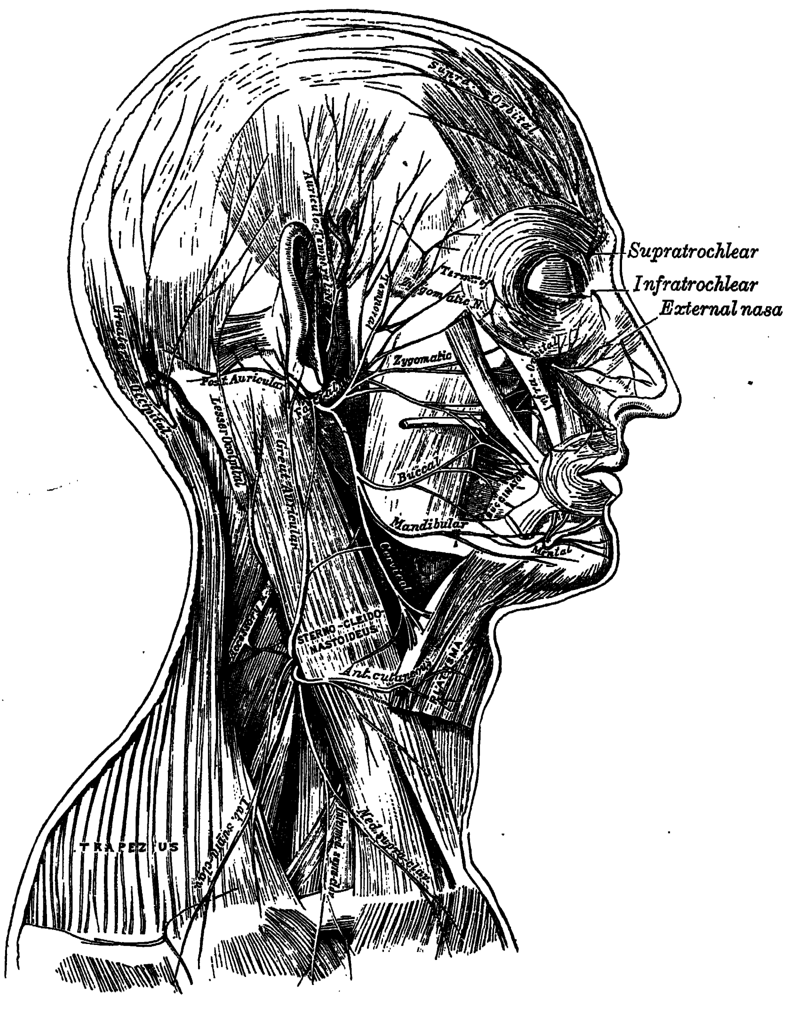
The *ascending branches* pass upwards to the submandibular region, and form a plexus with the cervical branch of the facial nerve, beneath the platysma;

others pierce that muscle, and are distributed to the skin of the upper and front parts of the neck.

The *descending branches* pierce the platysma, and are distributed to the skin of the side and front of the neck, as low as the sternum.

The **supraclavicular nerves** (figs. 968, 969) arise by a common trunk derived from the third and fourth cervical nerves. This trunk emerges from beneath the posterior border of the sternomastoid, descends under cover of the platysma and deep cervical fascia, and divides into medial, intermediate and lateral branches, which diverge from one another and pierce the deep fascia a little above the level of the clavicle.

FIG. 969.—The nerves of the right side of the scalp, face and side of neck.



The *medial supraclavicular nerves* cross obliquely over the external jugular vein and the clavicular and sternal heads of the sternomastoid, and supply the skin as far as the median plane. They furnish one or two filaments to the sternoclavicular joint.

The *intermediate supraclavicular nerves* cross the clavicle, and supply the skin over the pectoralis major and deltoid as low down as the level of the second rib. They communicate with the cutaneous branches of the upper intercostal nerves.

The *lateral supraclavicular nerves* pass obliquely across the outer surface of the trapezius and the acromion, and supply the skin of the upper and posterior parts of the shoulder.

Applied Anatomy.—Pains referred to the superficial terminal branches of the cervical plexus are not uncommon in caries of the cervical vertebræ, where pain may be felt radiating over the occipital bone, if the disease is situated high up in the vertebral column.

The Deep Branches of the Cervical Plexus. Medial Series

The **communicating branches** consist of several filaments which pass from the loop between the first and second cervical nerves to the vagus, hypoglossal and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series of branches, viz. the meningeal, the nervus descendens hypoglossi, the nerve to the thyrohyoid and, possibly, the nerve to the geniohyoid (p. 1078). A communicating branch also passes from the fourth to the fifth cervical nerve, while each of the first four cervical nerves receives a grey ramus communicans from the superior cervical ganglion of the sympathetic trunk.

Muscular branches supply the rectus capitis lateralis, rectus capitis anterior, longus capitis and longus cervicis (longus colli) muscles.

The **nervus descendens cervicalis** (fig. 968) is formed usually by the union of two branches, one derived from the second cervical nerve and the other from the third. It passes downwards on the lateral side of the internal jugular vein, crosses in front of this vein a little below the middle of the neck, and forms a loop (*ansa hypoglossi*) with the descending branch of the hypoglossal nerve (p. 1078) in front of the sheath of the carotid vessels or in its substance. Not infrequently the nervus descendens cervicalis passes forwards between the internal jugular vein and the common carotid artery to reach the ansa hypoglossi (fig. 718).

The **phrenic nerve** contains motor and sensory fibres in the proportion of about two to one. It arises chiefly from the fourth cervical nerve, but receives a branch from the third and another from the fifth (fig. 968); the fibres from the fifth occasionally come through the nerve to the subclavius (p. 1096) and may descend for some distance into the thorax before joining the main trunk (accessory phrenic nerve). Formed at the lateral border of the scalenus anterior, and running obliquely across the front of that muscle, the phrenic nerve descends to the root of the neck, under cover of the sternomastoid, the inferior belly of the omohyoid, and the transverse cervical and suprascapular (transverse scapular) vessels (fig. 718). It next passes in front of the subclavian artery, between it and the subclavian vein, and, as it enters the thorax, crosses from the lateral to the medial side of the internal mammary artery (fig. 783). Within the thorax, it descends nearly vertically in front of the root of the lung, and then between the pericardium and the mediastinal pleura, to the diaphragm (fig. 785), where it divides into branches which pierce that muscle, and are distributed to its under-surface. In the thorax it is accompanied by the pericardiacophrenic branch of the internal mammary artery.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left. It descends in front of the scalenus anterior which separates it from the second part of the subclavian artery. It lies lateral to the right innominate vein and superior vena cava, and is separated by the pericardium from the right atrium of the heart. Its terminal fibres pass through the vena caval opening in the diaphragm.

The *left nerve* is rather longer than the right, owing to the inclination of the heart to the left side, and to the diaphragm being lower on this than on the right side. At the root of the neck it crosses in front of the first part of the subclavian artery, and is itself crossed by the thoracic duct. In the superior mediastinum it lies between the left common carotid and left subclavian arteries, and crosses superficial to the vagus nerve just above the level of the arch of the aorta. It next crosses the arch of the aorta and passes in front of the root of the left lung to reach the left side of the pericardium, by which it is separated from the left ventricle of the heart.

Each nerve supplies branches to the pericardium and pleura, and at the root of the neck is joined by a filament from the sympathetic, and, occasionally, by one from the ansa hypoglossi.

From the *right nerve*, one or two filaments pass with phrenic branches of the cœliac plexus to join in a small *phrenic ganglion*; and branches from this ganglion are distributed to the falciform and coronary ligaments of the liver, the suprarenal gland and inferior vena cava. From the *left nerve*, filaments pass to join the phrenic branches of the cœliac plexus, but without any ganglionic enlargement; and a twig is distributed to the left suprarenal gland.

Applied Anatomy.—In addition to its supply from the phrenics, the diaphragm receives innervation from the lower seven intercostal nerves at its periphery. This double sensory innervation explains the varied distribution of the referred pains that may be felt in different cases of infection or inflammation of the diaphragm, such as may occur in pleurisy or pneumonia affecting its upper surface, on the one hand, or in peritonitis attacking its lower surface on the other. For example, if it is the more central part of the diaphragm that becomes inflamed in a case of acute peritonitis, the patient may complain of pain and tenderness in the area of distribution of the cutaneous branches of the fourth and fifth cervical nerves, with the result that disease of the shoulder-joint or supraclavicular region is erroneously suspected, and the peritonitis is missed. On the other hand, if the periphery of the diaphragm chances to become infected in a patient with acute pleurisy or pneumonia, he may complain of acute pain and tenderness in the area of distribution of the cutaneous branches of the lower intercostal nerves, and may also exhibit rigidity of the underlying abdominal muscles, with the result that an acute intra-abdominal infection is erroneously diagnosed and a laparotomy is performed for the relief of a supposed appendicitis, cholecystitis or localised peritonitis.

The Deep Branches of the Cervical Plexus. Lateral Series

Communicating branches.—The lateral series of deep branches of the cervical plexus communicates with the accessory nerve, in the substance of the sternomastoid, in the posterior triangle and under cover of the trapezius.

Muscular branches are distributed to the sternomastoid, trapezius, levator scapulæ and scalenus medius muscles.

The branch for the sternomastoid is derived from the second cervical nerve; the trapezius and levator scapulæ receive branches from the third and fourth cervical nerves, those to the trapezius crossing the posterior triangle obliquely at a lower level than the accessory nerve. The scalenus medius receives twigs either from the third or fourth cervical nerves, or occasionally from both.

The Brachial Plexus

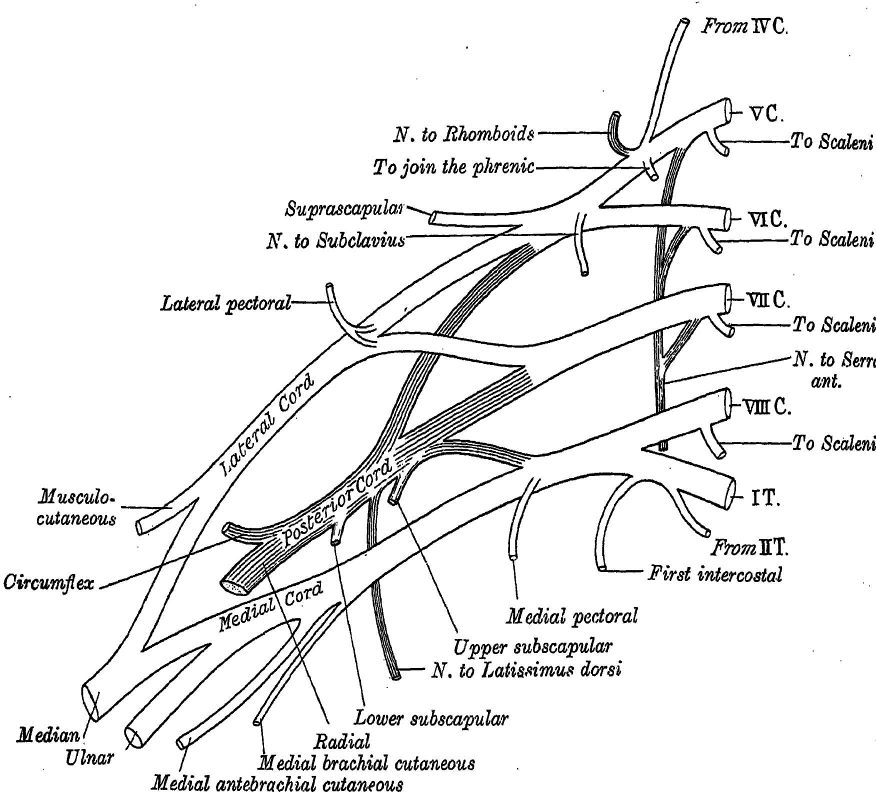
The **brachial plexus** (fig. 970) is formed by the union of the anterior primary rami of the lower four cervical nerves and the greater part of the anterior primary ramus of the first thoracic nerve; the fourth cervical nerve usually gives a branch to the fifth cervical, and the first thoracic nerve frequently receives one from the second thoracic. These nerves constitute the *roots* of the plexus, which extends from the lower part of the side of the neck to the axilla. The roots are nearly equal in size, but their mode of communication is subject to some variation. The following is, however, the most constant arrangement. The fifth and sixth cervical nerves unite at the lateral border of the scalenus medius to form the *upper trunk* of the plexus. The eighth cervical and first thoracic nerves unite behind the scalenus anterior to form the *lower trunk* of the plexus, while the seventh cervical nerve itself constitutes the *middle trunk*. These three trunks run downwards and laterally and as—sometimes before—they pass behind the clavicle, each splits into an *anterior* and a *posterior* division.* The anterior divisions of the upper and middle trunks unite to form a cord, which is situated on the lateral side of the axillary artery, and is called the *lateral cord* of the plexus. The anterior division of the lower trunk passes down at first behind and then on the medial side of the axillary artery, and forms the *medial cord* of the brachial plexus; this cord frequently receives fibres from the seventh cervical nerve. The posterior divisions of all three

* The posterior division of the lower trunk is very much smaller than the others, and is frequently derived from the eighth cervical nerve before the trunk is formed.

trunks unite to form the *posterior cord* of the plexus, which is situated at first above and then behind the axillary artery.

Relations.—*In the neck*, the brachial plexus lies in the posterior triangle in the angle between the clavicle and the lower part of the posterior border of the sternomastoid, being covered by the skin, platysma and deep fascia; it is crossed by the supraclavicular nerves, the nerve to the subclavius, the inferior belly of the omohyoid, the external jugular vein and the transverse cervical artery (fig. 971). It emerges between the scalenus anterior and scalenus medius; its upper part lies above the third part of the subclavian artery, while the lower trunk is placed behind the artery; the plexus next passes behind the clavicle, the subclavius and the suprascapular (transverse scapular) vessels, and lies

FIG. 970.—A plan of the brachial plexus.



upon the first digitation of the serratus anterior and the subscapularis. *In the axilla* the lateral and posterior cords of the plexus are on the lateral side of the first part of the axillary artery, and the medial cord behind it. The cords surround the second part of the axillary artery on three sides, the medial cord lying on the medial side, the posterior cord behind, and the lateral cord on the lateral side of the artery. In the lower part of the axilla the cords split into the nerves for the upper limb.

Close to their exit from the intervertebral foramina the fifth and sixth cervical nerves receive grey rami communicantes from the middle cervical ganglion, and the seventh and eighth cervical similar rami from the inferior cervical ganglion, of the sympathetic trunk (p. 1145). The first thoracic nerve receives a grey ramus from, and contributes a white ramus to, the first thoracic ganglion of the sympathetic trunk.

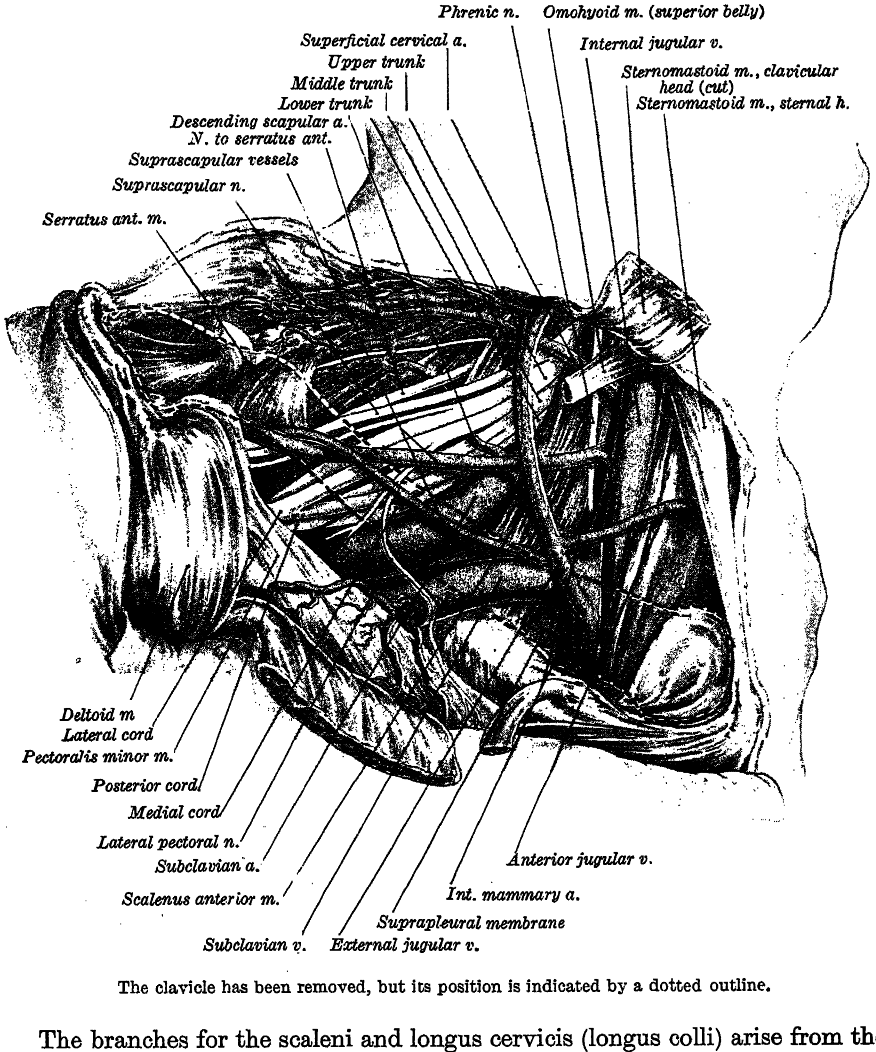
The branches of the brachial plexus.—The branches of the brachial plexus are usually subdivided into two groups, viz. those arising above the clavicle (*supraclavicular*) and those below that bone (*infraclavicular*).

The Supraclavicular Branches

The supraclavicular branches may be grouped as follows : (*a*) those arising from the roots, and (*b*) those arising from the trunks of the plexus.

From the roots of the plexus.	1. To scaleni and longus cervicis	5, 6, 7, 8 C.
	2. To join phrenic nerve . .	5 C.
	3. Nerve to rhomboids . .	5 C.
	4. Nerve to serratus anterior .	5, 6, 7 C.
From the trunks of the plexus.	1. Nerve to subclavius . .	5, 6 C.
	2. Suprascapular nerve . .	5, 6 C.

Fig. 971.—A dissection of the brachial plexus of the right side, viewed from the anterolateral aspect.



The clavicle has been removed, but its position is indicated by a dotted outline.

The branches for the scaleni and longus cervicis (longus colli) arise from the lower four cervical nerves close to their points of exit from the intervertebral foramina.

On the scalenus anterior the phrenic nerve is joined by a branch from the fifth cervical nerve.

The **nerve to the rhomboids** arises from the fifth cervical nerve, pierces the scalenus medius, passes on to the deep surface of the levator scapulæ, to which it occasionally gives a twig, and runs in company with the deep branch of the

transverse cervical artery on the anterior surfaces of the rhomboids; it ends by supplying these muscles.

The **nerve to the serratus anterior** (fig. 971) usually arises by three roots from the fifth, sixth, and seventh cervical nerves, but the root from the seventh nerve may be absent. The roots from the fifth and sixth nerves pierce the scalenus medius, while that from the seventh passes laterally in front of the muscle. The nerve descends behind the brachial plexus and the first part of the axillary vessels, resting on the outer surface of the serratus anterior. It is continued down to the lower border of that muscle, supplying, in its course, filaments to each of its digitations.

The **nerve to the subclavius** is a small nerve which arises from the point of junction of the fifth and sixth cervical nerves; it descends in front of the plexus and the third part of the subclavian artery, and is usually connected by a filament with the phrenic nerve. It then passes behind the subclavian vein and reaches the subclavius muscle, which it supplies.

The **suprascapular nerve** (fig. 977) is a large nerve which arises from the upper trunk of the brachial plexus. It runs laterally deep to the trapezius and the omohyoid, and enters the supraspinous fossa through the suprascapular notch, passing below the suprascapular ligament; it then runs deep to the supraspinatus, and curves round the lateral border of the spine of the scapula in company with the suprascapular (transverse scapular) artery to gain the infraspinous fossa. In the supraspinous fossa it gives two branches to the supraspinatus muscle, and articular filaments to the shoulder-joint and acromioclavicular joint; and in the infraspinous fossa it gives two branches to the infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

The Infraclavicular Branches

The infraclavicular branches are derived from the three cords of the brachial plexus, but their fibres may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

Lateral cord	Lateral pectoral	5, 6, 7 C.
	Musculocutaneous	5, 6, 7 C.
	Lateral root of median	6, 7 C.
Medial cord	Medial pectoral	8 C., 1 T.
	Medial cutaneous of forearm	
	Medial cutaneous of arm	
	Medial root of median	
	Ulnar *	(7), 8 C., 1 T.
Posterior cord	Upper subscapular	5, 6 C.
	Lower subscapular	5, 6 C.
	Circumflex	5, 6 C.
	Nerve to latissimus dorsi	6, 7, 8 C.
	Radial	5, 6, 7, 8 C., 1 T.

The **pectoral nerves** (fig. 976) supply the pectoralis major and pectoralis minor.

The *lateral pectoral nerve* (lateral anterior thoracic nerve), the larger of the two, may arise by two roots from the anterior divisions of the upper and middle trunks, or by a single root from the point where these divisions unite to form the lateral cord of the plexus; it receives its fibres from the fifth, sixth, and seventh cervical nerves. It crosses the axillary artery and vein, pierces the clavipectoral fascia, and is distributed to the deep surface of the pectoralis major. It sends a filament to join the medial pectoral nerve and form with it a loop in front of the first part of the axillary artery; through this loop the lateral pectoral nerve distributes some fibres to the pectoralis minor.

The *medial pectoral nerve* (medial anterior thoracic nerve) receives its fibres from the eighth cervical and first thoracic nerves, and arises from the medial cord of the plexus while that cord is still posterior to the axillary artery. It

* See footnote on p. 1101.

curves forwards between the axillary artery and vein, and unites in front of the artery with a filament from the lateral pectoral nerve. It then enters the deep surface of the pectoralis minor and supplies that muscle. Two or three branches pierce the pectoralis minor, and others may pass round its inferior border, to end in the pectoralis major.

The **subscapular nerves**, two in number, spring from the posterior cord of the plexus, and through it from the fifth and sixth cervical nerves.

The *upper subscapular nerve*, the smaller, enters the upper part of the subscapularis, and is frequently represented by two branches.

The *lower subscapular nerve* supplies the lower part of the subscapularis, and ends in the teres major; the latter muscle is sometimes supplied by a separate branch.

The **nerve to latissimus dorsi** (thoracodorsal nerve), a branch of the posterior cord of the plexus, derives its fibres from the sixth, seventh and eighth cervical nerves; it accompanies the subscapular artery along the posterior wall of the axilla and supplies the latissimus dorsi, in which it may be traced as far as the lower border of the muscle.

The **circumflex nerve** (axillary nerve) (fig. 977) arises from the posterior cord of the brachial plexus, its fibres being derived from the fifth and sixth cervical nerves. It lies at first on the lateral side of the radial nerve and is placed behind the axillary artery, and in front of the subscapularis. At the lower border of that muscle it winds backwards in close relation to the lowest part of the articular capsule of the shoulder-joint, and, in company with the posterior circumflex humeral vessels, passes through a quadrangular space bounded above by the subscapularis, in front, and the teres minor, behind, below by the teres major, medially by the long head of the triceps and laterally by the surgical neck of the humerus. The nerve ends by dividing into an anterior and a posterior branch.

The *anterior branch*, accompanied by the posterior circumflex humeral vessels, winds round the surgical neck of the humerus, deep to the deltoid, as far as the anterior border of the muscle, supplying it, and giving a few small cutaneous branches which pierce the muscle and ramify in the skin covering its lower part.

The *posterior branch* supplies the teres minor and the posterior part of the deltoid; upon the branch to the teres minor an oval enlargement (pseudoganglion) usually exists. The posterior branch then pierces the deep fascia and is continued as the *upper lateral cutaneous nerve of the arm*, which sweeps round the posterior border of the deltoid and supplies the skin over the lower two-thirds of the posterior part of this muscle, and the skin covering the long head of the triceps (figs. 972, 973).

The trunk of the circumflex nerve gives an articular filament which enters the shoulder-joint below the subscapularis.

The **musculocutaneous nerve** (fig. 976) arises from the lateral cord of the brachial plexus, opposite the lower border of the pectoralis minor, its fibres being derived from the fifth, sixth, and seventh cervical nerves. It pierces the coracobrachialis and runs downwards and laterally between the biceps and the brachialis to reach the lateral side of the arm; a little below the elbow it pierces the deep fascia on the lateral side of the tendon of the biceps and is continued into the forearm as the *lateral antebrachial cutaneous nerve*. In its course through the arm it supplies the coracobrachialis, both heads of the biceps and the greater part of the brachialis. The branch to the coracobrachialis leaves the musculocutaneous nerve before that nerve enters the muscle; it receives its fibres from the seventh cervical nerve, and in some instances arises directly from the lateral cord of the brachial plexus. The branches to the biceps and brachialis leave the musculocutaneous nerve after it has pierced the coracobrachialis; that supplying the brachialis gives a filament to the elbow-joint. The nerve also sends a small branch to the humerus; this branch enters the bone with the nutrient artery.

The *lateral cutaneous nerve of the forearm* (fig. 972) passes deep to the cephalic vein, and descends along the radial border of the forearm to the wrist. It supplies the skin over the lateral half of the anterior surface of the forearm and distributes branches which turn round the radial border of the forearm to

communicate with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsal surface of the carpus. The nerve then passes downwards

Fig. 972.—The cutaneous nerves of the right upper limb. Anterior surface.

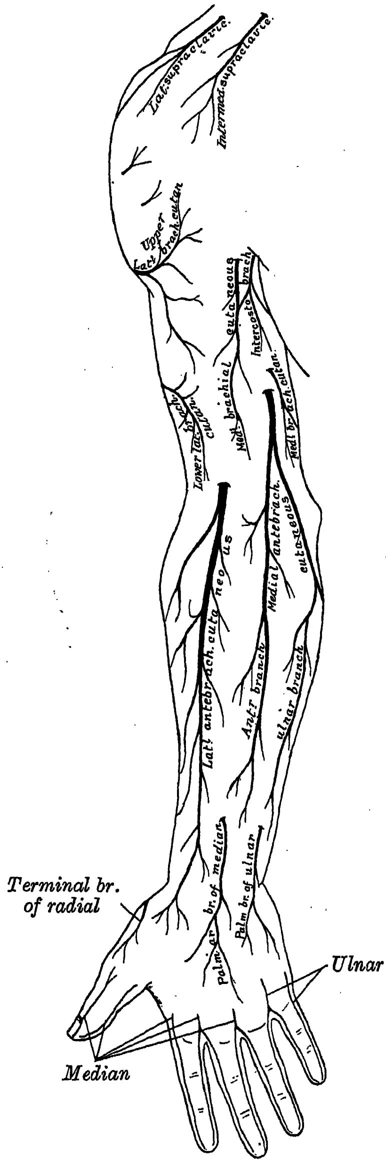


Fig. 973.—A diagram showing the segmental distribution of the cutaneous nerves of the right upper limb. Anterior surface.

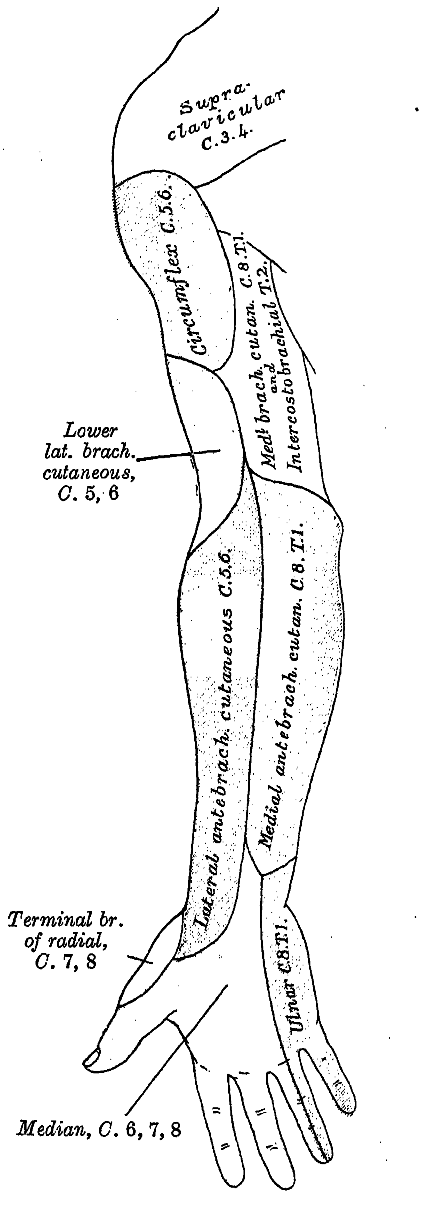

to the ball of the thumb, where it ends in cutaneous filaments. It communicates with the terminal branch of the radial nerve, and with the palmar cutaneous branch of the median nerve.

The musculocutaneous nerve presents frequent irregularities. It may run behind the coracobrachialis or on rare occasions it may pass through the biceps. It may adhere for some distance to the median nerve and then pass behind the biceps instead of through the coracobrachialis. Some of the fibres of the

median nerve may run for some distance in the musculocutaneous nerve and then leave it to join their proper trunk ; less frequently the reverse is the case, and the median nerve sends a branch to join the musculocutaneous nerve. Occasionally it gives a filament to the pronator teres and, sometimes, it may replace the branches of the radial nerve to the dorsal surface of the thumb.

The **medial cutaneous nerve of the forearm** (fig. 976) arises from the medial cord of the brachial plexus. It derives its fibres from the eighth cervical and first thoracic nerves, and at its commencement is placed between the axillary artery and vein. Near the axilla it supplies a filament which pierces the fascia and is distributed to the skin covering the biceps, almost as far as the elbow. The nerve then runs down the arm on the medial side of the brachial artery, pierces the deep fascia with the basilic vein about the middle of the arm, and divides into an anterior and a posterior branch.

The *anterior branch*, the larger, passes usually in front of, but occasionally behind, the median cubital vein (median basilic vein). It then descends on the front of the medial side of the forearm, distributing filaments to the skin as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve (fig. 972).

The *posterior branch* passes obliquely downwards on the medial side of the basilic vein, in front of the medial epicondyle of the humerus, winds round to the back of the forearm, and descends on its medial side as far as the wrist, distributing filaments to the skin. It communicates with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the dorsal branch of the ulnar nerve (fig. 974).

The **medial cutaneous nerve of the arm** is distributed to the skin on the medial side of the arm (fig. 972). It is the smallest branch of the brachial plexus, and, arising from the medial cord, receives its fibres from the eighth cervical and first thoracic nerves. It passes through the axilla and crosses in front of, or behind, the axillary vein. It then runs on the medial side of this vein, and communicates with the intercostobrachial nerve. It descends along the medial side of the brachial artery to the middle of the upper arm, where it pierces the deep fascia, and is distributed to the skin of the dorsal surface of the lower one-third of the arm over its medial half, extending as far as the elbow ; some filaments are lost in the skin in front of the medial epicondyle, and others over the olecranon. It communicates with the posterior branch of the medial cutaneous nerve of the forearm.

In some subjects the medial brachial cutaneous and intercostobrachial nerves are connected by two or three filaments, which form a plexus in the axilla. In others the intercostobrachial nerve is large and may be reinforced by a part of the lateral cutaneous branch of the third intercostal nerve ; it then takes the place of the medial brachial cutaneous nerve, receiving from the brachial plexus a communicating filament which represents the latter nerve ; occasionally this filament is wanting.

The **median nerve** (fig. 976) arises by two roots, one from the lateral and the other from the medial cord of the brachial plexus ; these embrace the lower part of the axillary artery, uniting either in front or on the lateral side of that vessel. Its fibres are derived from the (fifth), sixth, seventh, and eighth cervical and first thoracic nerves. As the median nerve descends through the arm, it lies at first lateral to the brachial artery ; about the level of the insertion of the coracobrachialis it crosses in front of, occasionally behind, the artery, and then descends on its medial side to the bend of the elbow, where it is situated behind the bicipital aponeurosis (lacertus fibrosus), and is separated from the elbow-joint by the brachialis. It enters the forearm between the two heads of the pronator teres ; here it crosses the ulnar artery, but is separated from it by the deep head of the pronator teres. It passes behind the tendinous bridge which connects the humero-ulnar to the radial head of the flexor digitorum sublimis and descends through the forearm under cover of, and adherent to, that muscle, lying on the flexor digitorum profundus. About 5 cm. above the flexor retinaculum (transverse carpal ligament) it is crossed by the oblique lateral border of the radial head of the flexor digitorum sublimis and becomes more superficial. It now lies between the tendons of the flexor digitorum

sublimis and the flexor carpi radialis, behind, but rather to the lateral side of, the tendon of the palmaris longus. It then passes behind the flexor retinaculum and gains the palm of the hand. In its course through the forearm it is accompanied by the median artery, a branch of the anterior interosseous artery.

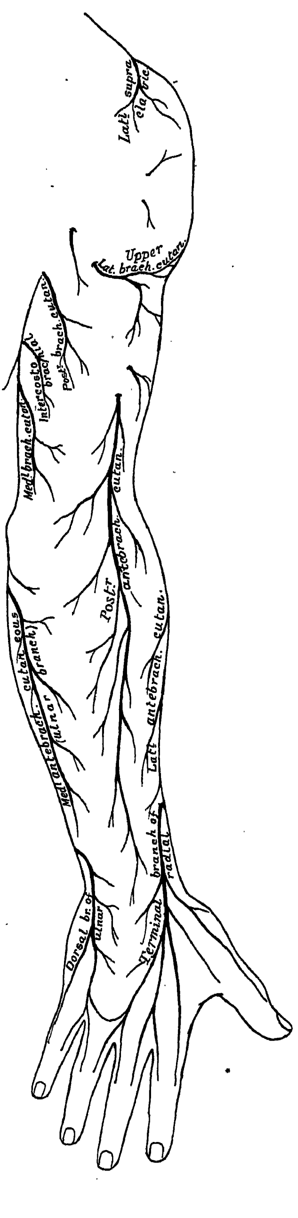

Fig. 974.—The cutaneous nerves of the right upper limb. Posterior surface.

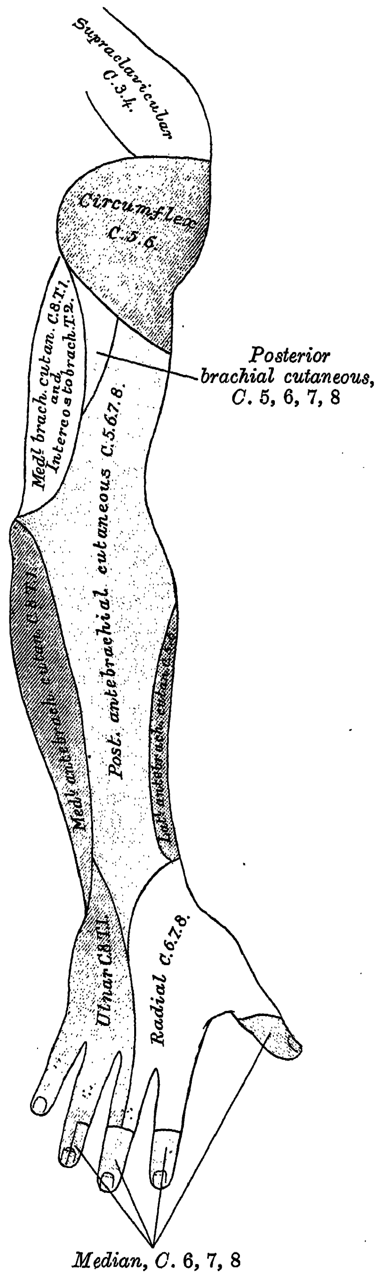

Fig. 975.—A diagram showing the segmental distribution of the cutaneous nerves of the right upper limb. Posterior surface.

Branches.—With the exception of the nerve to the pronator teres, which derives its fibres from the sixth cervical nerve and usually arises above the elbow-joint, the median nerve gives no branches in the arm. As it passes in front of the elbow, it supplies one or two twigs to the joint.

In the forearm its branches are : muscular, anterior interosseous, and palmar.

The *muscular branches* are derived from the nerve near the elbow and supply all the superficial muscles on the front of the forearm, except the flexor carpi ulnaris.

The *anterior interosseous nerve* accompanies the anterior interosseous artery along the front of the interosseous membrane of the forearm, in the interval between the flexor pollicis longus and flexor digitorum profundus, supplying the whole of the former and the lateral half of the latter muscle ; it sends branches into the deep surface of the pronator quadratus, and ends by supplying the wrist-joint.

The *palmar branch* of the median nerve arises at the lower part of the forearm. It pierces the deep fascia above the flexor retinaculum (transverse carpal ligament), and divides into a lateral and a medial branch ; the lateral branch supplies the skin over the thenar eminence, and communicates with the anterior branch of the lateral cutaneous nerve of the forearm ; the medial branch supplies the skin of the palm, and communicates with the palmar cutaneous branch of the ulnar nerve.

In the palm of the hand the median nerve is covered by the skin, the palmar aponeurosis and the superficial palmar arch, and rests on the tendons of the flexor muscles. Immediately after emerging from behind the flexor retinaculum it becomes enlarged and flattened, and splits into a lateral and a medial portion. The *lateral* portion of the nerve supplies a short, stout branch to the following muscles of the ball of the thumb, viz. the abductor brevis, the opponens and the flexor brevis, and then divides into three *palmar digital nerves* ; two of these supply the sides and the joints of the thumb, while the third gives a twig to the first lumbrical and is distributed to the radial side of the index finger. The *medial* portion of the nerve divides into two *palmar digital nerves*. The first of these gives a twig to the second lumbrical and runs towards the cleft between the index and middle fingers, where it divides into two collateral branches for the adjoining sides of these digits. The second runs towards the cleft between the middle and ring fingers, and splits into two collateral branches for the adjoining sides of these digits ; it receives a communicating branch from the ulnar nerve, and sometimes sends a twig to the third lumbrical.

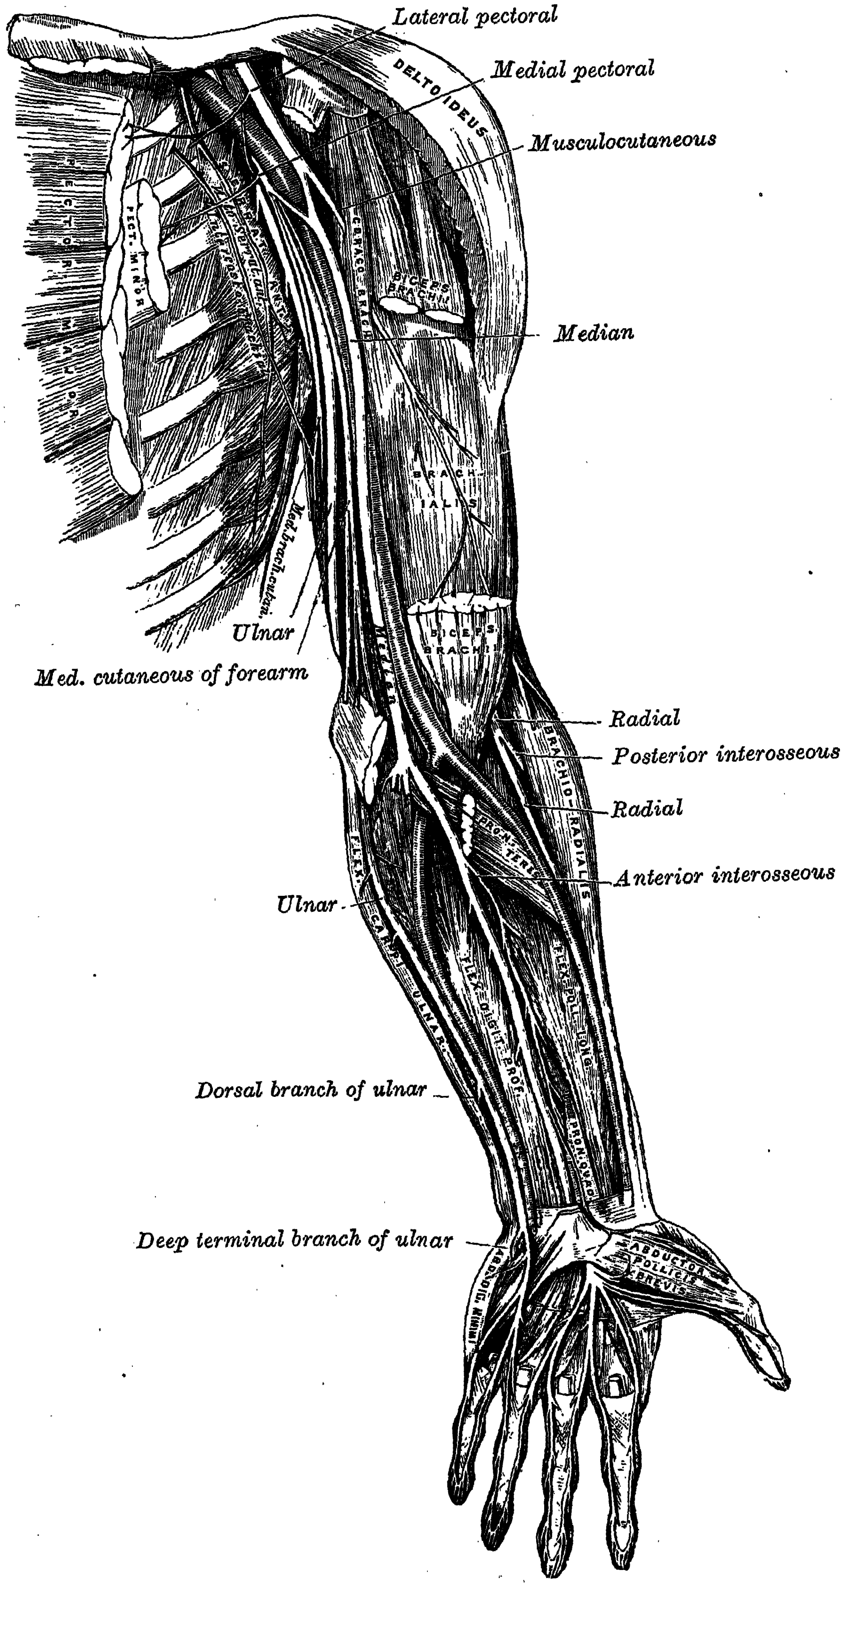
Opposite the base of the proximal phalanx, each collateral digital nerve gives off a dorsal branch, which joins the dorsal digital branch from the radial nerve, and supplies the skin on the dorsal surface of the phalanx. At the end of the digit, each collateral digital nerve divides into two branches ; one supplies the pulp of the finger, the other ramifies around and beneath the nail. On the fingers the collateral digital nerves are in front of the corresponding arteries, and they give articular twigs to the metacarpophalangeal and interphalangeal joints.

The **ulnar nerve** (fig. 976) arises from the medial cord of the brachial plexus, and derives its fibres from the seventh and eighth cervical and first thoracic nerves.* It runs downwards through the axilla on the medial side of the axillary artery, intervening between it and the axillary vein, and continues downwards on the medial side of the brachial artery as far as the middle of the upper arm. Here it pierces the medial intermuscular septum, and descends in front of the medial head of the triceps, to the interval between the medial epicondyle and the olecranon, accompanied by the (superior) ulnar collateral artery. At the elbow it lies in a groove on the back of the medial epicondyle, and as it enters the forearm between the two heads of the flexor carpi ulnaris, it lies on the posterior and oblique parts of the medial ligament (ulnar collateral ligament) of the elbow-joint. It descends along the medial side of the forearm, lying upon the flexor digitorum profundus ; its upper half is covered by the flexor carpi ulnaris ; its lower half lies on the lateral side of this muscle, and is covered by the skin and fasciæ. In the upper one-third of the forearm, the ulnar nerve

* Wilfred Harris (*Journal of Anatomy*, vol. xxxviii.) found a branch running from the seventh cervical nerve to the ulnar nerve in 86 per cent. of subjects, and believed, on clinical grounds, that the fibres of this branch were mainly motor to the Flexor carpi ulnaris.

E. A. Linell (*Journal of Anatomy*, vol. lv.) found a considerable bundle of seventh cervical nerve-fibres running from the lateral root of the median nerve to the ulnar nerve in 57 per cent. of subjects.

Fig. 976.—The nerves of the left upper limb.



is separated from the ulnar artery by a considerable interval, but in the rest of its extent it lies close to the medial side of the vessel. About 5 cm. above the wrist it gives off a dorsal branch, and it is then continued downwards into the hand, passing in front of the flexor retinaculum (transverse carpal ligament) on the lateral side of the pisiform bone and lying medial to and somewhat behind the ulnar artery. It passes behind the superficial part of the retinaculum (volar carpal ligament) and ends by dividing into a superficial and a deep terminal branch.

The branches of the ulnar nerve are: articular to the elbow-joint, muscular, palmar cutaneous, dorsal, and superficial terminal and deep terminal.

The *articular branches* to the elbow-joint are several small filaments which arise from the nerve as it lies between the medial epicondyle and olecranon.

The *muscular branches*, two in number, arise near the elbow; one supplies the flexor carpi ulnaris; the other, the medial half of the flexor digitorum profundus.

The *palmar cutaneous branch* arises about the middle of the forearm, and descends on the ulnar artery, giving some filaments to the vessel. It perforates the deep fascia and ends in the skin of the palm, after communicating with the palmar branch of the median nerve. It sometimes supplies the palmaris brevis.

The *dorsal branch* arises about 5 cm. above the wrist; it passes backwards deep to the flexor carpi ulnaris, perforates the deep fascia, and, running along the medial side of the back of the wrist and hand, divides into two, frequently three, dorsal digital nerves: one supplies the medial side of the little finger; the second the adjacent sides of the little and ring fingers. The third, when present, supplies the adjoining sides of the ring and middle fingers, but it may be replaced, wholly or partially, by a branch of the radial nerve, with which it always communicates on the dorsum of the hand. A branch is distributed to the metacarpal region of the hand, communicating with a twig from the radial nerve (fig. 974). On the little finger the dorsal digital nerves extend only as far as the base of the distal phalanx, and on the ring finger as far as the base of the middle phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the collateral digital branches of the ulnar nerve.

The *superficial terminal branch* supplies the palmaris brevis and the skin on the medial side of the hand, and divides into two palmar digital nerves. One of these supplies the medial side of the little finger; the other sends a twig to join the median nerve and then divides into two collateral branches for the adjoining sides of the little and ring fingers (fig. 976). The collateral branches are distributed to the fingers in the same manner as those of the median nerve.

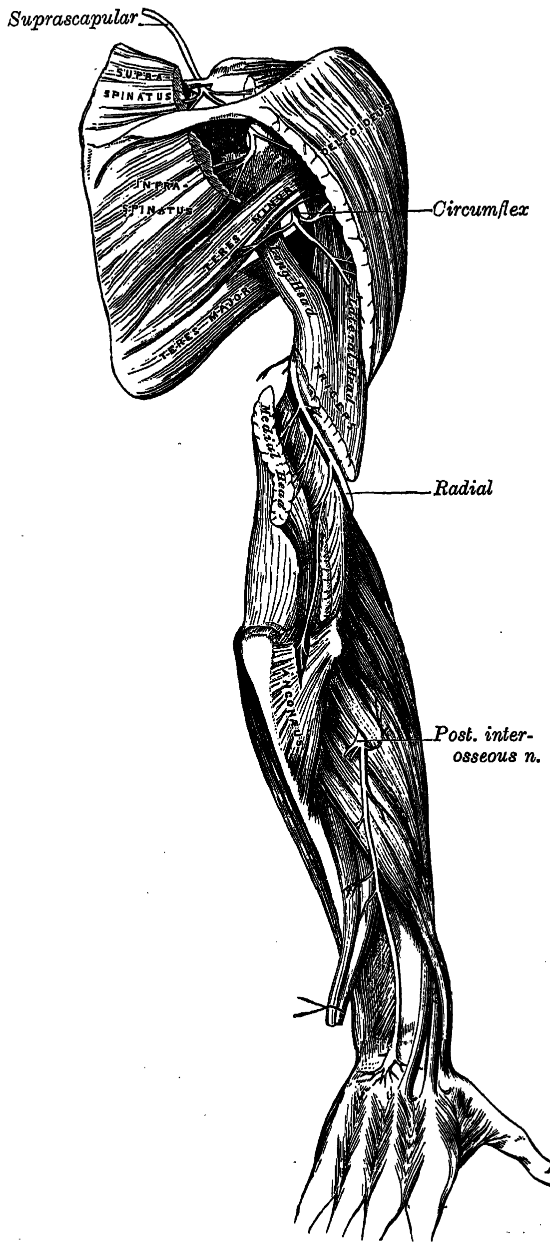
The *deep terminal branch*, accompanied by the deep branch of the ulnar artery, passes between the abductor digiti minimi and flexor digiti minimi; it then perforates the opponens digiti minimi and follows the course of the deep palmar arch behind the flexor tendons. At its origin it supplies the three short muscles of the little finger. As it crosses the hand, it gives branches to the interossei and to the third and fourth lumbricals; it ends by supplying the adductor pollicis and the first palmar interosseous muscle (deep portion of the flexor pollicis brevis). It also sends articular filaments to the wrist-joint.

It has been pointed out that the medial part of the flexor digitorum profundus is supplied by the ulnar nerve; the third and fourth lumbricals, which are connected with the tendons of this part of the muscle, are supplied by the same nerve. In like manner the lateral part of the flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical frequently receives an additional twig from the median nerve.

The **radial nerve** (fig. 977), which is the largest branch of the brachial plexus, derives its fibres from the fifth, sixth, seventh, and eighth cervical and first thoracic nerves. It descends behind the third part of the axillary artery and the upper part of the brachial artery, and in front of the subscapularis and the tendons of the latissimus dorsi and teres major. Accompanied by the arteria profunda brachii it inclines backwards between the long and medial heads of the triceps, and passes obliquely across the back of the humerus in the spiral groove (sulcus nervi radialis), and under cover of the lateral

head of the triceps. On reaching the lateral side of the humerus it pierces the lateral intermuscular septum and enters the anterior compartment of the arm. It then descends, lying deeply in the intermuscular furrow which is bounded on the medial side by the brachialis and on the lateral side by the brachioradialis, above, and the extensor carpi radialis longus, below. On reaching the front of the lateral epicondyle it gives off the posterior interosseous nerve. It then descends along the front of the lateral side of the upper two-thirds of the forearm, lying at first upon the supinator, lateral to the radial artery, and behind the brachioradialis. In the middle one-third of the fore-arm, it lies behind the same muscle, but is now close to the lateral side of the artery. It quits the artery about 7 cm. above the wrist, passes deep to the tendon of the brachioradialis, and, piercing the deep fascia, divides into five, sometimes four, dorsal digital nerves, which are distributed as follows: the first supplies the skin of the radial side and ball of the thumb, communicating with branches of the lateral cutaneous nerve of the forearm; the second supplies the medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers; the fifth communicates with a filament from the dorsal branch of the ulnar nerve, and supplies the adjoining sides of the middle and ring fingers,* but it is frequently replaced by the dorsal branch of the ulnar nerve. On the back of the hand the radial nerve usually communicates with the posterior and the lateral cutaneous nerves of the forearm.

Fig. 977.—The right suprascapular, circumflex, and radial nerves.



The branches of the radial nerve are: muscular, cutaneous, articular and the posterior interosseous nerve.

* According to Hutchison, the digital nerve to the thumb reaches only as far as the root of the nail; the one to the forefinger as far as the middle of the middle phalanx; and those to the middle and ring fingers not farther than the proximal interphalangeal joints.—*London Hospital Gazette*, vol. iii. p. 319.

The *muscular branches* supply the triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis, and are grouped as medial, posterior and lateral.

The medial muscular branches arise from the radial nerve on the medial side of the arm and supply the medial and long heads of the triceps; the branch to the medial head is a long, slender filament, which lies close to the ulnar nerve as far as the lower one-third of the arm, and is therefore frequently named the *ulnar collateral nerve.*

The posterior muscular branch, of large size, arises from the nerve as it lies in the spiral groove (sulcus nervi radialis). It divides into filaments which supply the medial and lateral heads of the triceps and the anconeus. The branch for the latter muscle is a long nerve which descends in the substance of the medial head of the triceps, and gives numerous branches to it. It is accompanied by a branch of the arteria profunda brachii, and passes behind the elbow-joint to end in the anconeus.

The lateral muscular branches supply the brachioradialis, extensor carpi radialis longus and the lateral part of the brachialis.

The *cutaneous branches* are the posterior cutaneous and the lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

The *posterior cutaneous nerve of the arm,* of small size, arises in the axilla. It runs round the long head of the triceps to the medial side of the arm and supplies the skin on its dorsal surface nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

The *lower lateral cutaneous nerve of the arm* perforates the lateral head of the triceps just below the insertion of the deltoid muscle. It then passes to the front of the elbow, lying close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm (fig. 972). The *posterior cutaneous nerve of the forearm* arises in common with the preceding branch. After perforating the lateral head of the triceps, it descends along the lateral side of the arm, and then along the back of the forearm to the wrist, supplying the skin in its course, and joining, near its termination, with dorsal branches of the lateral cutaneous nerve of the arm (fig. 974).

The **articular branches** are distributed to the elbow-joint.

The **posterior interosseous nerve** (deep branch of the radial nerve) (fig. 977) winds to the back of the forearm round the lateral side of the radius between the two planes of fibres of the supinator. It gives a branch to the extensor carpi radialis brevis, and another to the supinator before it enters the latter muscle, and as it traverses its substance it supplies additional branches to it. As soon as it escapes from the supinator on the back of the forearm it gives off three short branches—to the extensor digitorum, extensor digiti minimi and extensor carpi ulnaris—and two long branches—a medial to the extensor pollicis longus and the extensor indicis, and a lateral which supplies the abductor pollicis longus and ends in the extensor pollicis brevis. The nerve lies at first between the superficial and the deep muscles of the back of the forearm, but, at the lower border of the extensor pollicis brevis, it passes deep to the extensor pollicis longus and, diminished to a fine thread, runs down on the dorsal aspect of the interosseous membrane of the forearm. Finally it reaches the back of the carpus, where it presents a flattened and somewhat expanded termination from which filaments are distributed to the ligaments and articulations of the carpus.

Applied Anatomy.—The brachial plexus may be injured by falls from a height on to the side of the head and shoulder, whereby the nerves of the plexus are violently stretched; the upper trunk of the plexus sustains the greatest amount of injury, and the subsequent paralysis may be confined to the muscles supplied by the fifth nerve, viz. the deltoid, biceps, brachialis and brachioradialis, with sometimes the supraspinatus, infraspinatus and supinator. The position of the limb, under such conditions, is characteristic: the arm hangs by the side and is rotated medially; the forearm is extended and pronated. The arm cannot be raised from the side; all power of flexion of the elbow is lost, as is also supination of the forearm. This is known as Erb's paralysis, and a very similar condition is occasionally met with in new-born children, either from injury to the upper trunk from the pressure of the forceps used in effecting delivery, or from traction of the head in breech presentations. A second variety of partial palsy of the brachial plexus is known as

Klumpke's paralysis. In this it is the eighth cervical and first thoracic nerves that are injured, either before or after they have joined to form the lower trunk. The subsequent paralysis affects, principally, the intrinsic muscles of the hand and the flexors of the wrist and fingers.

The brachial plexus may also be injured by direct violence or a gunshot wound, by violent traction on the arm, or by effort at reducing a dislocation of the shoulder-joint; and the amount of paralysis will depend upon the amount of injury to the constituent nerves. When the entire plexus is involved, the whole of the upper extremity will be paralysed and anæsthetic. In some cases the injury appears to be rather a tearing away of the roots of the nerves from the spinal cord than a rupture of the nerves themselves. The brachial plexus in the axilla is often damaged from the presence of a crutch, producing the condition known as 'crutch paralysis.' In these cases the radial is the nerve most frequently implicated; the ulnar nerve suffers next in frequency. The median and radial nerves often suffer from 'sleep palsies,' paralysis from pressure coming on while the patient is profoundly asleep under the influence of alcohol or some narcotic.

Paralysis of the *nerve to serratus anterior* (long thoracic nerve) throws that muscle out of action, and may occur in porters, in whom the nerve is exposed to injury as it lies in the posterior triangle of the neck. The inferior angle of the scapula is drawn towards the median plane, by the unopposed action of the rhomboids and levator scapulæ, and tends to project backwards when the arm is held horizontally forwards. The arm cannot be raised above the horizontal unless the inferior angle of the scapula is pushed laterally and forwards for the patient.

The *circumflex nerve* (axillary nerve), on account of its course round the surgical neck of the humerus, is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint; paralysis of the deltoid, and anæsthesia of the skin over the lower part of that muscle, result. Paralysis of the deltoid renders complete abduction of the arm impossible. The associated paralysis of the teres minor is not easily demonstrated.

The *median nerve* is liable to injury in wounds of the forearm. When it is completely divided above the origin of its muscular and anterior interosseous branches, there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and little fingers is effected by that portion of the flexor digitorum profundus which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the interossei. The thumb cannot be flexed, opposed or abducted, and is maintained in a position of extension and adduction. There is loss in the power of pronating the forearm; the brachioradialis has the power of bringing the forearm into a position of mid-pronation, but beyond this no further pronation can be effected. The wrist can be flexed by the flexor carpi ulnaris, but flexion is combined with adduction of the hand. There is loss or impairment of sensation on the palmar surfaces of the thumb, index, middle, and radial half of the ring fingers, and on the dorsal surfaces of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation is limited to the back of the distal phalanx. Owing to the paralysis of the short muscles of the thumb which has already been described, an 'ape-like' hand is produced. More commonly, however, the nerve is injured just above the flexor retinaculum (transverse carpal ligament), when the power of flexion of the fingers and pronation of the forearm remains intact, unless the flexor tendons are also divided.

The *ulnar nerve* is also liable to be injured in wounds of the forearm, such injury leading to impaired power of ulnar flexion, and upon an attempt being made to flex the wrist, the hand is drawn to the radial side by the flexor carpi radialis; there is inability to spread out the fingers from paralysis of the interossei, and for the same reason the fingers, especially the ring and little fingers, cannot be flexed at the metacarpophalangeal joints or extended at the interphalangeal joints, and the hand assumes a claw shape from the action of the opposing muscles; there is loss of power of flexion in the little and ring fingers; and there is inability to adduct the thumb. The muscles of the hypothenar eminence become wasted. Sensation is lost, or impaired, in the skin supplied by the nerve. Wasting of the muscles which it supplies is not uncommonly seen where a 'cervical rib' is present, the lower end of the plexus passing across its upper surface.

The *radial nerve* also is frequently injured. In consequence of its close relationship to the humerus, it is often torn or injured in fractures of this bone, or subsequently involved during the repair of the fracture, and its functions are interfered with. It is also liable to be contused against the bone by kicks or blows, or to be divided in wounds of the arm. When paralysed, the hand is flexed at the wrist and lies flaccid. This is known as *wrist-drop*. The fingers are also flexed, and when an attempt is made to extend them, the last two phalanges only will be extended, through the action of the lumbrical and interosseous muscles; the first phalanges remain flexed. Extension of the wrist is impossible. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm be flexed so as to allow of the action of the biceps. The power of extension of the forearm is lost on account of paralysis of the triceps, if the injury to the nerve has taken place near its origin. As the radial nerve has only a very small area of exclusive supply, the extent of the anæsthesia associated with

severe injuries to the nerve is surprisingly small and is confined to a limited region on the lateral part of the dorsum of the hand.

Occasionally the whole plexus is moved up one segment. In this event the contribution of the fourth cervical nerve is large and that from the first thoracic nerve correspondingly small. The condition is termed "pre-fixation" of the plexus. The opposite condition, in which the whole plexus is moved one segment caudally, is termed "post-fixation" of the plexus. It is characterised by a large contribution from the second thoracic nerve, and a correspondingly small contribution from the fifth cervical.

THE ANTERIOR PRIMARY RAMI OF THE THORACIC NERVES

The **anterior primary rami of the thoracic nerves** (fig. 978) are twelve in number on each side. Eleven of them are situated between the ribs, and are therefore termed *intercostal*; the twelfth lies below the last rib and is frequently termed the *subcostal nerve*. Each nerve is connected with the adjoining ganglion of the sympathetic trunk by a grey and a white ramus communicans; occasionally these two rami are enclosed in a common sheath, but, as a rule, they remain separate and the grey ramus joins the nerve proximal to the point at which the white ramus leaves it. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the parietes of the thorax; the lower five supply parietes of the thorax and abdomen; the lower seven supply fibres to the diaphragm; the subcostal nerve is distributed to the abdominal wall and the skin of the buttock. Communicating branches link the intercostal nerves to one another in the posterior parts of the intercostal spaces and, in addition, the lower five communicate freely as they traverse the abdominal wall.*

The upper thoracic nerves.—The anterior primary ramus of the first thoracic nerve divides into a large and a small branch. The large branch ascends in front of the neck of the first rib on the lateral side of the superior intercostal artery, and enters the brachial plexus (p. 1093). The small branch is the *first intercostal nerve*; it runs along the first intercostal space, and ends on the front of the chest as the first anterior cutaneous branch of the thorax. Occasionally this small anterior cutaneous branch is wanting. The first intercostal nerve as a rule gives off no lateral cutaneous branch; but sometimes it sends a small branch to communicate with the intercostobrachial. The first thoracic nerve frequently receives a connecting twig from the second nerve; this twig ascends in front of the neck of the second rib.

The anterior primary rami of the second, third, fourth, fifth, and sixth thoracic nerves pass forwards (fig. 979) in the intercostal spaces below the intercostal vessels. At the back of the chest they lie between the pleura and the posterior intercostal membranes, but in most of their course they run between the internal intercostal muscles and the intercostales intimi (intracostales) (p. 553). Where the latter muscles are absent, the nerves lie in contact with the parietal pleura. Near the sternum, they cross in front of the internal mammary artery and sternocostalis (transversus thoracis) muscle, pierce the internal intercostals, the anterior intercostal membranes, and the pectoralis major, and are now named the *anterior cutaneous nerves of the thorax*; they supply the skin of the front of the thorax; the anterior cutaneous branch of the second nerve may be connected to the medial supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the intercostal muscles, the levatores costarum, the serratus posterior superior, and the sternocostalis. At the front of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

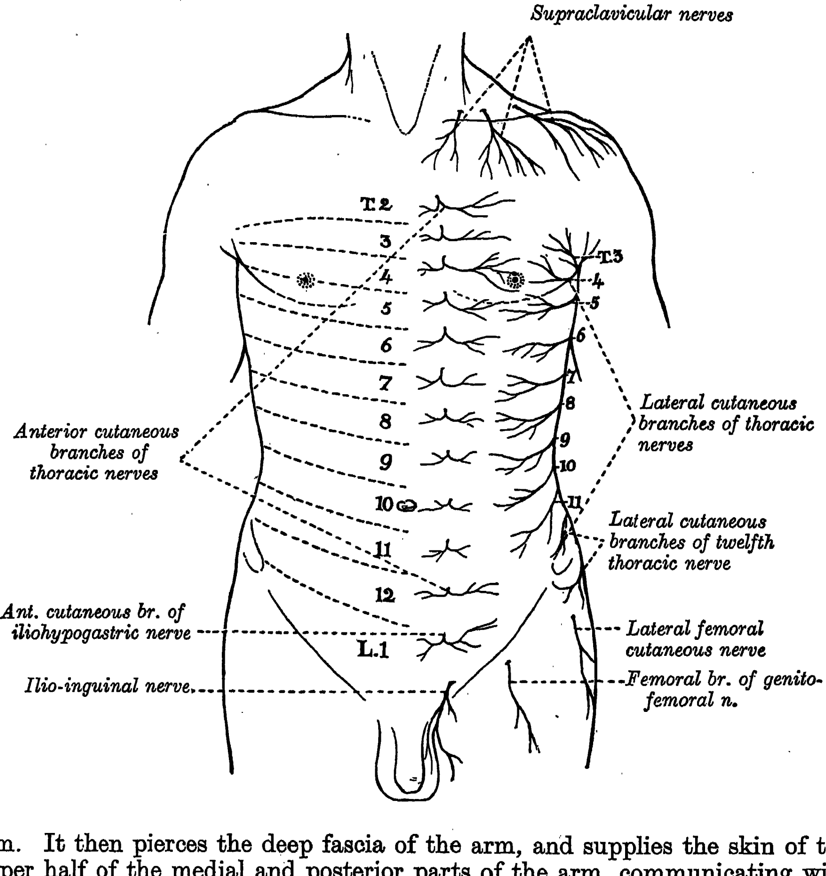
Each intercostal nerve, except the first, gives off a *collateral branch** and a *lateral cutaneous branch* before it reaches the angle of the rib. The collateral branch follows the lower border of the space in the same intermuscular interval as the main trunk, which it may, or may not, rejoin before it is distributed as

* F. Davies, R. J. Gladstone and E. P. Stibbe, *Journal of Anatomy*, vol. lxvi. 1932.

an additional anterior cutaneous nerve. The lateral cutaneous branch accompanies the main trunk for a time and then pierces the intercostal muscles obliquely. With the exception of the lateral cutaneous branch of the second intercostal nerve, each divides into anterior and posterior branches, which subsequently pierce the serratus anterior muscle. The *anterior branches* run forwards over the border of the pectoralis major and supply twigs to the overlying skin; those of the fifth and sixth nerves supply twigs to the upper digitations of the external oblique muscle. The *posterior branches* run backwards, and supply the skin over the scapula and latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is named the *intercostobrachial nerve* (fig. 976). It crosses the axilla to gain the medial side of the arm, and joins with a filament from the medial cutaneous nerve of the

FIG. 978.—A diagram showing the distribution of the cutaneous nerves on the front of the trunk.



arm. It then pierces the deep fascia of the arm, and supplies the skin of the upper half of the medial and posterior parts of the arm, communicating with the posterior brachial cutaneous branch of the radial nerve. The size of the intercostobrachial nerve is in inverse proportion to that of the medial brachial cutaneous nerve. A second intercostobrachial nerve is frequently given off from the anterior part of the lateral cutaneous branch of the third intercostal nerve; it supplies filaments to the axilla and to the medial side of the arm.

The lower thoracic nerves.—The anterior primary rami of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall.

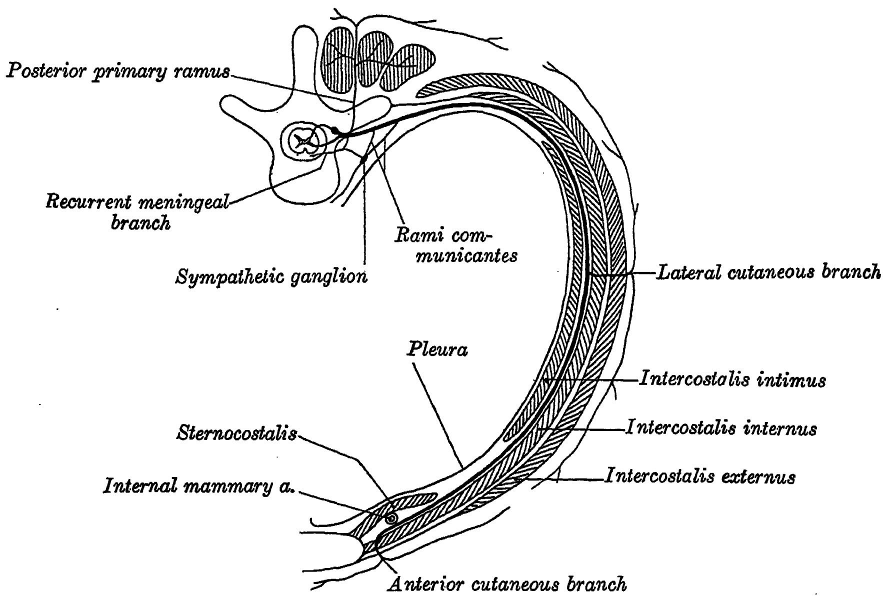
As they approach the anterior ends of the spaces in which they lie, the seventh and eighth nerves curve *upwards* and medially across the deep surface of the costal margin, insinuating themselves between the digitations of the transversus abdominis to gain the deep aspect of the posterior lamella of the aponeurosis of the internal oblique. Having pierced this layer, they lie behind the rectus abdominis muscle and continue upwards and medially (fig. 980) for a

short distance parallel with the costal margin. Both supply the rectus abdominis and, having passed through the muscle near its lateral edge, pierce the anterior wall of its sheath, to reach and supply the skin. It will be observed that both the seventh and the eighth intercostal nerves cross the costal margin medial to the lateral border of the rectus abdominis and therefore enter its sheath by piercing its posterior wall.

The ninth, tenth and eleventh intercostal nerves pass between the digitations of the transversus abdominis to gain the interval between that muscle and the internal oblique. In this intermuscular interval the ninth nerve runs almost *horizontally*, but the tenth and eleventh nerves run definitely downwards and medially. When they reach the lateral edge of the rectus abdominis, they pierce the posterior lamella of the internal oblique aponeurosis and pass behind the muscle. They end like the terminal branches of the seventh and eighth intercostal nerves.

The lower intercostal nerves supply the intercostal, the subcostal and the abdominal muscles, and the last three send branches to the serratus posterior

FIG. 979.—A diagram of the course of a typical intercostal nerve. The muscular and the collateral branches are not shown.

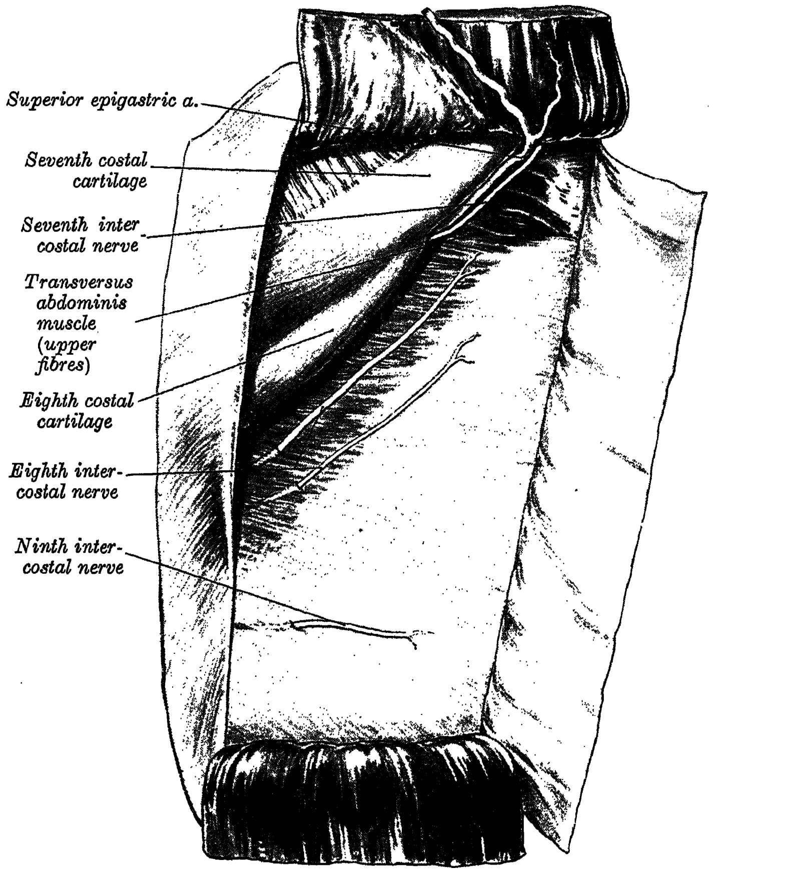


inferior. Like the upper intercostal nerves the lower intercostal nerves give off *collateral* and *lateral cutaneous branches* before they reach the angles of the ribs. The collateral branch may, or may not, rejoin the main trunk, but, if it does so, it leaves it again near the lateral border of the rectus abdominis and runs forwards below it (fig. 980). It pierces the muscle and the anterior wall of its sheath near the linea alba and supplies the skin. The lateral cutaneous branches pierce the intercostals and the external oblique muscle, in the same line as the lateral cutaneous branches of the upper thoracic nerves, and divide into anterior and posterior branches, which are distributed to the skin of the abdomen and back respectively; the anterior branches also supply twigs to the digitations of the external oblique muscle, and extend downwards and forwards nearly as far as the margin of the rectus abdominis; the posterior branches pass backwards to supply the skin over the latissimus dorsi. Each lateral cutaneous branch descends as it pierces the external oblique muscle and the superficial fascia so that it reaches the skin on a level with the corresponding anterior cutaneous branch and the cutaneous branch of the corresponding posterior primary ramus (p. 1087).

The anterior primary ramus of the twelfth thoracic nerve is larger than the others, and often gives a communicating branch to the first lumbar nerve.

Like the intercostal nerves it soon gives off a collateral branch. It accompanies the subcostal artery along the lower border of the twelfth rib, and passes behind the lateral arcuate ligament (lateral lumbocostal arch). It then runs behind the kidney, and in front of the upper part of the quadratus lumborum, perforates the aponeurosis of origin of the transversus, and passes forwards between that muscle and the obliquus internus, to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric nerve of the lumbar plexus, and gives a branch to the pyramidalis. The *lateral cutaneous branch* of the twelfth thoracic nerve pierces the internal and

FIG. 980.—A dissection to show the courses taken by the seventh, eighth and ninth intercostal nerves of the right side, after they enter the sheath of the rectus abdominis muscle.



The rectus abdominis muscle has been cut across; its upper part has been turned upwards, exposing most of the seventh and the anterior end of the eighth costal cartilage; its lower part has been turned downwards, exposing the posterior wall of the sheath.

external oblique muscles, gives a twig to the lowest slip of the latter, descends over the iliac crest about 5 cm. behind the anterior superior iliac spine (fig. 987), and is distributed to the skin of the front part of the buttock, some of its filaments reaching as low as the greater trochanter of the femur.

Applied Anatomy.—The lower seven thoracic nerves and the iliohypogastric branch of the first lumbar nerve supply the skin of the abdominal wall The sixth and seventh supply the skin over the 'pit of the stomach'; the eighth corresponds to about the position of the middle tendinous intersection of the rectus abdominis; the tenth to the umbilicus; the iliohypogastric supplies the skin over the pubis and superficial inguinal ring. In many diseases affecting the nerve-trunks at or near their origins, the pain is referred to their peripheral terminations. Thus, in Pott's disease of the vertebræ, children often suffer from pain in the abdomen. When the irritation is confined to a single pair of nerves the

sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen, and in these cases the situation of the sense of constriction may serve to localise the disease in the vertebral column. Where the bone disease is more extensive and two or more nerves are involved, a more general, diffused pain in the abdomen is felt.

Again, it must be borne in mind that the nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence, any irritation applied to the peripheral ends of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction ; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more rapid response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

The nerves supplying the abdominal muscles and skin, derived from the lower intercostal nerves, are intimately connected with the sympathetic nerves supplying the abdominal viscera through the lower thoracic ganglia, from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera, and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE ANTERIOR PRIMARY RAMI OF THE LUMBAR NERVES

The **anterior primary rami of the lumbar nerves** increase in size from the first to the last. They are joined, near their origins, by *grey rami communicantes* from the lumbar ganglia of the sympathetic trunk. These rami consist of long, slender branches which accompany the lumbar arteries round the sides of the vertebral bodies, under cover of the psoas major. Their arrangement is somewhat irregular : one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia : not infrequently the rami arise from the sympathetic trunk between two ganglia. The first and second, and sometimes the third, lumbar nerves are each connected with the lumbar part of the sympathetic trunk by a *white ramus communicans.*

The anterior primary rami of the lumbar nerves pass downwards and laterally behind the psoas major, or between its fasciculi. The first three nerves and the greater part of the fourth, form the *lumbar plexus.* The smaller part of the fourth nerve * joins with the fifth to form the *lumbosacral trunk,* which assists in the formation of the sacral plexus.

The Lumbar Plexus

The **lumbar plexus** (fig. 981) is situated in the posterior part of the psoas major, in front of the transverse processes of the lumbar vertebræ ; it is formed by the anterior primary rami of the first three lumbar nerves and the greater part of the anterior primary ramus of the fourth ; the first lumbar nerve receives a branch from the last thoracic nerve.

The mode in which it is arranged varies in different subjects, but the usual condition is the following. The first lumbar nerve, supplemented by a twig from the last thoracic, splits into an upper and a lower branch ; the upper,

* The fourth nerve is named the *nervus furcalis,* from the fact that it is subdivided between the two plexuses. In most cases the fourth lumbar is the *nervus furcalis* ; but this arrangement is frequently departed from. The third is occasionally the lowest nerve which enters the lumbar plexus, giving at the same time some fibres to the sacral plexus, and thus forming the nervus furcalis ; or both the third and fourth may be furcal nerves. When this occurs, the plexus is termed *high* or *prefixed.* More frequently the fifth nerve is divided between the lumbar and sacral plexuses, and constitutes the nervus furcalis ; and when this takes place, the plexus is distinguished as a *low* or *postfixed* plexus. These variations necessarily produce corresponding modifications in the sacral plexus.

larger branch divides into the iliohypogastric and ilio-inguinal nerves; the lower, smaller branch unites with a branch of the second lumbar to form the genitofemoral nerve. The remainder of the second nerve, the third nerve, and the part of the fourth nerve which joins the plexus, divide into ventral and dorsal branches. The ventral branch of the second unites with the ventral branches of the third and fourth nerves to form the obturator nerve. The dorsal branches of the second and third nerves each divide into a smaller and larger part; the smaller parts unite to form the lateral femoral cutaneous nerve, and the larger parts join with the dorsal branch of the fourth nerve to form the femoral nerve. The accessory obturator, when it exists, arises from the ventral branches of the third and fourth nerves.

The branches of the lumbar plexus may therefore be arranged as follows:

Muscular	12 T., 1, 2, 3, 4 L.
Iliohypogastric	1 L.
Ilio-inguinal	1 L.
Genitofemoral	1, 2 L.
	Dorsal divisions.
Lateral femoral cutaneous	2, 3 L.
Femoral	2, 3, 4 L.
	Ventral divisions.
Obturator	2, 3, 4 L.
Accessory obturator	3, 4 L.

Muscular branches are distributed to the quadratus lumborum from the twelfth thoracic and first three or four lumbar nerves; to the psoas minor from the first, and to the psoas major and iliacus from the second, third and fourth lumbar nerves.

The **iliohypogastric nerve** arises from the first lumbar nerve (fig. 981). It emerges from the upper part of the lateral border of the psoas major, and crosses obliquely behind the lower part of the kidney, and in front of the quadratus lumborum. Just above the iliac crest it perforates the posterior part of the transversus abdominis, and divides between that muscle and the obliquus internus abdominis into a lateral and an anterior cutaneous branch.

The *lateral cutaneous branch* pierces the internal and external oblique muscles immediately above the iliac crest at a point a little behind the iliac branch of the twelfth thoracic nerve; it is distributed to the skin of the anterior part of the side of the buttock.

The *anterior cutaneous branch* (fig. 978) runs between the obliquus internus and transversus, supplying twigs to both muscles. It then pierces the obliquus internus at a point about 2 cm. on the medial side of the anterior superior iliac spine, perforates the aponeurosis of the external oblique about 3 cm. above the superficial inguinal ring, and is distributed to the skin of the abdomen above the pubis.

The iliohypogastric nerve communicates with the last thoracic and ilio-inguinal nerves.

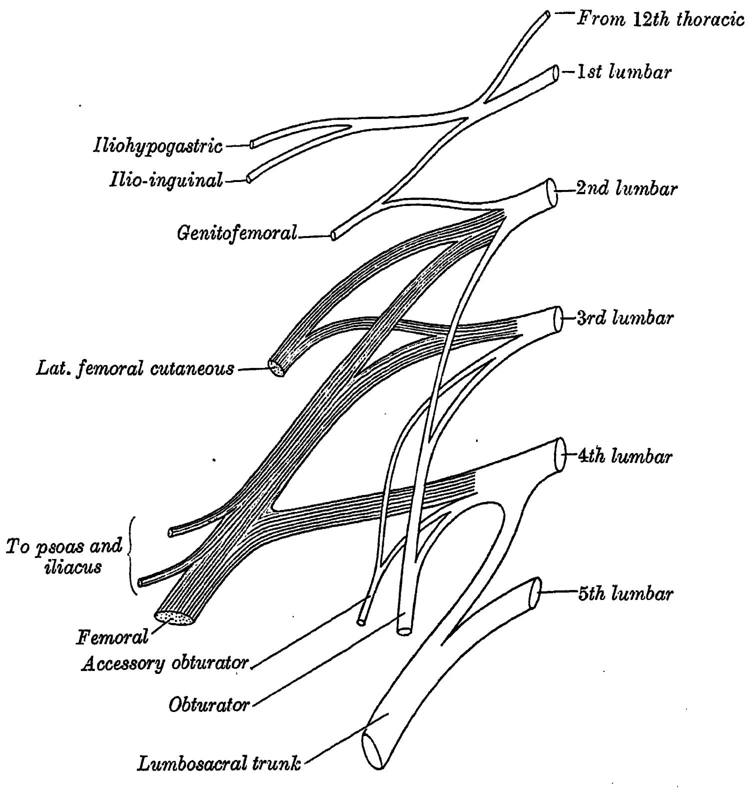
The **ilio-inguinal nerve**, smaller than the iliohypogastric nerve, arises with it from the first lumbar nerve (fig. 981). It emerges from the lateral border of the psoas major, with or just below the iliohypogastric nerve, and, passing obliquely across the quadratus lumborum and the upper part of the iliacus, perforates the transversus abdominis, near the anterior part of the iliac crest, and communicates with the iliohypogastric nerve. It then pierces the internal oblique muscle, distributing filaments to it, and, accompanying the spermatic cord through the superficial inguinal ring, is distributed to the skin of the upper and medial part of the thigh, to the skin over the root of the penis and upper part of the scrotum in the male (fig. 978), and to the skin covering the mons pubis and labium majus in the female.

The size of the ilio-inguinal nerve is in inverse proportion to that of the iliohypogastric. Occasionally it is very small, and ends by joining the iliohypogastric nerve; in such cases, a branch from the iliohypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. On the analogy of the intercostal nerves the ilio-inguinal nerve may be regarded as the collateral branch (p. 1107) of the first lumbar nerve, and the iliohypogastric as the main trunk, which gives off the lateral cutaneous branch.

The **genitofemoral nerve** arises from the first and second lumbar nerves (fig. 981). It passes obliquely forwards and downwards through the substance of the psoas major, and emerges near its medial border, opposite the third or fourth lumbar vertebra; it then descends on the surface of the psoas major, under cover of the peritoneum, and, crossing obliquely behind the ureter, divides at a variable distance above the inguinal ligament into the genital (external spermatic) and femoral (lumbo-inguinal) branches. The genitofemoral nerve frequently divides close to its origin, and its two branches then emerge separately through the psoas major.

The *genital branch* (external spermatic nerve) crosses the lower end of the external iliac artery, and enters the inguinal canal through the deep inguinal

Fig. 981.—A plan of the lumbar plexus.



ring; it supplies the cremaster, and gives a few filaments to the skin of the scrotum. In the female, it accompanies the round ligament of the uterus and ends in the skin of the mons pubis and labium majus.

The *femoral branch* (lumbo-inguinal nerve) descends on the lateral side of the external iliac artery, and sends a few filaments round it; it then crosses the deep circumflex iliac artery, and, passing behind the inguinal ligament, enters the femoral sheath, lying lateral to the femoral artery. It pierces the anterior layer of the femoral sheath and the fascia lata, and supplies the skin over the upper part of the femoral triangle (fig. 982). It communicates with the intermediate cutaneous nerve of the thigh, and gives a few twigs to the femoral artery.

The **lateral cutaneous nerve of the thigh** arises from the dorsal branches of the anterior primary rami of the second and third lumbar nerves (fig. 981). It emerges from the lateral border of the psoas major, and crosses the iliacus obliquely, running towards the anterior superior iliac spine. On the right side the nerve passes behind and lateral to the cæcum, from which it is separated by the fascia iliaca and the peritoneum; on the left side, it passes behind the lower part of the descending colon. It then passes behind the inguinal ligament

and in front of or through the sartorius into the thigh, where it divides into an anterior and a posterior branch (fig. 982).

Fig. 982.—The cutaneous nerves of the right lower limb. Anterior surface.

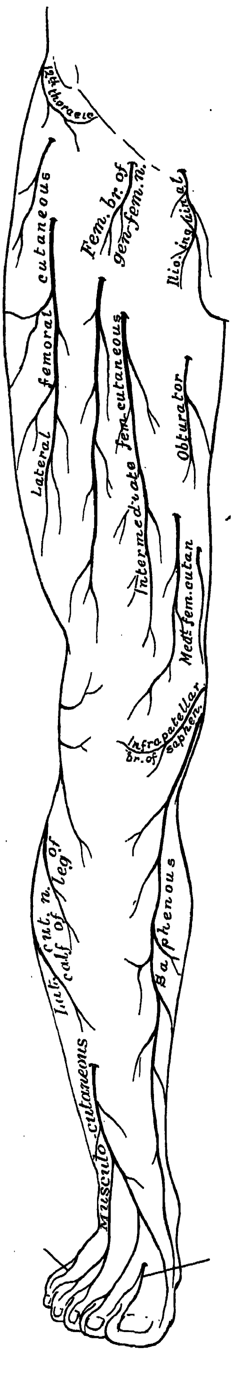


Fig. 983.—A diagram showing the segmental distribution of the cutaneous nerves of the right lower limb. Anterior surface.

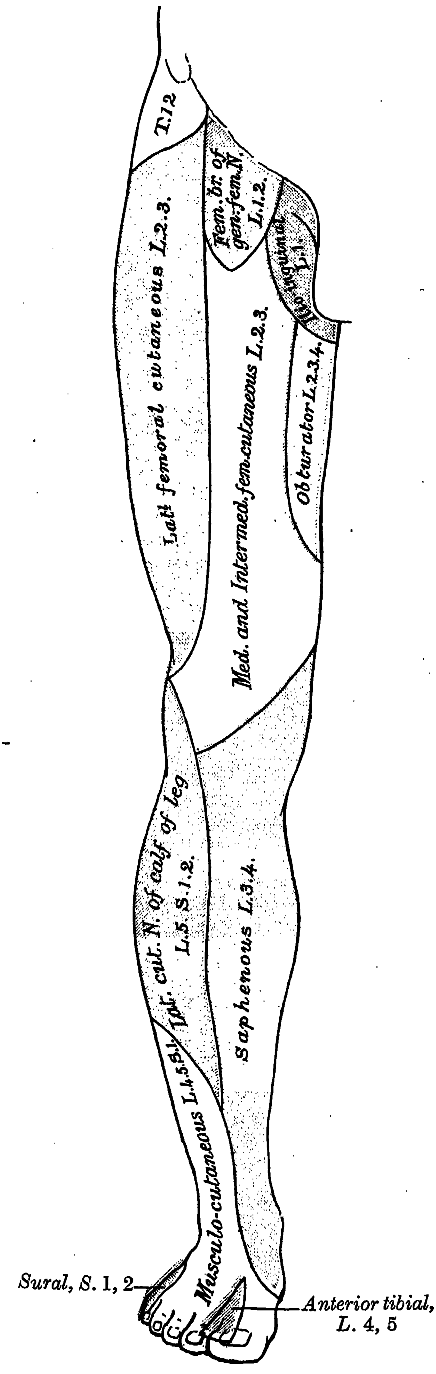


The *anterior branch* becomes superficial about 10 cm. below the anterior superior iliac spine, and is distributed to the skin of the anterior and lateral parts of the thigh, as far as the knee. Its terminal filaments frequently com-

municate with the cutaneous branches of the anterior division of the femoral nerve and with the infrapatellar branch of the saphenous nerve, forming with them the *patellar plexus*.

The *posterior branch* pierces the fascia lata at a higher level than the anterior branch, and subdivides into filaments which pass backwards to supply the skin on the lateral surface of the limb, from the level of the greater trochanter to about the middle of the thigh.

The **obturator nerve** arises from the ventral branches of the anterior primary rami of the second, third, and fourth lumbar nerves (fig. 981) ; the branch from the third is the largest, while that from the second is often very small. It descends through the fibres of the psoas major, and emerges from its medial border at the brim of the pelvis, where it passes behind the common iliac vessels, and on the lateral side of the internal iliac vessels. It then runs downwards and forwards along the lateral wall of the true pelvis, above and in front of the obturator vessels, to gain the upper part of the obturator foramen, through which it enters the thigh. At the foramen it divides into an anterior and a posterior branch, which are separated at first by a few fibres of the obturator externus, and lower down by the adductor brevis.

The *anterior branch* (fig. 984) leaves the pelvis in front of the obturator externus and descends in front of the adductor brevis, and behind the pectineus and adductor longus ; at the lower border of the latter muscle it communicates with the medial cutaneous and saphenous branches of the femoral nerve, forming a kind of plexus (subsartorial plexus). It then descends upon the femoral artery, to which it is finally distributed. Near the obturator foramen this branch gives an articular twig to the hip-joint. Behind the pectineus, it distributes branches to the adductor longus and gracilis, and usually to the adductor brevis, and in rare cases to the pectineus ; it receives a filament from the accessory obturator nerve when that nerve is present.

Occasionally the communicating branch to the medial cutaneous and saphenous branches of the femoral nerve is continued down, as a cutaneous branch, to the thigh and leg. When this is so, it emerges from behind the lower border of the adductor longus, descends along the posterior margin of the sartorius to the medial side of the knee, where it pierces the deep fascia, communicates with the saphenous nerve, and is distributed to the skin halfway down the medial side of the leg.

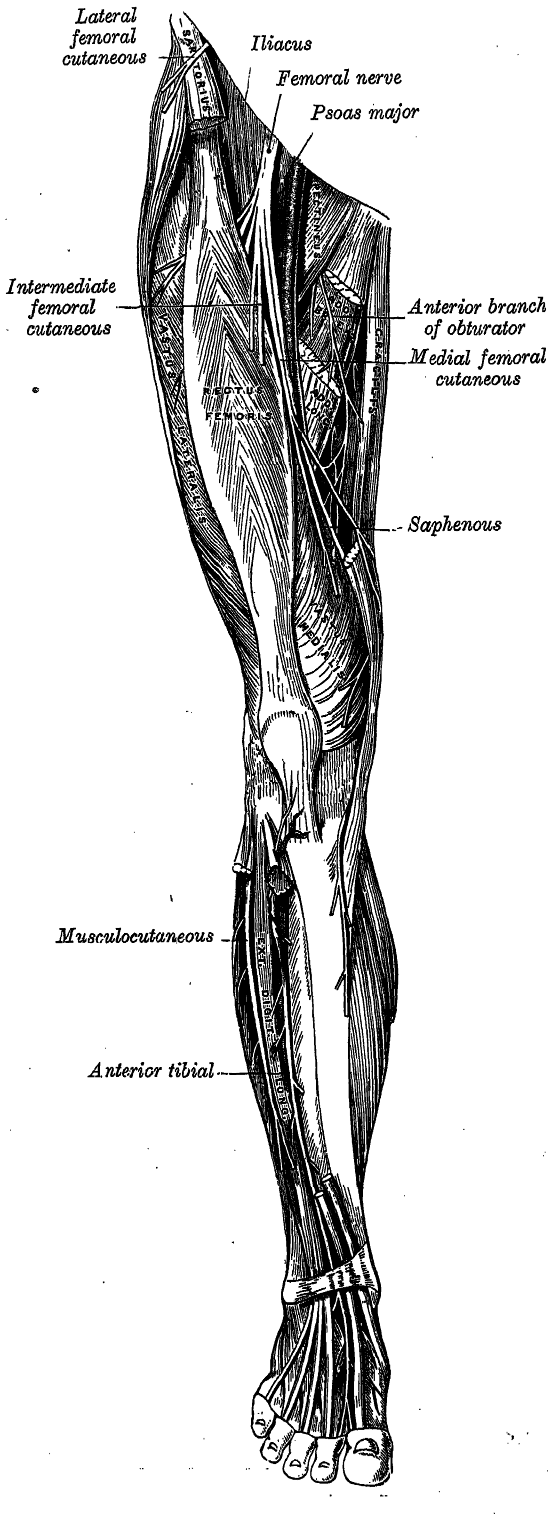
The *posterior branch* pierces the anterior part of the obturator externus, and supplies this muscle ; it then passes behind the adductor brevis on the front of the adductor magnus, and divides into branches which are distributed to the adductor magnus, and to the adductor brevis when this muscle does not receive a branch from the anterior division of the nerve. It frequently gives a slender *articular branch* to the knee-joint ; this branch perforates the lower part of the adductor magnus or passes through the opening which transmits the femoral artery, and enters the popliteal fossa ; it here descends upon the popliteal artery, to the back of the knee-joint, where it pierces the oblique posterior ligament of the knee, and is distributed to the articular capsule. It gives filaments to the popliteal artery.

The **accessory obturator nerve** (fig. 981) is present in about 29 per cent. of subjects. It is of small size, and arises from the ventral branches of the anterior primary rami of the third and fourth lumbar nerves. It descends along the medial border of the psoas major, crosses the superior ramus of the pubis behind the pectineus, and divides into branches. One branch enters the deep surface of the pectineus ; another goes to the hip-joint ; while a third communicates with the anterior branch of the obturator nerve. Occasionally the accessory obturator nerve is very small and supplies only the pectineus.

The **femoral nerve** (fig. 984), the largest branch of the lumbar plexus, arises from the dorsal branches of the anterior primary rami of the second, third and fourth lumbar nerves (fig. 981). It descends through the fibres of the psoas major, emerging from the muscle at the lower part of its lateral border, and passes down between it and the iliacus, deep to the iliac fascia ; it then passes behind the inguinal ligament to enter the thigh, and splits into an anterior and a posterior division. Behind the inguinal ligament it is separated from the femoral artery by a portion of the psoas major.

Within the abdomen the femoral nerve gives off small branches to the iliacus, the nerve to the pectineus, and a branch which is distributed upon the upper part of the femoral artery; the latter branch may arise in the thigh. The *nerve to the pectineus* arises from the medial side of the femoral nerve near the inguinal ligament, passes behind the femoral sheath and enters the anterior surface of the muscle.

Fig. 984.—The nerves of the right lower limb. Anterior surface.



The anterior division of the femoral nerve gives off the intermediate and medial cutaneous nerves of the thigh (fig. 982), and muscular branches to the sartorius.

The *intermediate cutaneous nerve of the thigh* pierces the fascia lata about 8 cm. below the inguinal ligament, either as two branches, or as a single trunk which quickly divides into two branches; these branches descend vertically along the front of the thigh, and supply the skin as low as the knee. They end in the patellar plexus (p. 1115). The lateral branch of the intermediate cutaneous communicates with the femoral branch of the genito-femoral nerve, and frequently pierces the sartorius.

The *medial cutaneous nerve of the thigh* lies at first on the lateral side of the femoral artery, but at the apex of the femoral triangle it crosses in front of the artery and divides into an anterior and a posterior branch. Before dividing, the nerve gives off a few filaments which pierce the fascia lata to supply the skin of the medial side of the thigh, in the neighbourhood of the long saphenous vein; one of these filaments emerges through the saphenous opening (fossa ovalis), and a second becomes subcutaneous about the middle of the thigh. The *anterior branch* runs downwards on the sartorius, perforates the fascia lata at the junction of the middle with the lower one-third of the thigh, and divides into two branches: one supplies

the skin as low as the medial side of the knee; the other crosses to the lateral side of the patella, communicating in its course with the infrapatellar branch of the saphenous nerve. The *posterior branch* descends along the posterior border of the sartorius to the knee, where it pierces the fascia lata, communicates with the saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the skin of the medial side of the leg. Beneath the fascia lata, at the lower border of the adductor longus, it joins to form a plexiform network (*subsartorial plexus*) with branches of the saphenous and obturator nerves. When the communicating branch from the obturator nerve is large and continued to the skin of the leg, the posterior branch of the medial cutaneous is small, and terminates in the plexus, occasionally giving off a few cutaneous filaments.

The *nerve to the sartorius* arises in common with the intermediate cutaneous nerve of the thigh.

The posterior division of the femoral nerve gives off the saphenous nerve, and supplies muscular branches to the quadriceps femoris, and articular branches to the knee-joint.

The **saphenous nerve** (fig. 984) is the largest cutaneous branch of the femoral nerve. It descends on the lateral side of the femoral artery and enters the subsartorial canal (adductor canal) (p. 786) where it crosses the artery obliquely from its lateral to its medial side. At the lower end of the canal it quits the artery, and emerges through the aponeurotic covering of the canal, accompanied by the saphenous branch of the descending genicular artery (arteria genu suprema). It descends vertically along the medial side of the knee behind the sartorius, pierces the fascia lata between the tendons of the sartorius and gracilis, and becomes subcutaneous. It then passes down the tibial side of the leg accompanied by the long saphenous vein, descends along the medial border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, and ends at the ankle; the other passes in front of the ankle, and is distributed to the skin on the medial side of the foot as far as the ball of the great toe, communicating with the medial branch of the musculocutaneous nerve (superficial peroneal nerve).

About the middle of the thigh, the saphenous nerve gives a branch to join the subsartorial plexus.

After leaving the adductor canal it gives off an *infrapatellar branch* (fig. 982), which pierces the sartorius and fascia lata, and is distributed to the skin in front of the patella. Above the knee this nerve unites with the medial and intermediate cutaneous nerves of the thigh; below the knee, with other branches of the saphenous nerve; and, on the lateral side of the joint, with branches of the lateral cutaneous nerve of the thigh, forming a plexiform network, termed the *patellar plexus*. The infrapatellar branch is occasionally small.

The *muscular branches* of the posterior division of the femoral nerve supply the quadriceps femoris. The branch to the rectus femoris enters the upper part of the deep surface of the muscle, and supplies a filament to the hip-joint. The branch to the vastus lateralis, of large size, accompanies the descending branch of the lateral circumflex femoral artery to the lower part of the muscle, and sends an articular filament to the knee-joint. The branch to the vastus medialis descends through the upper part of the subsartorial canal, on the lateral side of the saphenous nerve and the femoral vessels. It enters the muscle about its middle, and gives off a filament, which can usually be traced downwards on the surface of the muscle, to the knee-joint. The branches to the vastus intermedius, two or three in number, enter the anterior surface of the muscle about the middle of the thigh; a filament from one of these descends through the muscle to the articularis genu and the knee-joint.

THE ANTERIOR PRIMARY RAMI OF THE SACRAL AND COCCYGEAL NERVES

The **anterior primary rami of the sacral and coccygeal nerves** form the sacral and coccygeal plexuses. Those of the upper four sacral nerves enter the pelvis through the anterior sacral foramina, that of the fifth between the sacrum

and coccyx, while that of the coccygeal nerve curves forwards below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral nerves are large ; the third, fourth and fifth diminish progressively ; the coccygeal nerve is the smallest. Each of these nerves receives a *grey ramus communicans* from the corresponding ganglion of the sympathetic trunk. *Visceral efferent fibres* arise from the second, third and fourth sacral nerves, but they do not join the neighbouring sympathetic ganglia ; they are named the *pelvic splanchnic nerves*, and consist of parasympathetic fibres which pass directly to minute ganglia on the walls of the pelvic viscera (p. 1152).

The Sacral Plexus

The **sacral plexus** (fig. 985) is formed by the lumbosacral trunk, the anterior primary rami of the first, second and third sacral nerves, and part of the anterior primary ramus of the fourth sacral nerve.

The lumbosacral trunk comprises a part of the anterior primary ramus of the fourth lumbar nerve, and the whole of the anterior primary ramus of the fifth lumbar nerve ; it appears at the medial margin of the psoas major and descends over the pelvic brim and in front of the sacro-iliac joint to join the first sacral nerve.

The anterior primary ramus of the fourth sacral nerve divides into an upper and a lower branch ; the upper branch enters the sacral plexus ; the lower descends to assist in forming the coccygeal plexus.

Relations.—The sacral plexus lies on the posterior wall of the pelvic cavity in front of the piriformis (fig. 986), and behind the internal iliac (hypogastric) vessels, the ureter and the pelvic colon, on the left side, and the terminal coils of the ileum, on the right side. The superior gluteal vessels run between the lumbosacral trunk and the first sacral nerve, or between the first and second sacral nerves, and the inferior gluteal vessels between the anterior primary rami of the first and second, or second and third, sacral nerves.

The nerves forming the sacral plexus converge towards the lower part of the greater sciatic foramen, and unite to form a flattened band, from the anterior and posterior surfaces of which several branches arise ; the band itself is continued as the sciatic nerve.

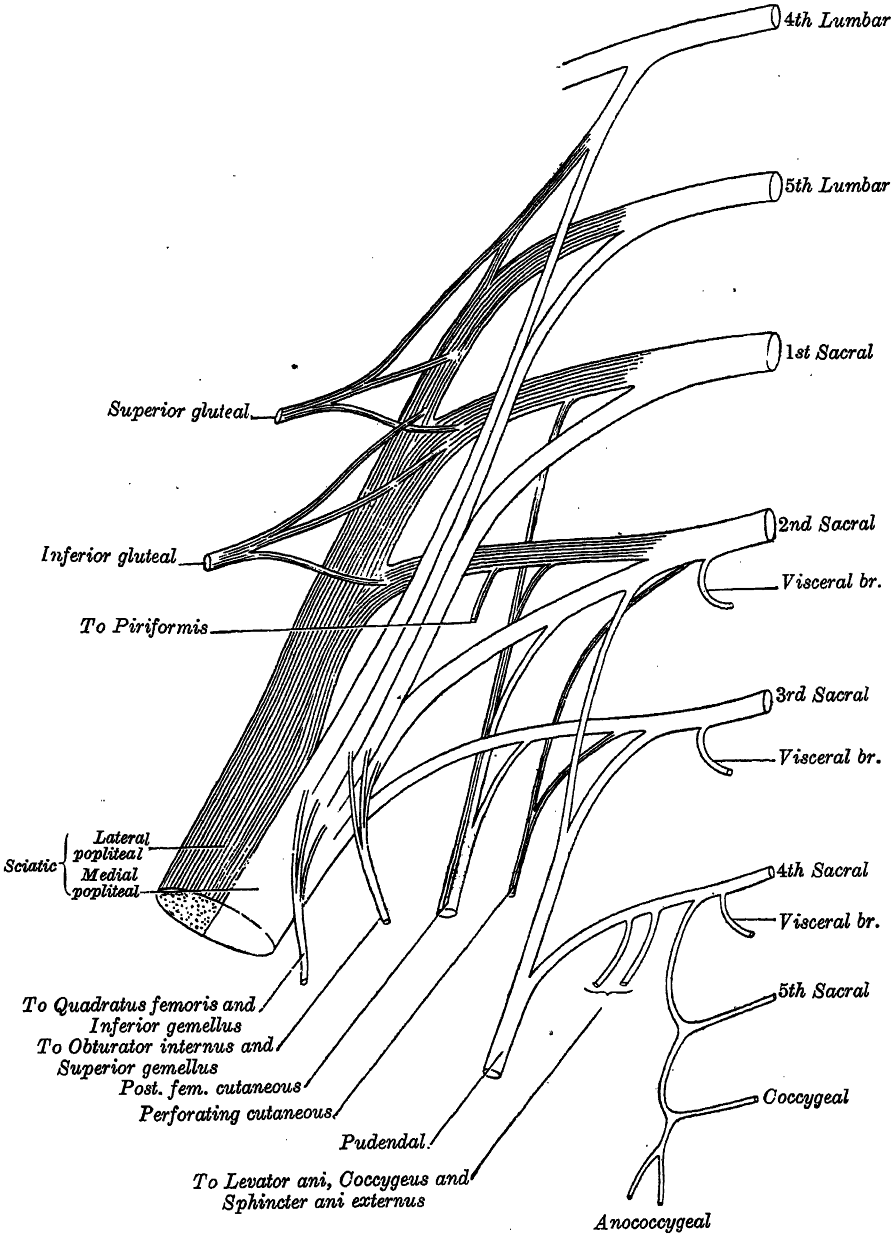
The nerves entering the plexus split into ventral and dorsal divisions ; the nerves arising from these divisions are as follows :

	Ventral divisions.	Dorsal divisions.
Nerve to quadratus femoris and gemellus inferior	4, 5 L., 1 S.	
Nerve to obturator internus and gemellus superior	5 L., 1, 2 S.	
Nerve to piriformis		(1) 2 S.
Superior gluteal		4, 5 L., 1 S.
Inferior gluteal		5 L., 1, 2 S.
Posterior femoral cutaneous	2, 3 S.	1, 2 S.
Sciatic: Medial popliteal	4, 5 L., 1, 2, 3 S.	
Sciatic: Lateral popliteal		4, 5 L., 1, 2 S.
Perforating cutaneous		2, 3 S.
Pudendal	2, 3, 4 S.	
Nerves to levator ani, coccygeus and sphincter ani externus	4 S.	
Pelvic splanchnics	2, 3, (4) S.	

The **nerve to the quadratus femoris and gemellus inferior** arises from the ventral branches of the anterior primary rami of the fourth and fifth lumbar and first sacral nerves (fig. 985) ; it leaves the pelvis through the greater sciatic foramen below the piriformis, and, running down on the ischium deep to the sciatic nerve, the gemelli and the tendon of the obturator internus, supplies a twig to the gemellus inferior, and enters the anterior surface of the quadratus femoris ; it gives an articular branch to the hip-joint.

The **nerve to the obturator internus and gemellus superior** arises from the ventral branches of the anterior primary rami of the fifth lumbar and first and second sacral nerves (fig. 985). It leaves the pelvis through the greater sciatic foramen below the piriformis, and gives a branch which enters the upper part

FIG. 985.—A plan of the sacral and coccygeal plexuses.

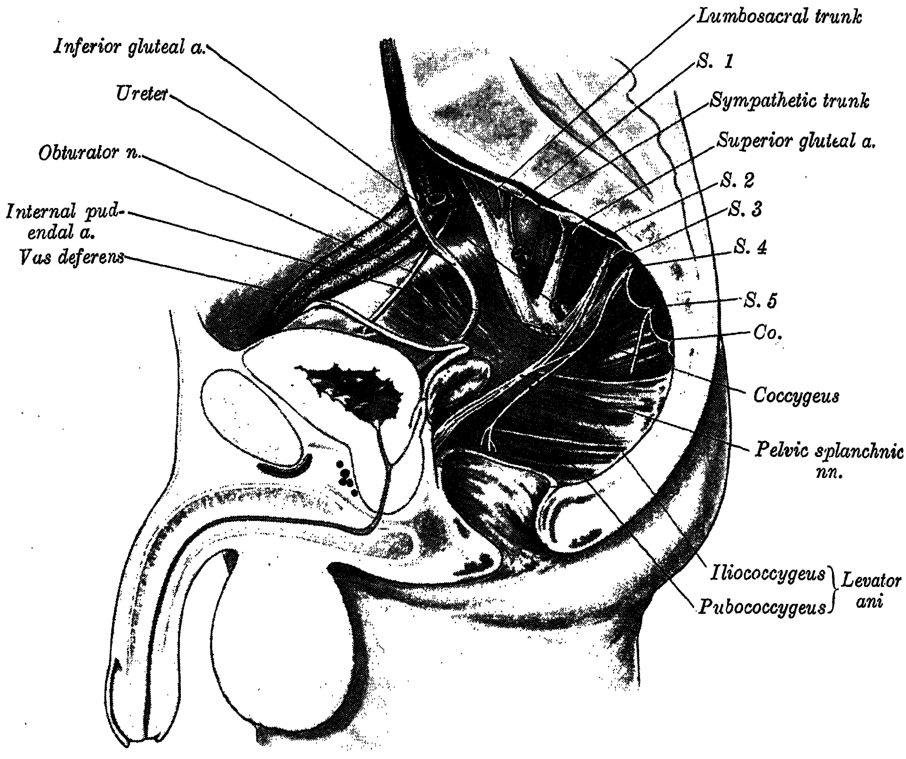


of the posterior surface of the gemellus superior. It then crosses the ischial spine on the lateral side of the internal pudendal vessels, re-enters the pelvis through the lesser sciatic foramen, and pierces the pelvic surface of the obturator internus.

The **nerve to the piriformis** arises usually from the dorsal branches of the anterior primary rami of the first and second sacral nerves; it enters the anterior surface of the muscle.

The **superior gluteal nerve** arises from the dorsal branches of the anterior primary rami of the fourth and fifth lumbar and first sacral nerves (fig. 985) : it leaves the pelvis through the greater sciatic foramen above the piriformis, accompanied by the superior gluteal vessels, and divides into a superior and an inferior branch. The *superior* branch accompanies the upper branch of the deep division of the superior gluteal artery and ends in the gluteus minimus. The *inferior* branch runs with the lower branch of the deep division of the superior gluteal artery across the gluteus minimus ; it gives twigs to the gluteus medius and gluteus minimus, and ends in the tensor fasciæ latæ.

Fig. 986.—A dissection of the side wall of the pelvis, showing the sacral and coccygeal plexuses.



The **inferior gluteal nerve** arises from the dorsal branches of the anterior primary rami of the fifth lumbar and first and second sacral nerves : it leaves the pelvis through the greater sciatic foramen, below the piriformis, and divides into branches which enter the deep surface of the gluteus maximus.

The **posterior cutaneous nerve of the thigh** arises from the dorsal branches of the anterior primary rami of the first and second, and from the ventral branches of the anterior primary rami of the second and third, sacral nerves (fig. 985), and issues from the pelvis through the greater sciatic foramen below the piriformis. It then descends under cover of the gluteus maximus with the inferior gluteal artery, lying posterior or medial to the sciatic nerve. It runs down the back of the thigh superficial to the long head of the biceps femoris, and deep to the fascia lata ; at the back of the knee it pierces the deep fascia and accompanies the short saphenous vein as far as the middle of the calf of the leg, its terminal twigs communicating with the sural nerve.

Its branches are all cutaneous, and are distributed to the gluteal region, the perineum, and the back of the thigh and leg.

The *gluteal branches*, three or four in number, turn upwards round the lower border of the gluteus maximus, and supply the skin covering the lower and lateral part of that muscle.

Fig. 987.—The cutaneous nerves of the right lower limb. Posterior surface.

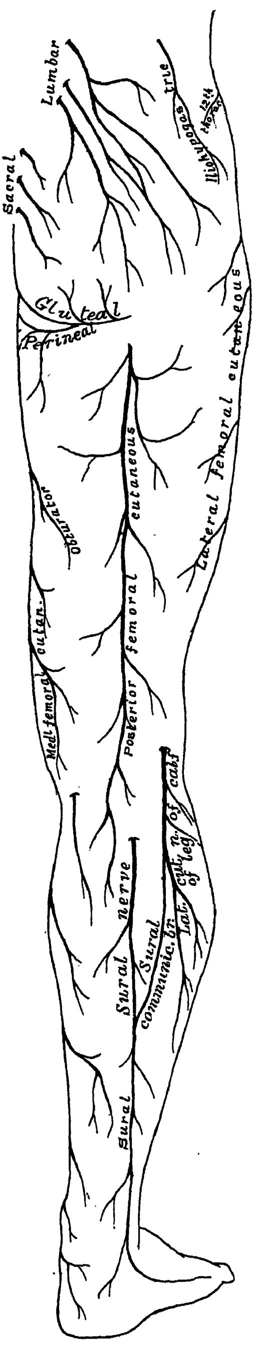


Fig. 988.—A diagram showing the segmental distribution of the cutaneous nerves of the right lower limb. Posterior surface.

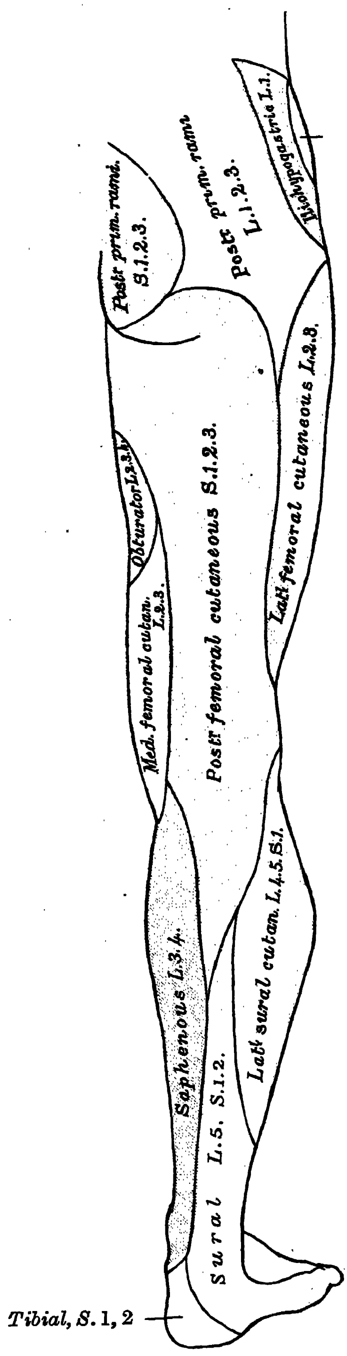

FIG. 989.—The nerves of the right lower limb.* Posterior aspect.

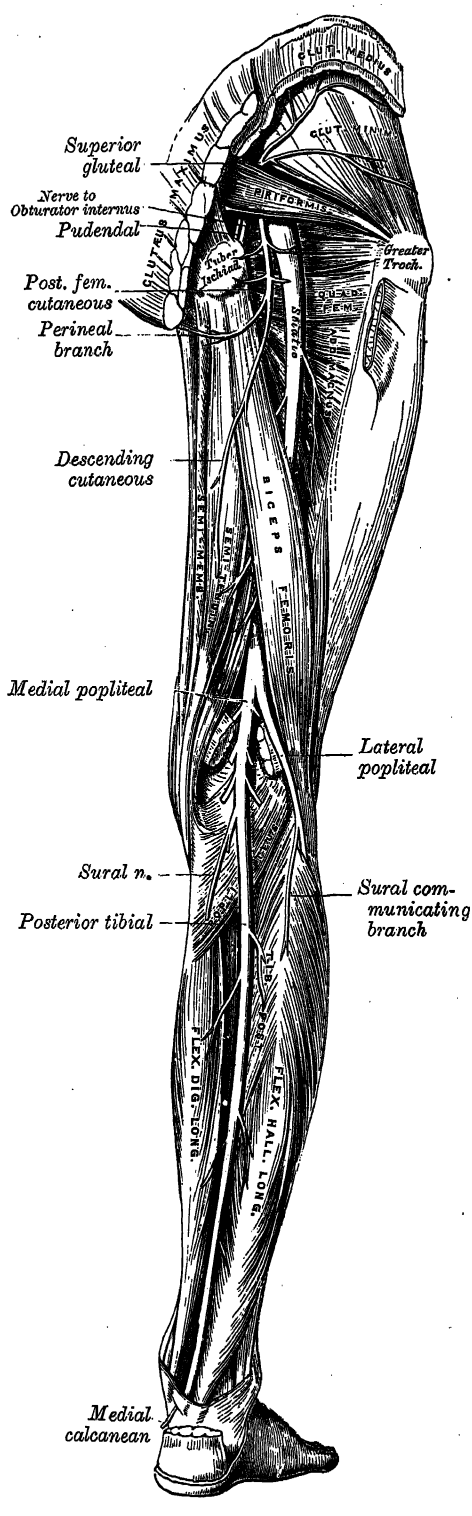

The *perineal branch* distributes twigs to the skin at the upper and medial side of the thigh, and then curves forwards across the origin of the hamstrings, below the ischial tuberosity; it pierces the fascia lata, and runs beneath the superficial fascia of the perineum to the skin of the scrotum in the male, and of the labium majus in the female, joining with the inferior hæmorrhoidal and the scrotal branches of the perineal nerve.

The *branches to the back of the thigh and leg* consist of numerous filaments derived from both sides of the nerve, and distributed to the skin covering the back and medial side of the thigh, the popliteal fossa and the upper part of the back of the leg (fig. 987).

The **sciatic nerve** (figs. 985, 989) is the largest nerve in the body and at its commencement it measures 2 cm. in breadth. It is the continuation of the flattened band of the sacral plexus. It passes out of the pelvis through the greater sciatic foramen, below the piriformis muscle, descends between the greater trochanter of the femur and the tuberosity of the ischium, and along the back of the thigh to about its lower one-third, where it divides into two large branches, named the medial popliteal (tibial) and lateral popliteal (common peroneal) nerves. This division may take place at any point between the sacral plexus and the lower one-third of the thigh, and in all cases the independence of the two nerves can be shown by dissection. When the division occurs at the plexus, the lateral popliteal nerve usually pierces the piriformis. The nerve also gives off articular and muscular branches.

In the upper part of its course the nerve is placed under cover of the gluteus maximus, and rests first upon the posterior surface of the ischium, the nerve to the quadratus femoris intervening; it then crosses the obturator internus and gemelli, and passes on to the quadratus femoris, by which it is separated from the obturator externus and the hip-joint; it is accompanied on its medial side by the posterior

* N.B.—In this diagram the gluteus maximus, the gluteus medius and the superficial muscles of the calf of the leg have been removed.

cutaneous nerve of the thigh and the inferior gluteal artery. Lower down it lies upon the adductor magnus, and is crossed obliquely by the long head of the biceps femoris.

The *articular branches* of the sciatic nerve arise from the upper part of the nerve, and supply the hip-joint by perforating the posterior part of its capsule; they are sometimes derived from the sacral plexus.

The *muscular branches* of the sciatic nerve are distributed to the biceps femoris, semitendinosus, semimembranosus and adductor magnus; the branches to the semimembranosus and adductor magnus arise by a common trunk. The nerve to the short head of the biceps femoris comes from the lateral popliteal (common peroneal) part, while the other muscular branches arise from the medial popliteal (tibial portion), of the sciatic nerve.

The **medial popliteal nerve** (tibial nerve) (fig. 989), the larger, terminal branch of the sciatic nerve, arises from the ventral branches of the anterior primary rami of the fourth and fifth lumbar and first, second and third sacral nerves. It descends along the back of the thigh and through the middle of the popliteal fossa, to the lower part of the popliteus muscle, whence it passes with the popliteal artery deep to the arch of soleus, and is thereafter continued into the leg as the *posterior tibial nerve*. In the thigh it is overlapped by the hamstring muscles above, but it becomes more superficial in the popliteal fossa, where it lies lateral to, and some distance from, the popliteal vessels; it is superficial to these vessels opposite the knee-joint and then crosses to the medial side of the popliteal artery. In the lower part of the popliteal fossa, the nerve is covered by the contiguous margins of the two heads of the gastrocnemius.

The branches of this nerve are: articular, muscular and sural.

Articular branches, usually three in number, supply the knee-joint; one branch accompanies the superior, and another the inferior, medial genicular artery; the third branch runs with the middle genicular artery.

The *muscular branches* arise from the nerve as it lies between the two heads of the gastrocnemius muscle; they supply that muscle, as well as the plantaris, soleus and popliteus. The nerve to the soleus enters the superficial surface of the muscle. The branch for the popliteus descends, crossing the popliteal vessels obliquely, and turns round the lower border of the muscle to be distributed to its deep surface; it supplies small branches to the tibialis posterior, an articular twig to the upper tibiofibular joint, a medullary branch to the tibia, and an interosseous branch, which descends close to the fibula, and can be traced to the inferior tibiofibular joint.

The *sural nerve* (medial sural cutaneous nerve) descends between the two heads of the gastrocnemius, and, piercing the deep fascia about the middle of the back of the leg, is joined by the sural communicating branch of the lateral popliteal nerve (fig. 987). It then passes downwards near the lateral margin of the tendo calcaneus, and close to the short saphenous vein, to the interval between the lateral malleolus and the calcaneum; it supplies the skin of the lateral and posterior part of the lower one-third of the leg. It runs forwards below the lateral malleolus, and is continued along the lateral side of the foot and little toe, communicating on the dorsum of the foot with the musculocutaneous (superficial peroneal) nerve. In the leg, its branches communicate with those of the posterior cutaneous nerve of the thigh.

The **posterior tibial nerve** begins at the lower border of the popliteus, where it is directly continuous with the medial popliteal nerve; it descends in company with the posterior tibial vessels to the interval between the heel and the medial malleolus, where it ends under cover of the flexor retinaculum (laciniate ligament) by dividing into the medial and lateral plantar nerves. In the upper part of its course it is covered posteriorly by the superficial muscles of the calf, but in the lower third of the leg it is covered only by the skin and fasciæ, although it is overlapped sometimes by the medial edge of the flexor hallucis longus muscle. Above, it lies on the medial side of the posterior tibial vessels, but it soon crosses behind them and descends to its point of bifurcation along their lateral side. In most of its course it lies on the tibialis posterior, but in the lower part of the leg it comes into relation with the posterior surface of the tibia.

The branches of this nerve are articular, muscular, medial calcanean and medial and lateral plantar.

The *articular branch* arises from the posterior tibial nerve just above its terminal bifurcation, and supplies the ankle-joint.

The *muscular branches* arise either independently or by a common trunk. They supply the soleus, on its deep surface, the tibialis posterior, the flexor digitorum longus and the flexor hallucis longus ; the branch to the last muscle accompanies the peroneal vessels.

The *medial calcanean branches* perforate the flexor retinaculum (laciniate ligament), and supply the skin of the heel and medial side of the sole of the foot.

FIG. 990.—The plantar nerves of the right foot.

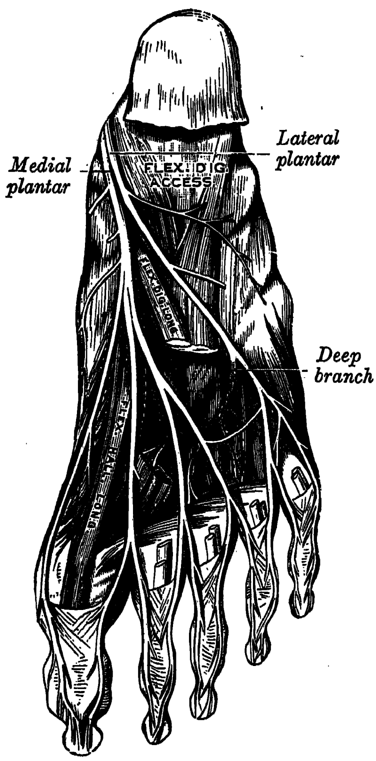

FIG. 991.—A diagram showing the segmental distribution of the cutaneous nerves of the sole of the right foot.

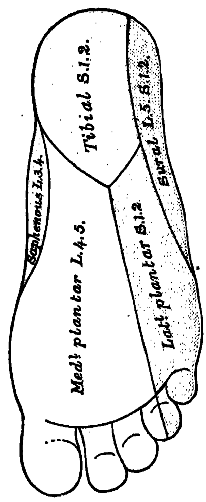


The **medial plantar nerve** (fig. 990), the larger of the two terminal divisions of the posterior tibial nerve, accompanies the medial plantar artery and lies on the lateral side of the vessel. From its origin under cover of the flexor retinaculum it passes deep to the abductor hallucis, and, appearing between this muscle and the flexor digitorum brevis, gives off a digital nerve to the medial side of the great toe and finally divides opposite the bases of the metatarsal bones into three plantar digital nerves.

Branches.—Cutaneous branches pierce the plantar aponeurosis between the abductor hallucis and the flexor digitorum brevis and are distributed to the skin of the sole of the foot.

Muscular branches supply the abductor hallucis, the flexor digitorum brevis, the flexor hallucis brevis and the first lumbrical muscle ; those for the abductor hallucis and flexor digitorum brevis arise from the trunk of the nerve near its origin and enter the deep surfaces of the muscles ; the branch for the flexor hallucis brevis springs from the digital nerve to the medial side of the great toe, and that for the first lumbrical muscle from the first plantar digital nerve.

Articular branches supply the articulations of the tarsus and metatarsus.

The *digital nerve of the great toe* supplies the flexor hallucis brevis and the skin on the medial side of the great toe.

The *three plantar digital nerves* pass between the divisions of the plantar aponeurosis, and each splits into two branches. Those of the first plantar digital nerve supply the adjacent sides of the great and second toes ; those of the second, the adjacent sides of the second and third toes ; and those of the third, the adjacent sides of the third and fourth toes. The third plantar digital nerve receives a communicating branch from the lateral plantar nerve ; the first gives a twig to the first lumbrical muscle. Each digital branch gives off cutaneous and articular filaments and opposite the distal phalanx sends upwards a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. *It will be observed that the digital branches of the medial plantar nerve are similar in their distribution to those of the median nerve in the hand. The muscles supplied by the two nerves also correspond closely.* In the hand, the median nerve supplies the abductor and the flexor pollicis brevis, the opponens pollicis and the first and second lumbricals. The opponens muscle is absent in the foot, but the abductor and short flexor of the great toe and the first lumbrical are all supplied by the medial plantar nerve. As the flexor digitorum brevis corresponds to the flexor digitorum sublimis (median nerve) of the upper limb, the only real difference consists in the innervation of the second lumbrical muscle.

The lateral plantar nerve (fig. 992) supplies the skin of the fifth toe and lateral half of the fourth, as well as most of the deep muscles, *its distribution being similar to that of the ulnar nerve in the hand.* It passes forwards obliquely in company with the lateral plantar artery, which lies on the lateral side of the nerve, and reaches the lateral side of the foot near the tubercle of the fifth metatarsal bone. It passes between the flexor digitorum brevis and the flexor digitorum accessorius (quadratus plantæ), and ends in the interval between the former muscle and the abductor digiti minimi by dividing into a superficial and a deep branch. Before its division, it supplies the flexor digitorum accessorius and abductor digiti minimi.

The *superficial branch* splits into two plantar digital nerves ; of these the lateral supplies the lateral side of the little toe, the flexor digiti minimi brevis, and the two interosseous muscles of the fourth intermetatarsal space ; the medial communicates with the third plantar digital branch of the medial plantar nerve and divides into two branches which supply the adjoining sides of the fourth and fifth toes.

The *deep branch* accompanies the lateral plantar artery on the deep surface of the tendons of the flexor muscles and the adductor hallucis, and supplies the second, third and fourth lumbricals, the adductor hallucis and all the interosseous muscles (except those of the fourth intermetatarsal space). The nerves to the second and third lumbricals pass forwards deep to the transverse head of the adductor hallucis, and then pass downwards and backwards across its anterior (or distal) border to reach the muscles (fig. 992).

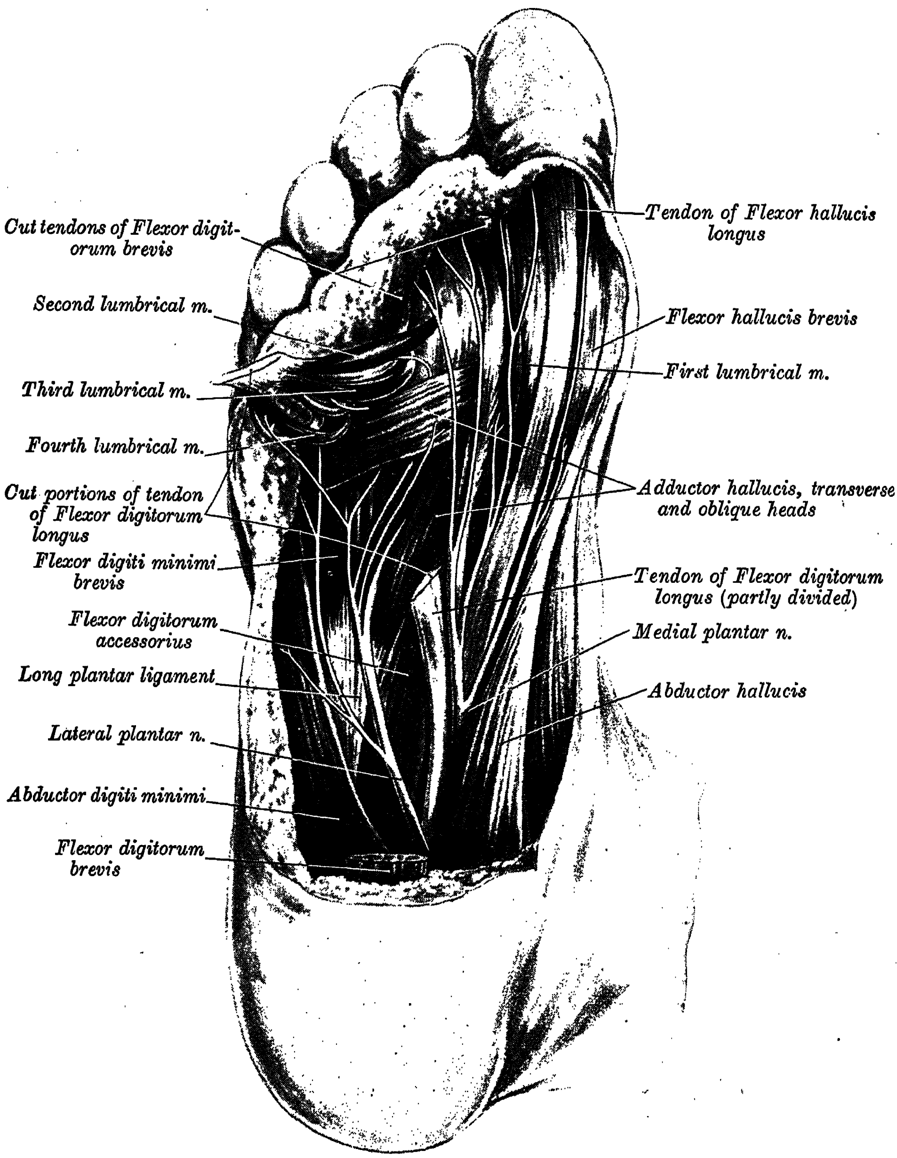
The lateral popliteal nerve (common peroneal nerve) (fig. 989), about one-half the size of the medial popliteal, is derived from the dorsal branches of the anterior primary rami of the fourth and fifth lumbar and the first and second sacral nerves. It descends obliquely along the lateral side of the popliteal fossa to the head of the fibula, close to the medial margin of the biceps femoris muscle. It lies between the tendon of the biceps femoris and the lateral head of the gastrocnemius muscle, winds round the lateral surface of the neck of the fibula deep to the peroneus longus, and divides into the musculocutaneous (superficial peroneal) and anterior tibial (deep peroneal) nerves. Previous to its division it gives off articular and cutaneous branches.

The *articular branches* are three in number ; two of these accompany the superior and inferior lateral genicular arteries to the knee ; the upper one occasionally arises from the trunk of the sciatic nerve. The third, named the recurrent articular nerve, is given off at the point of division of the lateral popliteal nerve ; it ascends with the anterior recurrent tibial artery through the tibialis anterior to the front of the knee-joint.

The *cutaneous branches*, two in number, frequently spring from a common trunk ; they are the lateral cutaneous nerve of the calf of the leg and the sural communicating branch.

The *lateral cutaneous nerve of the calf of the leg* supplies the skin on the anterior, posterior and lateral surfaces of the proximal part of the leg. The *sural communicating branch* arises near the head of the fibula, runs obliquely across the lateral head of the gastrocnemius to the middle of the leg, and joins with the sural nerve (p. 1123). It occasionally descends as a separate branch as far as the heel.

FIG. 992.—A dissection of the lateral and medial plantar nerves of the right foot.



Most of the flexor digitorum brevis has been removed. The flexor digitorum longus has been partially divided and its distal end has been turned forwards together with the second, third and fourth lumbrical muscles.

The **anterior tibial nerve** (deep peroneal nerve) (fig. 984) begins at the bifurcation of the lateral popliteal nerve, between the fibula and proximal part of the peroneus longus, passes obliquely forwards deep to the extensor digitorum longus to the front of the interosseous membrane, where it comes into relation with the anterior tibial artery in the upper one-third of the leg ; it then descends with the artery to the front of the ankle-joint, where it divides into lateral and

medial terminal branches. It lies at first on the lateral side of the anterior tibial artery, then in front of it, and again on its lateral side at the ankle-joint.

In the leg, the anterior tibial nerve supplies *muscular branches* to the tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius, and an *articular branch* to the ankle-joint.

The *lateral terminal branch* of the anterior tibial nerve passes across the tarsus, deep to the extensor digitorum brevis, and having become enlarged, like the posterior interosseous nerve at the wrist, supplies the extensor digitorum brevis. From the enlargement three minute *interosseous branches* are given off which supply the tarsal joints, and the metatarsophalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The *medial terminal branch* of the anterior tibial nerve runs forwards on the dorsum of the foot, and lies on the lateral side of the dorsalis pedis artery. At the first interosseous space it communicates with the medial branch of the musculocutaneous (superficial peroneal) nerve, and divides into two dorsal digital nerves, which supply the adjacent sides of the great and second toes. Before it divides it gives off an *interosseous branch* which supplies the metatarsophalangeal joint of the great toe and sends a filament to the first dorsal interosseous muscle.

The **musculocutaneous nerve** (superficial peroneal nerve) (fig. 984) begins at the bifurcation of the lateral popliteal nerve and lies at first between the peroneus longus and the peroneus brevis. It then passes forwards between the peronei and the extensor digitorum longus, pierces the deep fascia at the lower one-third of the leg, and divides into a medial and a lateral branch. In its course between the muscles, it gives off muscular branches to the peroneus longus and peroneus brevis, and filaments to the skin of the lower part of the leg.

The *medial branch* passes in front of the ankle-joint, and divides into two dorsal digital nerves, one of which supplies the medial side of the great toe, the other, the adjacent sides of the second and third toes. It communicates with the saphenous nerve and with the anterior tibial nerve (fig. 982).

The *lateral branch*, the smaller, passes along the lateral part of the dorsum of the foot, and divides into dorsal digital branches, which supply the contiguous sides of the third and fourth, and of the fourth and fifth toes. It also supplies the skin of the lateral side of the ankle, and communicates with the sural nerve (fig. 982).

The branches of the musculocutaneous nerve supply the skin of the dorsal surfaces of all the toes excepting the lateral side of the little toe and the adjoining sides of the great and second toes, the former being supplied by the sural nerve, and the latter by the medial terminal branch of the anterior tibial nerve. Frequently some of the lateral branches of the musculocutaneous are absent, and their places are then taken by branches of the sural nerve.

The **perforating cutaneous nerve** usually arises from the posterior aspects of the second and third sacral nerves. It pierces the lower part of the sacrotuberous ligament, and, winding round the inferior border of the gluteus maximus, supplies the skin covering the medial and lower parts of that muscle.

The perforating cutaneous nerve may arise from the pudendal nerve or it may be absent; in the latter case its place may be taken by a branch from the posterior cutaneous nerve of the thigh or by a branch from the third and fourth, or fourth and fifth, sacral nerves.

The **pudendal nerve** derives its fibres from the second, third and fourth sacral nerves (fig. 985). Passing between the piriformis and the coccygeus, it leaves the pelvis through the lower part of the greater sciatic foramen and enters the buttock, where it crosses the spine of the ischium on the medial side of the pudendal artery. It accompanies this artery through the lesser sciatic foramen into the pudendal canal (p. 573) on the lateral wall of the ischiorectal fossa; in the posterior part of this canal it gives off the inferior hæmorrhoidal, and then divides into the perineal nerve, and the dorsal nerve of the penis or clitoris.

The *inferior hæmorrhoidal nerve* occasionally arises directly from the sacral plexus; it pierces the medial wall of the pudendal canal, crosses the ischiorectal fossa with the inferior rectal vessels, and is distributed to the sphincter ani externus and to the skin round the anus. Branches of this nerve commun-

icate with the perineal branch of the posterior cutaneous nerve of the thigh and with the scrotal nerve.

The *perineal nerve*, the inferior and larger terminal branch of the pudendal nerve, runs forwards below the internal pudendal artery. It accompanies the perineal artery and divides into scrotal (or labial) and muscular branches.

The *scrotal branches* are two, a medial and a lateral. They pierce, or pass superficial to, the perineal membrane (inferior fascia of the urogenital diaphragm), and run forwards along the lateral part of the urethral triangle in company with the scrotal branches of the perineal artery; they are distributed to the skin of the scrotum, and communicate with the perineal branch of the posterior cutaneous nerve of the thigh. In the female the corresponding nerves (*labial branches*) supply the labium majus.

The muscular branches are distributed to the transversus perinei superficialis, bulbocavernosus, ischiocavernosus, transversus perinei profundus and sphincter urethræ. A branch, termed the *nerve to the urethral bulb*, is given off from the nerve to the bulbocavernosus; it pierces this muscle, and supplies the corpus spongiosum penis (corpus cavernosum urethræ), ending in the mucous membrane of the urethra.

The *dorsal nerve of the penis* runs forwards above the internal pudendal artery along the ramus of the ischium, and accompanies the artery along the margin of the inferior ramus of the pubis, on the deep surface of the perineal membrane. It pierces the membrane, and gives a branch to the corpus cavernosum penis. It then passes forwards, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, to the dorsum of the penis, and ends in the glans penis. In the female the corresponding nerve (*dorsal nerve of the clitoris*) is very small, and supplies the clitoris.

The **visceral branches** arise from the second, third and fourth sacral nerves, and are distributed to the pelvic viscera. They are termed the *pelvic splanchnic nerves* (p. 1138).

The **muscular branches** are derived from the fourth sacral, and supply the levator ani, coccygeus and sphincter ani externus. The branches to the levator ani and coccygeus enter their pelvic surfaces; that to the sphincter ani externus (perineal branch of fourth sacral nerve) reaches the ischiorectal fossa by piercing the coccygeus or by passing between it and the levator ani. Cutaneous filaments from this branch supply the skin between the anus and the coccyx.

The coccygeal plexus.—The coccygeal plexus is formed by a small descending branch from the anterior primary ramus of the fourth sacral nerve, and the anterior primary rami of the fifth sacral and coccygeal nerves. The anterior primary ramus of the fifth sacral nerve emerges from the sacral hiatus and turns forwards round the lateral margin of the sacrum below the cornu. It pierces the coccygeus muscle to gain its pelvic surface and is then joined by a descending filament from the fourth sacral nerve. The small trunk so formed descends on the pelvic surface of the coccygeus and unites with the minute anterior primary ramus of the coccygeal nerve, which descends from the sacral hiatus, turns round the lateral margin of the coccyx and pierces the coccygeus to gain the pelvis. This small trunk constitutes the *coccygeal plexus*. The anococcygeal nerves arise from this plexus, and consist of a few fine filaments which pierce the sacrotuberous ligament and supply the skin in the region of the coccyx.

The Morphology of the Spinal Nerves and the Limb Plexuses

A typical spinal nerve divides shortly after its origin into a posterior and an anterior primary ramus. The posterior primary ramus passes dorsally and penetrates the dorsal muscle mass. It divides into medial and lateral branches, one of which terminates, as a rule, in the skin of the dorsal aspect of the trunk.

The anterior primary ramus proceeds laterally and forwards into the body wall. In the first part of its course it establishes connexions with the sympathetic system and then, as it courses forwards in the substance of the somatopleure, it gives off a lateral branch which passes towards the surface and divides into anterior and posterior branches. The nerve is then continued onwards and terminates not far from the median plane by distributing its anterior terminal branches to the skin of the body wall.

The spinal nerves which conform to the primitive arrangement in their behaviour are the nerves of those segments which have retained to a large extent their metameric characters, viz. T. 2-L. 1. In the cervical and lumbosacral regions the primitive metameric arrangement has disappeared to a large extent and the conditions have been profoundly altered by the development of the limbs. With the disappearance of metamerism the derivatives of adjoining myotomes fuse with one another, and the muscles so formed retain in whole or in part their primitive segmental innervation. The musculature of the limbs develops *in situ* in the mesodermal core of the limb bud, but phylogenetically it may be regarded as a derivative of the myotomes of the segments which are concerned in the formation of the limb. The fusion of derivatives from adjoining myotomes is indicated in the composite origin of the nerves to most of the limb muscles.

The typical spinal nerves are distributed according to a very definite plan. The posterior primary ramus passes backwards and downwards lateral to the articular processes and divides into a medial and a lateral branch which penetrate the deep muscles of the back. Both branches innervate the muscles amongst which they lie, and either the one or the other becomes superficial and supplies a band of skin extending from the posterior median line to the scapular line.

The anterior primary ramus is connected to the corresponding ganglion on the sympathetic trunk by both a white and a grey ramus communicans. After innervating the subvertebral muscles, it passes round the body wall supplying branches to the lateral muscles of the trunk, and in the neighbourhood of the midaxillary line gives off a lateral branch which pierces the overlying muscles and divides into an anterior and a posterior division for the supply of the skin. The main trunk is continued forwards in the body wall and, after supplying the ventral muscles, distributes its terminal branches to the skin.

The behaviour of the anterior primary rami of the spinal nerves of the segments which have lost their obvious metamerism is greatly modified, and the initial modification is seen in the manner in which adjoining nerves unite to form the cervical, brachial, lumbosacral and coccygeal plexuses.

The *cervical plexus*.—The cutaneous branches of this plexus are homologous with the anterior terminal and the lateral branches of the typical spinal nerves. The anterior cutaneous nerve of the neck and the medial supraclavicular nerves represent the anterior terminal branches ; the lesser occipital and the lateral supraclavicular represent the lateral branches, while the great auricular and the intermediate supraclavicular probably represent elements of both branches.

The *brachial plexus*.—In the formation of the brachial and lumbosacral plexuses the division of the constituent nerves of the plexus into anterior or ventral and posterior or dorsal branches is characteristic. This arrangement is obvious in the brachial plexus, where the posterior branches of the three constituent trunks unite to form the posterior cord, and it conforms to the differentiation of the primitive musculature of the limb into a ventral or flexor and a dorsal or extensor group.

It has been urged that the dorsal branches correspond to the lateral branches of the typical spinal nerves, and that the ventral branches represent the anterior portions of these nerves and their anterior terminal branches. On the other hand, the position of the developing limb-bud on the ventrilateral aspect of the trunk and the behaviour of the first and second thoracic nerves provide considerable support for the view that the constituent nerves of the great limb-plexuses represent only the lateral branches of the typical spinal nerves. The second thoracic nerve sends its lateral cutaneous branch into the upper limb as the intercostobrachial nerve, and the size of this nerve varies inversely with the size of the direct contribution which the second thoracic nerve makes to the brachial plexus. Otherwise the second thoracic behaves like a typical spinal nerve. The first thoracic nerve sends a large contribution to the brachial plexus, and this is clearly homologous with the lateral branch. The remainder of the nerve, despite its small size, behaves in a typical manner, although its fine anterior cutaneous branch is often awanting, and, when present, only supplies a limited area of skin.

The *lumbosacral plexus*.—The division of the constituent nerves of the lumbar and sacral plexuses into anterior or ventral and posterior or dorsal divisions is not so obvious as the corresponding division in the brachial plexus, but it can be demonstrated anatomically that the obturator and the medial popliteal (tibial) nerves arise from ventral and the femoral and lateral popliteal (peroneal) nerves from dorsal divisions. The lateral branches of the twelfth thoracic and first lumbar nerves are drawn down over the iliac crest to assist in the innervation of the skin of the buttock, but otherwise these nerves behave as typical spinal nerves. The second lumbar nerve behaves in a manner which renders its interpretation difficult, since it not only gives a substantial contribution to the lumbar plexus but also possesses both an anterior terminal branch, the genital branch of the genitofemoral nerve, and a lateral cutaneous offset, represented by the lateral cutaneous nerve of the thigh and the femoral branch of the genitofemoral nerve. The anterior terminal portions of the third, fourth and fifth lumbar and the first sacral nerves are suppressed, but the corresponding portions of the second and third sacral nerves supply the skin, etc., of the perineum.

The Distribution of the Spinal Nerves to the Skin of the Trunk and Limbs

The cutaneous branches of the typical spinal nerves supply consecutive bands of skin which slope downwards as they are traced round the body from the dorsal to the ventral median line. The upper part of each band receives additional innervation from the nerve of the zone above and its lower part from the nerve of the zone below. Modifications of this arrangement are found in the areas supplied by the cervical, brachial and lumbosacral plexuses.

The first cervical nerve gives off no cutaneous branches. The second cervical nerve usually distributes its cutaneous offsets to the skin of the head, from the vertex backwards to the neighbourhood of the superior nuchal line, the cranial surface and the posterior part of the lateral surface of the auricle, the skin over the angle of the mandible and below the chin (fig. 949). The third cervical nerve supplies a very oblique band of skin, commencing behind over the back of the scalp and the upper part of the back of the neck and passing forwards and downwards across the side of the neck. The area increases in extent as it is traced forwards, and in the ventral median line extends from the hyoid bone down to the level of first rib. The fourth cervical nerve supplies the upper half or more of the back of the neck, and the area widens as it is traced downwards and forwards round the side of the neck to the anterior aspect of the trunk. It supplies the skin over the clavicle and first intercostal space, as well as over the acromion and the upper part of the deltoid muscle.

Each of these three areas is overlapped by the succeeding area, but the amount of overlapping is slight and is greater where the posterior primary rami are involved.

The cutaneous distribution of the nerves of the brachial plexus becomes intelligible only when reference is made to an early stage in the development of the upper limb. In a human embryo of the fourth week the upper limb is represented by a small, somewhat flattened elevation on the ventrilateral aspect of the trunk opposite to the lower four cervical and the first thoracic segments. The ectoderm covering it is directly continuous with the ectoderm of the trunk and draws its nerve supply from the nerves of the corresponding segments. The limb-bud possesses ventral and dorsal surfaces and preaxial, or cephalic, and postaxial, or caudal, borders. The fifth cervical nerve supplies a strip on each surface immediately adjoining the preaxial border, and the first thoracic nerve has a corresponding distribution along the postaxial border. The intervening nerves supply corresponding, parallel strips of skin on both the ventral and dorsal surfaces (fig. 132). As the limb elongates the central nerves of the plexus become buried in its proximal part and reach the skin only in its distal part, and the nerves of the adjoining segments (C. 4 and T. 2) become drawn in to supply the skin at the root of the limb (fig. 975). The preaxial border becomes the lateral aspect and the postaxial border the medial aspect of the limb (p. 101). The highest nerves of the brachial plexus therefore supply

the skin over the lateral aspect of arm and forearm, and the lowest nerves the skin over their medial aspects. Owing to the fact that the central nerves of the plexus are buried in the proximal part of the limb, immediately adjoining areas of skin are innervated by the nerves of widely separated segments (fig. 973), and it is to be remembered that the areas supplied by such nerves do not overlap one another.

On the anterior surface of the upper limb the lateral aspect is supplied by the fifth and sixth cervical nerves and the medial aspect by the eighth cervical and the first and second thoracic nerves. The seventh cervical nerve does not reach the skin until it gains the hand. In the proximal part of the limb the sixth and eighth cervical nerves are also buried, and on the front of the trunk adjoining the limb none of the nerves of the plexus, with the occasional exception of the first thoracic, reach the skin.

The *ventral axial line* is drawn from the median plane laterally across the trunk and the front of the shoulder and is continued down the front of the limb to the wrist. It passes between the areas supplied by spinal nerves which are separated by one or more segments.

The *dorsal axial line* occupies a corresponding position on the dorsal aspect of the limb. It does not, however, continue beyond the elbow, for branches of the seventh cervical nerve, contained in the posterior cutaneous nerve of the forearm, reach the skin over the proximal part of the forearm.

The *skin of the trunk* is supplied by the spinal nerves T. 2 to L. 1, inclusive, and by the sacral nerves, with the exception of the first, and by the coccygeal nerve. These nerves supply consecutive curved bands of skin, of which the upper are almost horizontal while the lower are disposed very obliquely. The upper half of each band receives additional supply from the nerve above and the lower half from the nerve below, so that no appreciable loss of sensibility follows the section of any typical spinal nerve. It is convenient to remember that the band which includes the subcostal angle is supplied by the seventh thoracic nerve and that the umbilicus lies in the upper part of the band supplied by the tenth thoracic nerve.

The areas supplied by the posterior primary rami of these nerves are limited laterally by the dorsilateral line, which commences above on the back of the head and runs downwards and laterally to the medial end of the acromion. It is then continued downwards to the posterior aspect of the greater trochanter of the femur where it curves medially to the coccyx. The cutaneous strips supplied by the posterior primary rami do not correspond exactly to the strips supplied by the anterior primary rami, for they differ both in their breadth and in their position.

On the upper part of the anterior aspect of the thorax the third and fourth cervical areas adjoin the first and second thoracic areas (fig. 978), owing to the fact that the intervening nerves have been drawn off to supply the upper limb, and a similar but less extensive gap is found on the posterior aspect of the trunk.

A corresponding arrangement is found in the lower part of the trunk, but it is not so obvious owing to the approximation of the lower limbs to one another. The first lumbar area adjoins the second sacral area at the root of the penis and scrotum, for the intervening nerves have been drawn off to supply the lower limb.

The *skin of the lower limb* is innervated by the nerves of the segments from which it is derived, viz. L. 2-S. 2. The arrangement originally is precisely similar to the arrangement in the upper limb, but its identification in the adult has been rendered difficult on account of the torsion of the lower limb in the early stages of its development (p. 101). As a result the pre- and post-axial borders cannot be recognised so easily as in the upper limb, and the ventral and dorsal axial lines curve round the limb as they descend.

The preaxial border commences above on the middle of the front of the thigh and runs down to the knee. It then curves medially as it descends to the medial malleolus to gain the medial side of the foot and the hallux. The postaxial border commences above in the gluteal region and descends to the popliteal fossa. It then inclines laterally as it descends to the lateral malleolus to gain the lateral side of the foot. The *ventral* and *dorsal axial lines* necessarily

exhibit a corresponding obliquity. The ventral axial line commences above at the medial end of the inguinal ligament and runs down the medial side of the thigh to the knee. It then winds round the medial side of the calf and terminates on the back of the leg at the point where the fifth lumbar nerve reaches the skin (fig. 988). The dorsal axial line commences in the lateral part of the gluteal region and descends on the posterolateral aspect of the thigh to the knee. It then curves round the lateral side of the leg and terminates on the anterior aspect, where the fibres of the fifth lumbar nerve reach the skin.

The Distribution of the Spinal Nerves to the Muscles of the Body

Each spinal nerve originally supplies the musculature derived from the myotome of the same segment. In cases where the derivatives of any one myotome persist as separate entities, they retain their original nerve-supply, but when derivatives of adjoining myotomes fuse, the resultant muscle does not necessarily retain its supply from each of the corresponding nerves, although it may and frequently does retain them all. Since the limb muscles develop *in situ* in the mesodermal core of the developing limb, it is impossible to identify the individual segments from which any muscle is derived by the study of its mode of development. The union of the individual spinal nerves and their branches in the brachial and lumbosacral plexuses renders impossible the identification by anatomical methods of the root value of the individual motor nerves. Recourse, therefore, must be had to clinical observations and experimental work on monkeys. The results obtained by these methods are not entirely satisfactory, and although there is substantial agreement with regard to certain muscles, there is considerable divergence of opinion with regard to many others, as may be seen from the accompanying table, in which italics are used to denote the muscles concerning which there is lack of agreement.

Applied Anatomy.—The lumbar plexus passes through the psoas major, and therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genitofemoral nerve is the one which is most frequently implicated. This nerve is also of importance as it is concerned in one of the principal superficial reflexes employed in the investigation of diseases of the spinal cord. If the skin over the medial side of the thigh just below the inguinal ligament (the part supplied by the femoral branch of the genitofemoral nerve) be tickled in the male child, the testis will be retracted, through the action of the cremaster muscle, which is supplied by the genital branch of the genitofemoral nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex shows that the portion of the spinal cord from which the first and second lumbar nerves are derived is in a normal condition.

The femoral nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the superior ramus of the pubis, at or near the point where this nerve crosses the bone. When this nerve is paralysed the patient is unable to flex his hip completely, on account of the paralysis of the iliacus; or to extend the knee on the thigh, on account of paralysis of the quadriceps femoris; there is complete paralysis of the sartorius, and usually of the pectineus. There is loss of sensation down the front and medial side of the thigh, except in that part supplied by the genitofemoral and ilio-inguinal nerves. There is also loss of sensation down the medial side of the leg and foot as far as the ball of the great toe.

The obturator nerve is rarely paralysed alone, but occasionally in association with the femoral. The principal interest attached to it is in connexion with its supply to the knee, pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient may not always complain of pain in that articulation, but on the medial side of the knee, or in the knee-joint itself, both of these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing may occur in sacro-iliac disease; or in cases of pathological growth of the ovary or tubal inflammation; or in cancer of the pelvic colon; and even in cases where masses of hardened fæces are impacted in this portion of the gut, pain is complained of in the knee. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. When the obturator nerve is paralysed the patient is unable to press his knees together or to cross one leg over the other on account of paralysis of the adductor muscles. Lateral rotation of the thigh is impaired from paralysis of the obturator externus. Sometimes there is loss of sensation in the upper half of the medial side of the leg.

TABLE OF THE MUSCLES SUPPLIED BY THE INDIVIDUAL SPINAL NERVES

N.B.—The root value of the innervation of muscles printed in heavy type may be regarded as reliable. The root value of the innervation of muscles printed in italics is very doubtful.

The sciatic nerve is liable to be pressed upon by various forms of pelvic tumour, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumours growing from the pelvic viscera, and, sometimes, accumulation of fæces in the rectum, may cause pressure on the nerve inside the pelvis, and give rise to sciatica. Most cases of sciatica, however, are due to neuritis of the sciatic nerve. The inflamed nerve, or any of its branches, is often sensitive to pressure, particularly in certain ‘ tender spots ’ (e.g. near the posterior iliac spine, at the sciatic notch, about the middle of the back of the thigh, in the popliteal fossa, below the head of the fibula, behind the malleoli, or on the dorsum of the foot), and pain is felt whenever extension of the leg is attempted and the nerve is stretched. Paralysis of the sciatic nerve is rarely complete ; when the lesion occurs high up there is palsy of the biceps femoris, semimembranosus and semitendinosus, and of all the muscles below the knee. If the lesion be lower down, there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of

the leg, which is supplied by the posterior femoral cutaneous, and in the area supplied by the saphenous nerve (p. 1117). Lesions of the lateral popliteal nerve cause paralysis of the tibialis anterior, the peronei, the long extensors of the toes and the short extensor on the dorsum of the foot. ' Foot-drop ' follows, dorsal flexion of the toes and eversion of the foot being impossible. Later on, talipes of the equinovarus type results, due to the contracture of the unopposed posterior crural group of muscles.

Frequently the sciatic nerve has been exposed and stretched, or has been acupunctured, for the relief of sciatica. It can easily be marked out on the surface of the thigh (p. 1470).

The position of the lateral popliteal nerve, close behind the tendon of the biceps femoris, on the lateral side of the popliteal fossa, is of considerable practical importance. Owing to the proximity of the nerve the tenotomy of the biceps tendon should be performed by open operation. Where this nerve winds round the neck of the fibula, it is also liable to be severed accidentally. Section of the nerve results in complete ' foot-drop,' from paralysis of the anterior tibial group of muscles, and inversion of the foot, from the unopposed action of the tibialis posterior, the peronei being paralysed, together with anæsthesia of the parts supplied by the nerve, and the limb frequently becomes blue and cold, and may develop ' trophic ' sores.

THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system comprises the splanchnic or visceral components of the nervous system (p. 882), and its fibres are distributed to the various viscera, glands and blood-vessels and to unstriped muscle in general. We have already seen that the development of a limiting sulcus in the lateral wall of the neural tube is a constant feature throughout the vertebrate series, and that as a result a motor area or basal lamina can be differentiated from a sensory area or alar lamina. Further, the nuclei which arise in the dorsal (or lateral) part of the basal lamina constitute the general visceral efferent column, while those which arise in the adjoining part of the alar lamina constitute the visceral afferent column (fig. 840). Certain of the constituents of the autonomic system are so intimately connected anatomically with the somatic system that they have already been dealt with, but it is necessary to repeat, in part, the descriptions already given to enable the student to obtain a comprehensive survey of the autonomic system as a whole.

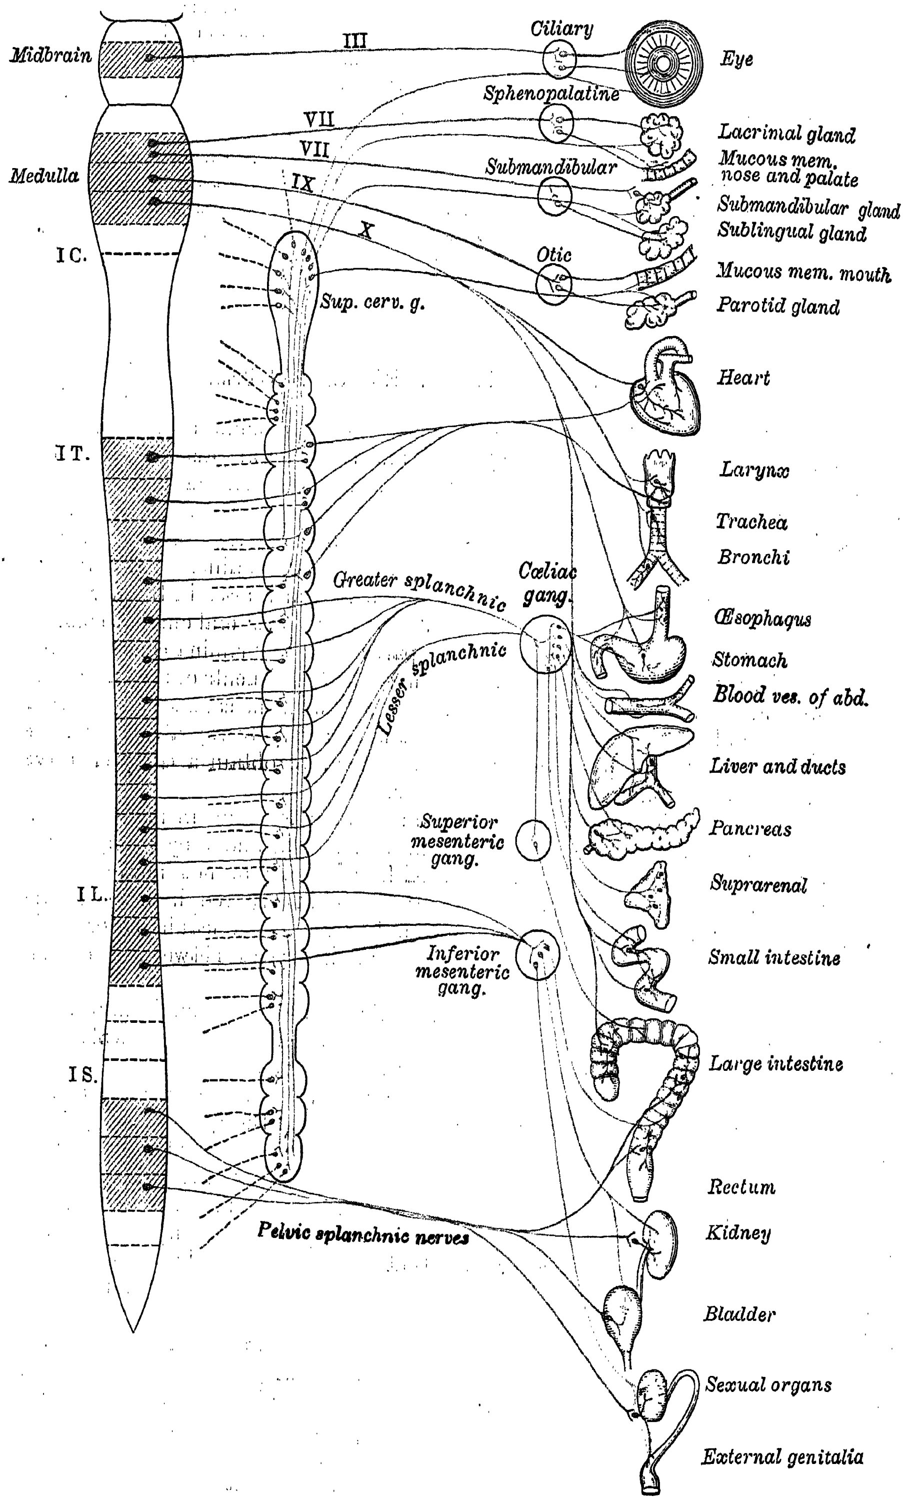
The efferent fibres of the autonomic system take origin in nuclei of cell-groups in the mid-brain, hind-brain and spinal cord, and they emerge from the central nervous system as medullated fibres. They do not, however, pass direct to their distribution. Instead they are interrupted in a peripheral ganglion, and are there relayed to their destination by unmedullated or finely medullated fibres. Two neurones, therefore, are interposed between the central nervous system and the visceral effectors.

No such distinguishing feature marks the afferent autonomic fibres. So far as is known all afferent autonomic fibres are the peripheral branches of nerve-cells placed in the ganglia of the cranial or spinal nerves.

The autonomic nervous system can be subdivided into two more or less complementary parts, viz.: the *parasympathetic* and the *sympathetic systems*, partly on anatomical, partly on physiological and partly on pharmacological grounds. Anatomically it can be demonstrated that most of the viscera of the body receive their nerve-supply from two sources, one source being the parasympathetic system and the other the sympathetic system. Physiologically it can be shown for most of these viscera that the influences of these two systems are antagonistic to one another.* Pharmacologically, it has been found that certain poisons which paralyse the sympathetic nerve endings do not affect the parasympathetic nerves, and *vice versa*. In addition, the sympathetic system comprises two gangliated trunks, together with their communications and their branches of distribution and subsidiary ganglia, so that it constitutes a definite anatomical entity, whereas the parasympathetic system utilises certain of the cranial and certain of the sacral spinal nerves as its pathways and does not lend itself readily for anatomical demonstration.

* For a discussion of the chemical changes involved, see Sir H. H. Dale's Croonian Lecture: " Some chemical factors in the control of the circulation," *Lancet*, 1929.

FIG. 993.—A diagram of the efferent side of the autonomic nervous system. (After Meyer and Gottlieb.) The parasympathetic fibres are represented by *blue*, and the sympathetic fibres, by *red* lines; the interrupted red lines indicate post-ganglionic fibres to the cranial and spinal nerves.



THE PARASYMPATHETIC SYSTEM

The parasympathetic system has a limited origin from the cranial and sacral ends of the central nervous system, but has a very wide field of distribution. It is characteristic of the fibres of this system that they are all relayed in ganglia which are situated peripherally, many of them being small collections of nerve-cells lying in the walls of the viscera themselves and quite invisible to the unaided eye. The parasympathetic fibres are found in (1) the oculomotor, (2) the facial, (3) the glossopharyngeal, (4) the vagus and accessory nerves, and also (5) in the second and third (and fourth) sacral nerves.

(1) The oculomotor parasympathetic fibres take origin in the mid-brain, and it is believed that they are derived from the Edinger-Westphal nucleus (p. 947). The preganglionic fibres travel in the nerve and leave by the branch which it supplies to the inferior oblique muscle to enter the ciliary ganglion. There they are relayed, and the postganglionic fibres leave the ganglion in the short ciliary nerves, which pierce the sclerotic and run fowards in the peri-choroidal space, to be distributed to the ciliary muscle (p. 1170) and the sphincter pupillæ (p. 1171).

(2) The facial nerve contains efferent parasympathetic fibres which arise in the superior salivary nucleus (p. 1059). They travel in the facial nerve, leaving it a little above the stylomastoid foramen in the chorda tympani, which traverses the tympanic cavity and ultimately reaches the lingual nerve. In this way they are conveyed to the submandibular region, where they enter the submandibular (submaxillary) ganglion, in which the secretomotor fibres for the submandibular salivary gland are relayed (*see also* p. 1272). The secretomotor fibres for the sublingual gland are continued forwards in the lingual nerve after they have been relayed in the submandibular ganglion (*see also* p. 1272). Electrical stimulation of the chorda tympani produces dilatation of the vessels of both these salivary glands in addition to a secretomotor effect. In addition, the facial nerve probably contains efferent parasympathetic fibres which are secretomotor to the lacrimal gland. They travel by the nerve of the pterygoid canal and are relayed in the sphenopalatine ganglion.

(3) The glossopharyngeal contains efferent parasympathetic fibres, which are secretomotor to the parotid gland. They arise in the inferior salivary nucleus (p. 1068) and travel in the glossopharyngeal nerve and its tympanic branch (p. 1069). After traversing the tympanic plexus, they enter the lesser superficial petrosal nerve and so reach the otic ganglion. There they are relayed and travel by communicating branches to the auriculotemporal nerve, by which they are conveyed to the parotid gland. Electrical stimulation of the lesser superficial petrosal nerve produces a vasodilator as well as a secretomotor effect.

The glossopharyngeal nerve also contains afferent fibres, which convey general visceral sensibility from the wall of the pharynx, and probably end in the dorsal nucleus of the vagus. The parent cells are situated in the inferior ganglion of the glossopharyngeal nerve. It is doubtful whether these fibres should be included under the parasympathetic system.

(4) The vagus and the cranial part of the accessory nerve contain a very large proportion of parasympathetic fibres. The efferent fibres arise in the dorsal nucleus of the vagus (p. 1069) and travel in the vagus nerve and in its pulmonary, cardiac, œsophageal, gastric, intestinal, etc., branches. They are all relayed in minute ganglia which lie in the walls of the individual viscera. The cardiac nerves are the depressor nerves of the heart. They take part in the formation of the cardiac plexuses (p. 1149) and are then relayed in ganglia which are distributed freely over the surfaces of both atria in the subepicardial tissue. Their terminal fibres are distributed to the atria and the atrioventricular bundle, and it is only through the latter structure that the vagus can exert any control over the ventricular muscle.* According to Woollard,† the smaller branches of the coronary arteries are mainly innervated by the vagus, whereas their larger branches, though possessing a double innervation, obtain their chief

* Cullis, W., and Tribe, E., *Journal of Physiology*, vol. xlvi. 1913.

† H. H. Woollard, *Journal of Anatomy*, vol. lx.

source of supply from the sympathetic system. The *pulmonary branches* are motor to the muscles of the bronchi, which are circularly disposed and are therefore bronchoconstrictors. The *gastric branches* are secretomotor to the glands and motor to the muscular coats of the stomach, but they inhibit the action of the pyloric sphincter. The *intestinal branches* have a corresponding action on the small intestine, being secretomotor to the glands and motor to the muscular coats of the gut, but inhibitory to the ileocolic sphincter. They are distributed through the myenteric (Auerbach's) plexus and the plexus of the submucosa (Meissner's plexus), which are described with the structure of the intestines.

Afferent fibres of the vagus convey general visceral sensibility from the alimentary canal and also, possibly, from the heart, lungs, etc. The parent cells are situated in the inferior ganglion (ganglion nodosum) (p. 1070) and the central branches of their axons terminate in the dorsal nucleus of the vagus. It is doubtful whether these fibres should be included under the parasympathetic system.

(5) The anterior primary rami of the second, third and (fourth) sacral nerves give off visceral branches which pass directly to the pelvic viscera. They constitute the *pelvic splanchnic nerves*, and they unite with branches of the sympathetic pelvic plexuses. Minute ganglia are situated at the points of union and in the walls of the individual viscera. In these ganglia the sacral parasympathetic fibres are relayed.

The pelvic splanchnic nerves supply: (*a*) the rectum, with visceromotor fibres; (*b*) the bladder, with visceromotor, and its sphincter with inhibitory fibres; (*c*) the uterus, with visceromotor fibres; and (*d*) the erectile tissue of the penis or clitoris with vasodilator fibres. In addition, filaments from these nerves are said * to pass upwards through the hypogastric plexus and to be distributed to the colon along all the branches of the inferior mesenteric artery.

Afferent fibres from the pelvic viscera traverse the pelvic splanchnic nerves. Their parent cells are situated in the ganglia on the posterior nerve-roots of the second, third and (fourth) sacral nerves. It is doubtful whether these fibres should be included under the parasympathetic system.

THE SYMPATHETIC SYSTEM

The **sympathetic nervous system,** which is the larger subdivision of the autonomic nervous system, includes the two gangliated sympathetic trunks, their branches, plexuses and subsidiary ganglia. It has a much wider distribution than the parasympathetic system, for it innervates all the sweat glands of the skin, the erector muscles of the hairs and the muscular walls of all the blood-vessels, in addition to the heart, lungs and other viscera. The fibres which it distributes are all derived from the central nervous system, but little is known concerning their central connexions and pathways. There is good ground for believing that in cats a higher sympathetic centre, which can influence heart-rate and control carbohydrate metabolism, exists in the lower part of the lateral wall of the third ventricle.† The fibres which arise in this part of the hypothalamus descend through the brain-stem, where they lie in the dorsal part of the formatio reticularis, and can be traced into the spinal cord. The efferent fibres from the central nervous system arise from the lateral column of the grey substance of the spinal cord and emerge in the anterior nerve-roots of the thoracic and upper lumbar nerves. The limitation of this outflow from the spinal cord to a specific region is remarkable and has not been satisfactorily explained.

The ganglia on the sympathetic trunks are the first part of the system to develop, and they are derived from the primitive spinal ganglia, which originate from the neural crest (p. 108). Originally, therefore, the ganglia on the sympathetic trunk correspond numerically to the ganglia on the posterior nerve-roots of the spinal nerves, but fusion of adjoining ganglia is not uncommon, and in man there are rarely more than twenty-two or twenty-three,

* E. D. Telford and J. S. B. Stopford, *British Medical Journal*, March 31, 1934.

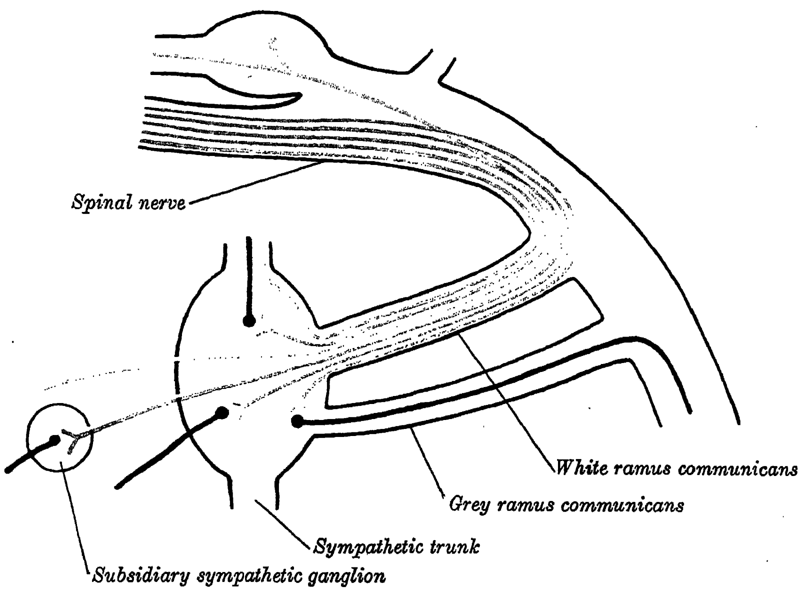
† J. Beattie, G. R. Brow and C. N. H. Long, *Phil. Trans.* B, vol. cvi. 1930.

and there may be fewer discrete ganglia. The subsidiary ganglia of the sympathetic system are derivatives of the ganglia of the trunks.

The efferent fibres from the spinal cord to the sympathetic system are always interrupted in a sympathetic ganglion. It follows that the efferent fibres distributed by the sympathetic system are in every case the axons of nerve-cells situated within a sympathetic ganglion. These fibres can conveniently be differentiated as *preganglionic* and *postganglionic fibres*.

Two varieties of communicating branches connect the ganglia on the sympathetic trunk with the spinal nerves. These are termed *grey* and *white rami communicantes*. At least one *grey ramus communicans* connects each spinal nerve to the corresponding sympathetic ganglion. It conveys postganglionic fibres from the ganglion to the nerve for distribution to the blood-vessels, sweat glands and arrectores pilorum muscles in its area.

FIG. 994.—A scheme to show the destination of the preganglionic fibres of a white ramus communicans. The preganglionic fibres are shown in *red* and the postganglionic fibres in *black*. An afferent sympathetic fibre is shown in *blue*.



One *white ramus communicans* connects each of the thoracic and the first, second and, sometimes, the third lumbar nerves to the corresponding sympathetic ganglion. It conveys efferent preganglionic fibres from the nerve to the ganglion and, in addition, it transmits afferent visceral fibres from the ganglion to the nerve.

The afferent fibres which travel in the sympathetic system are the peripheral branches of unipolar cells situated in the spinal ganglia. They therefore conform to the arrangement already described for the parasympathetic system.

Structure of the sympathetic ganglia.—The constituent nerve-cells of the sympathetic ganglia are surrounded by a nucleated capsule, like the nerve-cells in the spinal ganglia, but unlike them they are usually multipolar. This is not surprising, for the sympathetic cells are stations on an efferent pathway and must be equipped to receive stimuli from more than one source. Examination of the Nissl's bodies has shown that their size and arrangement is sufficiently constant to justify the view that, despite differences in the behaviour and arrangement of their dendrites and axons, all these cells belong to one type.

The dendrites may pierce the capsule and ramify in the intercellular areas, but in many cases they break up within the capsule. These intracapsular plexuses may be situated on one side of the cell, constituting a *glomerulus*, and two or three neighbouring cells may participate in the formation of a glomerulus. The terminals of the preganglionic fibres break up into fine plexuses which

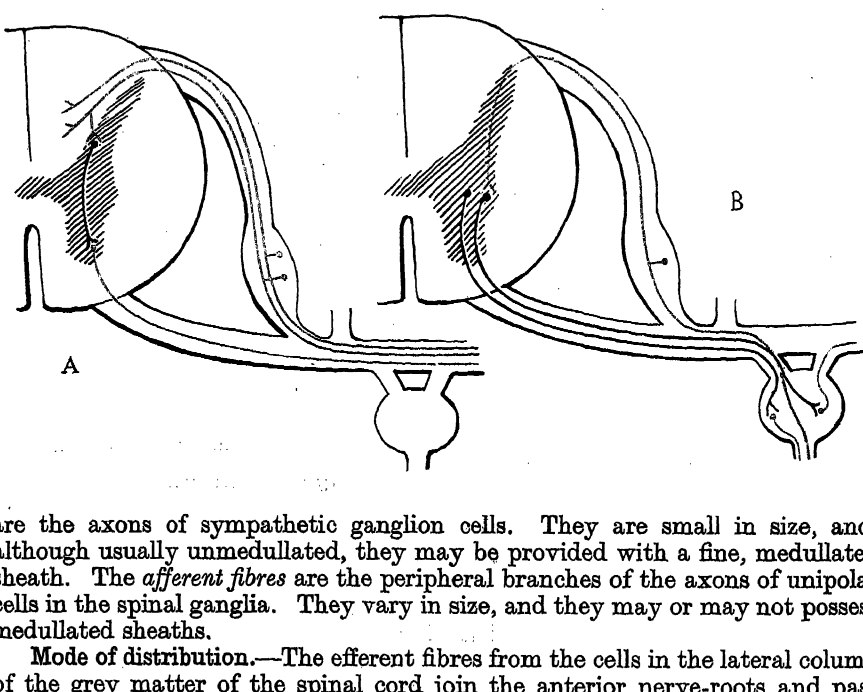
establish synaptic relations with the extracapsular dendrites, or they may form a network which may be either pericapsular or pericellular in position.

The axons of the sympathetic cells are usually fine, unmedullated fibres, but they do occasionally possess a thin sheath of myelin. They are destined either to pass directly to their distribution in one of the medial branches of the sympathetic trunk or to pass by a grey ramus communicans to join a spinal nerve, through which they are distributed. They may, however, ascend to a higher or descend to a lower level in the sympathetic trunk before leaving it. There is no evidence of the existence of any interganglionic association fibres.

The axons of the cells in the subsidiary ganglia pass directly to their distribution.

Structure of the sympathetic nerves.—The *preganglionic fibres* are all derived from the cells in the lateral column of the grey matter of the spinal cord. They are usually small in size and are medullated. The *postganglionic fibres*

Fig. 995.—Diagrams of the central connexions of the somatic fibres (A) and sympathetic fibres (B) of a typical spinal nerve. Afferent fibres, *blue*: connector neurones, *black*: efferent fibres, *red*.



are the axons of sympathetic ganglion cells. They are small in size, and, although usually unmedullated, they may be provided with a fine, medullated sheath. The *afferent fibres* are the peripheral branches of the axons of unipolar cells in the spinal ganglia. They vary in size, and they may or may not possess medullated sheaths.

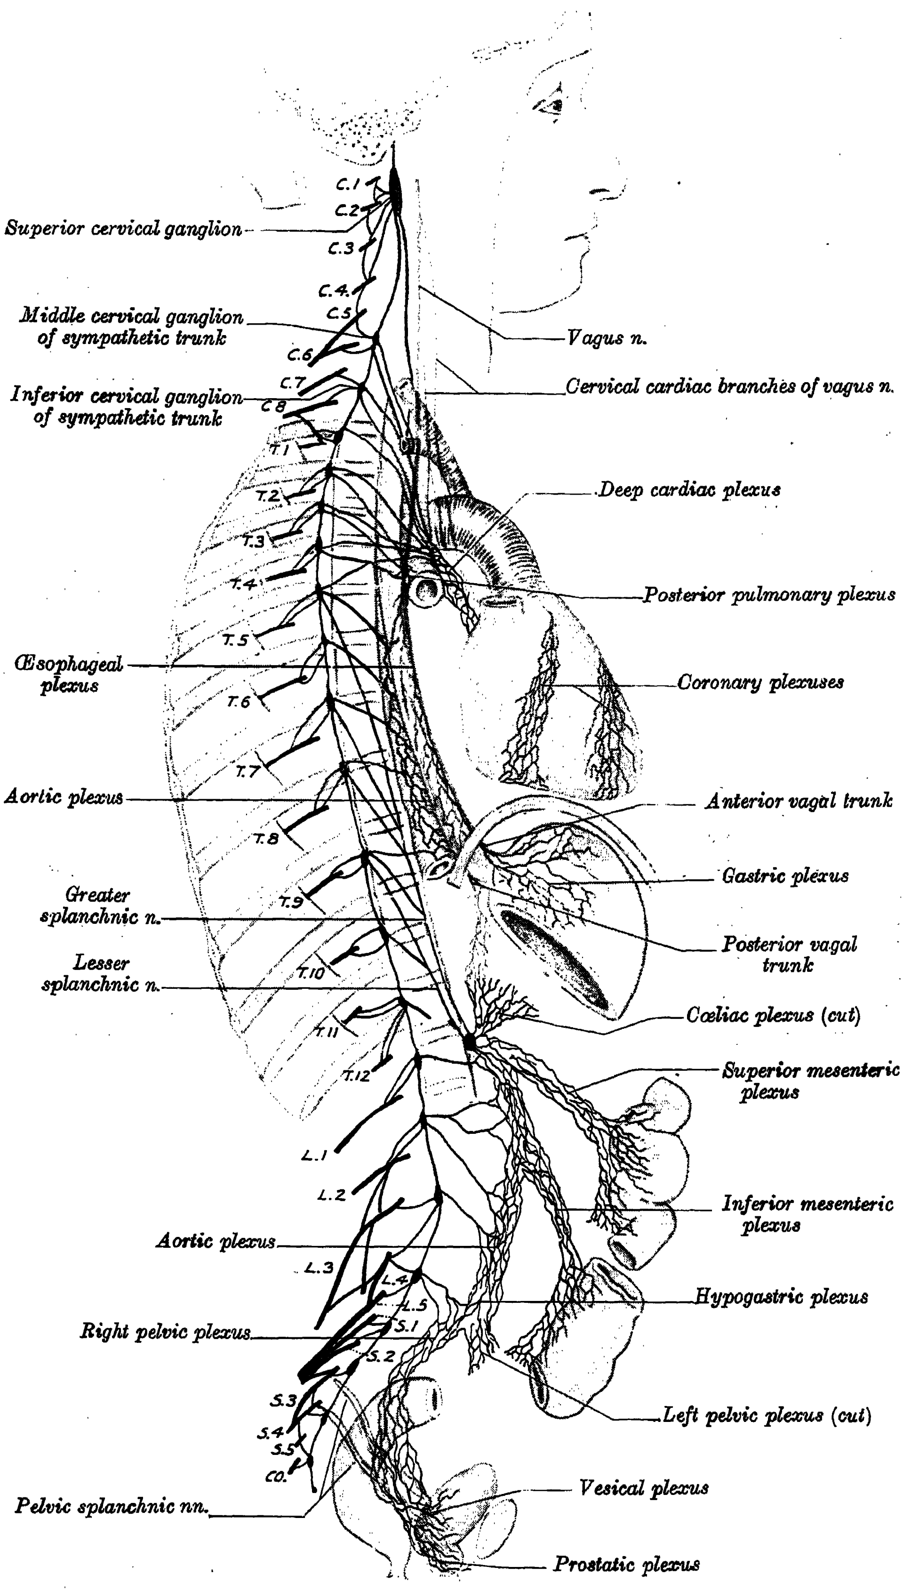
Mode of distribution.—The efferent fibres from the cells in the lateral column of the grey matter of the spinal cord join the anterior nerve-roots and pass into the anterior primary rami of the spinal nerves, T. 1 to L. 2 or 3. They leave the nerves, almost at once, and are conveyed by white rami communicantes to the corresponding ganglia on the sympathetic trunks.

The preganglionic fibres may behave in a number of different ways thereafter. (*a*) They may end in the ganglion by arborising with the dendrites of a ganglion cell ; (*b*) they may pass through the ganglion and ascend to a ganglion at a higher level or descend to one at a lower level before terminating ; (*c*) they may pass through the ganglion without being interrupted, emerge in one of its medial branches and enter a subsidiary ganglion, where they are relayed.

The postganglionic fibres may be arranged in two groups : (*a*) those arising from the ganglia on the sympathetic trunks, and (*b*) those arising from subsidiary ganglia.

(*a*) Postganglionic fibres arising from a ganglion on the sympathetic trunk may reach their distribution in a variety of ways. (1) They may pass back to the corresponding spinal nerve along its grey ramus communicans. Such fibres are distributed by both rami of the spinal nerve to the blood-vessels, sweat-glands, hairs, etc., in its zone of supply. (2) They may pass in a medial branch

FIG. 996.—The right sympathetic trunk and its connexions with the thoracic, abdominal and pelvic plexuses. (After Schwalbe.)



of the ganglion to be distributed to some particular viscus or viscera. (3) They may ascend to a higher level or descend to a lower level before leaving the sympathetic trunk either in one of its medial branches or in a grey ramus communicans. *Postganglionic fibres never travel in a white ramus communicans.*

(*b*) Postganglionic fibres arising from a subsidiary sympathetic ganglion pass direct to their distribution in one of the branches of the ganglion, although they may have to traverse a plexus *en route.*

The afferent fibres are the peripheral branches of unipolar cells in the ganglia on the posterior nerve-roots of the spinal nerves, T. 1 to L. 2 or 3. Very little is known about the end organs with which they are associated. The fibres travel through the sympathetic ganglia without being interrupted and traverse the white rami communicantes to gain the spinal nerve.

The **sympathetic trunks** are two gangliated nerve cords which extend from the base of the skull to the coccyx. In the neck the trunk is placed behind the carotid sheath and in front of the transverse processes of the cervical vertebræ; in the thorax it is placed on the heads of the ribs; in the abdomen on the anterolateral aspect of the bodies of the lumbar vertebræ; and in the pelvis, on the front of the sacrum, medial to the anterior sacral foramina. In front of the coccyx the two trunks meet each other in a terminal ganglion, termed the *ganglion impar.*

In the neck the ganglia are reduced to three in number by the fusion of adjoining ganglia, and from the upper end of the superior ganglion the internal carotid nerve takes origin. This nerve constitutes an upward continuation of the sympathetic trunk, and it accompanies the internal carotid artery through the carotid canal into the skull. In the thorax there are usually eleven ganglia, but the number may be decreased to ten or increased to twelve. There are usually four ganglia in the lumbar region, and four or five in the sacral region.

Functional significance.—Our knowledge of the functional significance of the sympathetic system is very incomplete, and most of the available information concerns the efferent rather than the afferent components.

The fibres which pass to the spinal nerves by the grey rami communicantes supply vasoconstrictor fibres to the blood-vessels, secretomotor fibres to the sweat glands and motor fibres to the arrectores pilorum muscles in the area supplied by the corresponding spinal nerve. In addition, as Boeke has demonstrated, they are distributed to certain of the fibres in voluntary muscles. Hunter and Royle have endeavoured to prove that these sympathetic fibres are concerned with muscle tonus and are responsible for the spasticity of an upper neurone paralysis. The evidence, however, is inconclusive, but their experiments have drawn attention to the fact that, when the sympathetic innervation of voluntary muscle is cut off, the onset of fatigue is abnormally rapid.

The innervation of the individual viscera and of the structures in the head and neck will be dealt with in a subsequent section.

The Cephalic Part of the Sympathetic System

The **cephalic part** of the sympathetic system on each side begins as the **internal carotid nerve,** which is continued upwards from the superior cervical ganglion of the sympathetic trunk. This nerve is soft in texture, and of a reddish colour, and contains postganglionic fibres derived from the cells of the superior cervical ganglion. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, one of which lies on the lateral and the other on the medial side of the artery.

The *lateral branch,* the larger of the two, gives filaments to the internal carotid artery, and forms the lateral part of the *internal carotid plexus.*

The *medial branch* also supplies filaments to the internal carotid artery, and, continuing onwards, forms the medial part of the internal carotid plexus (cavernous plexus).

The **internal carotid plexus** surrounds the internal carotid artery, and occasionally presents a small gangliform swelling on the under side of the vessel, sometimes termed the *carotid ganglion.* The lateral part of the plexus communicates with the trigeminal (semilunar) and sphenopalatine ganglia, and

with the abducent nerve and the tympanic branch of the glossopharyngeal nerve ; it distributes filaments to the wall of the carotid artery.

The branches communicating with the abducent nerve consist of one or two filaments which join that nerve as it lies upon the lateral side of the internal carotid artery. The communication with the sphenopalatine ganglion is effected by a branch named the *deep petrosal* ; this branch perforates the cartilage filling the foramen lacerum, and joins the greater superficial petrosal nerve to form the nerve of the pterygoid canal, which passes through the pterygoid canal to the sphenopalatine ganglion. The communication with the tympanic branch of the glossopharyngeal nerve is effected by the *superior* and *inferior caroticotympanic nerves*, which traverse the posterior wall of the carotid canal.

The medial part of the internal carotid plexus (cavernous plexus), is situated below and on the medial side of that part of the internal carotid artery which is placed by the side of the sella turcica, in the cavernous sinus. It gives branches to the internal carotid artery, and communicates with the oculomotor, trochlear, ophthalmic and abducent nerves, and with the ciliary ganglion.

The branch to the oculomotor nerve joins that nerve at its point of division ; the branch to the trochlear nerve joins the latter as it lies in the lateral wall of the cavernous sinus ; filaments are connected with the medial side of the ophthalmic nerve ; and one joins the abducent nerve. The filament to the ciliary ganglion arises from the anterior part of the plexus and enters the orbit through the superior orbital fissure ; it may join the ganglion directly ; it may unite with the communicating branch from the nasociliary nerve to the ganglion (p. 1045) ; or, it may travel via the ophthalmic nerve and its nasociliary branch. Its fibres pass through the ciliary ganglion without being interrupted and run in the short ciliary nerves to be distributed to the dilatator pupillæ muscle. The preganglionic fibres concerned leave the spinal cord in T. 1, and pass to the first thoracic sympathetic ganglion. They then ascend in the cervical part of the sympathetic trunk to reach the superior cervical ganglion, where they are relayed.

The terminal filaments from the internal carotid plexus are prolonged as plexuses around the anterior and middle cerebral arteries and the ophthalmic artery : along the anterior and middle cerebral arteries they may be traced to the pia mater ; along the ophthalmic artery they pass into the orbit where they accompany each of the branches of that vessel. The filaments prolonged on the anterior communicating artery connect the sympathetic nerves of the right and left sides.

The Cervical Part of the Sympathetic System

The **cervical part** of each sympathetic trunk consists of three ganglia distinguished, according to their positions, as the superior, middle, and inferior, and connected by intervening cords (fig. 996). This part sends grey rami communicantes to all the cervical spinal nerves,* but receives no white rami communicantes from them ; its spinal fibres are derived from the white rami communicantes of the upper thoracic nerves, and enter the corresponding thoracic ganglia of the sympathetic trunk, through which they ascend into the neck. In their course the grey rami communicantes may pierce the longus capitis or the scalenus anterior muscle.

The **superior cervical ganglion,** the largest of the three, is placed opposite the second and third cervical vertebræ. It is of a reddish-grey colour and usually fusiform in shape, sometimes broad and flattened, and occasionally constricted at intervals ; it is believed to be formed by the coalescence of four ganglia, corresponding with the upper four cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery ; behind, with the longus capitis muscle. The internal carotid nerve (p. 1142) ascends from the upper end of the ganglion into the cranial cavity ; the lower end of the ganglion is united by the connecting trunk with the middle cervical ganglion.

Its branches may be divided into lateral, medial and anterior.

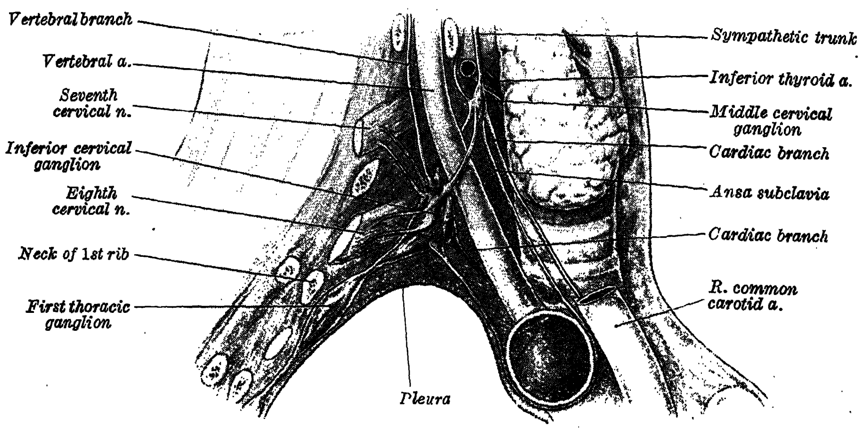
The **lateral branches** of the superior cervical ganglion consist of grey rami communicantes to the upper four cervical nerves and to certain of the cranial nerves. Sometimes the branch to the fourth cervical nerve comes from the

* T. K. Potts (*Journal of Anatomy*, vol. lix. part ii.) has traced as many as three grey rami to each of the lower four cervical nerves.

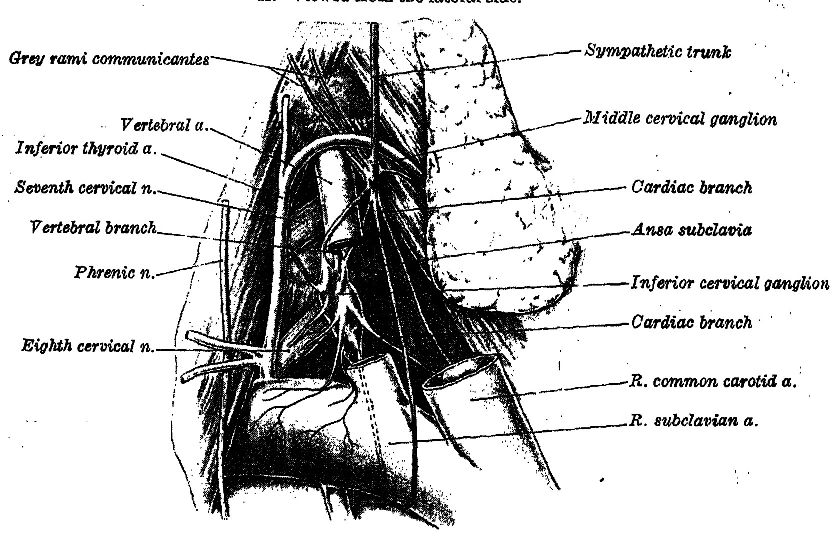
trunk connecting the superior and middle cervical ganglia. Delicate filaments run to the inferior ganglion (ganglion nodosum) of the vagus, and to the hypoglossal nerve; and a branch, named the *jugular nerve*, ascends to the base of the skull, and divides into two twigs, one of which joins the inferior (petrous) ganglion of the glossopharyngeal, and the other the superior (jugular) ganglion of the vagus.

The **medial branches** of the superior cervical ganglion are the laryngopharyngeal and cardiac branches.

FIG. 997.—The middle and inferior cervical ganglia of the right side.



A. Viewed from the lateral side.



B. The same. Viewed from in front.

The *laryngopharyngeal branches* give twigs to the carotid body, and pass to the side of the pharynx, where they join with branches from the glossopharyngeal and vagus nerves to form the *pharyngeal plexus* (p. 1069).

The *cardiac branch* arises by two or more filaments from the superior cervical ganglion, and occasionally receives a twig from the trunk connecting the superior with the middle cervical ganglion. It is said to contain only efferent fibres, which arise in the upper thoracic segments of the spinal cord. It runs down the neck behind the common carotid artery, and in front of the longus cervicis (longus colli) muscle; and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve. The course of the nerve of the right side then differs from that of the left. The *right nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the innominate artery to the back of the arch of the aorta, where it joins the deep part of the cardiac

plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two cardiac branches from the vagus nerve join it; and as it enters the thorax it is joined by a filament from the recurrent laryngeal nerve. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion. The *left nerve*, in the thorax, runs in front of the left common carotid artery and across the left side of the arch of the aorta, to the superficial part of the cardiac plexus. Sometimes it descends on the right side of the aorta and ends in the deep part of the cardiac plexus.

The **anterior branches** of the superior cervical ganglion ramify upon the common carotid artery, and upon the external carotid artery and its branches, forming around each a delicate plexus in which small ganglia are occasionally found. The plexus surrounding the facial artery supplies a filament to the submandibular ganglion, and the plexus on the middle meningeal artery sends one offset to the otic ganglion, and another, termed the *external petrosal nerve*, to the ganglion of the facial nerve.

The **middle cervical ganglion** (fig. 997), the smallest of the three cervical ganglia, is occasionally wanting. It is usually placed opposite the sixth cervical vertebra, in front of, or close to, the inferior thyroid artery, or it may lie near to the inferior cervical ganglion (*vide infra*). It is probably formed by the coalescence of two ganglia corresponding with the fifth and sixth cervical nerves.

The ganglion sends grey rami communicantes to the fifth and sixth cervical nerves, and sometimes to the fourth and seventh, and gives off thyroid and cardiac branches. It is connected to the inferior cervical ganglion by two or more cords, one of which forms a loop around the subclavian artery, and supplies offsets to it. This loop is intimately related to the cervical pleura and is named the *ansa subclavia*.

The *thyroid branches* run along the inferior thyroid artery to the thyroid gland; they communicate with the superior cardiac, external laryngeal and recurrent laryngeal nerves.

The *cardiac branch*, the largest of the sympathetic cardiac branches, arises from the middle cervical ganglion, or from the trunk connecting the middle with the inferior cervical ganglion. On the *right side* it descends behind the common carotid artery, and at the root of the neck runs either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right half of the deep part of the cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent laryngeal nerves. On the *left side*, the nerve enters the thorax between the left carotid and subclavian arteries, and joins the left half of the deep part of the cardiac plexus.

The **inferior cervical ganglion** (fig. 997) is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib, behind the origin of the vertebral artery. Its form is irregular; it is larger than the middle cervical ganglion, and is frequently fused with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia corresponding with the seventh and eighth cervical nerves. In many cases, however, it may be fused with the first or even the first and second thoracic ganglia and is then termed the *stellate ganglion*—the usual condition in many animals. Not uncommonly it may be partly fused with the ganglia corresponding to the sixth, or fifth and sixth, cervical nerves. In the former case the middle cervical ganglion is small and in the latter case it may be absent entirely. This addition to the inferior cervical ganglion lies on an anterior plane to the ganglion proper* and is placed in front of the vertebral artery near its origin, the vessel being embraced by the connexions between the two. In this event the ansa subclavia takes origin from the additional part of the inferior cervical ganglion instead of from the middle cervical ganglion, but loops round the first part of the subclavian artery in the usual way.

The ganglion sends grey rami communicantes to the seventh and eighth cervical nerves, gives off a cardiac branch, supplies branches to blood-vessels, and not infrequently sends a branch to join the vagus nerve.

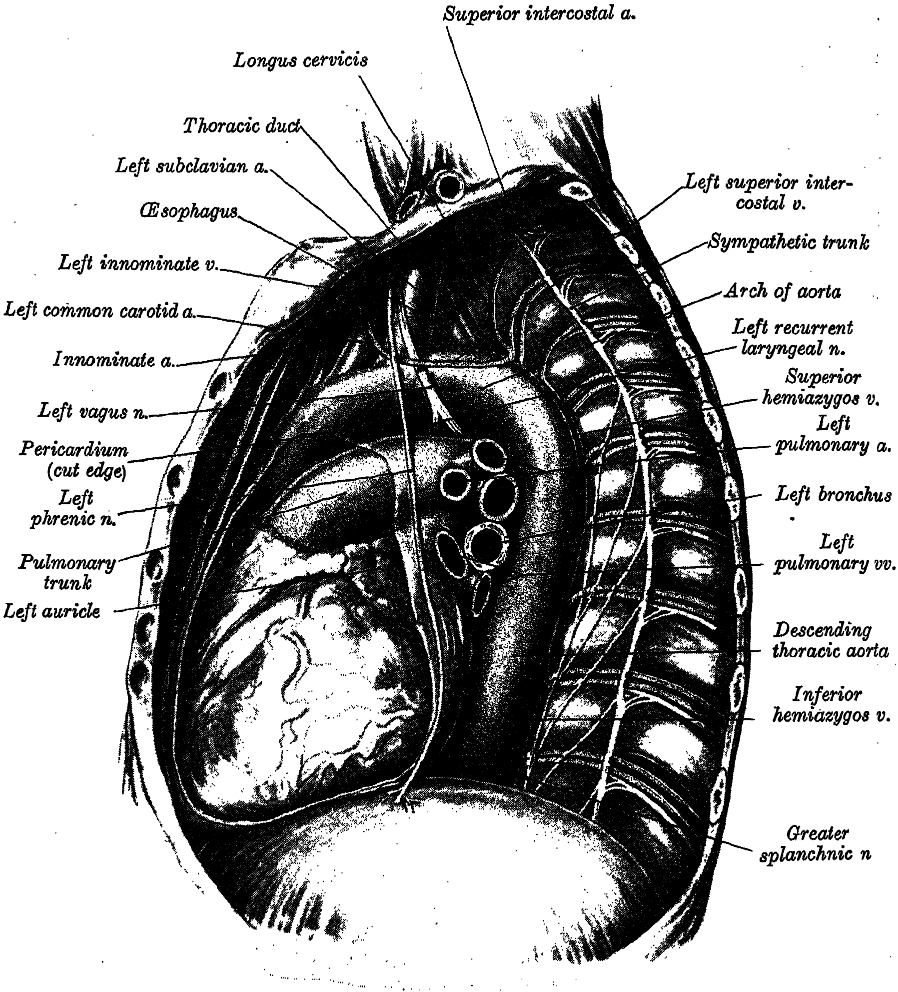
The *cardiac branch* arises from either the inferior cervical or the first thoracic ganglion. It descends behind the subclavian artery and along the front of

* This is the *ganglion intermédiaire* of French anatomists.

the trachea, to join the deep part of the cardiac plexus. Behind the subclavian artery it communicates with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion.

The *offsets to blood-vessels* form plexuses on the subclavian artery and its branches. The plexus on the vertebral artery forms a substantial cord which runs upwards behind the vessels and is continued on the basilar, posterior cerebral and cerebellar arteries. The plexus on the inferior thyroid artery

FIG. 998.—The thoracic portion of the left sympathetic trunk.



accompanies the artery to the thyroid gland, and communicates with the recurrent and external laryngeal nerves, with the cardiac branch of the superior cervical ganglion, and with the plexus on the common carotid artery. The axillary and the brachial arteries and their branches are not supplied by the subclavian plexus but by the branches of the brachial plexus, and especially by the median nerve. The fibres concerned arise in the inferior cervical ganglion and pass to the plexus along the grey rami communicantes. They travel for the most part in the lower trunk of the brachial plexus.

The Thoracic Part of the Sympathetic System (fig. 998)

The **thoracic part** of each sympathetic trunk comprises a series of ganglia, which usually correspond in number to that of the thoracic spinal nerves ; but,

on account of the occasional coalescence of two ganglia, their number is variable. The thoracic ganglia, with the exception of the last two or three, rest against the heads of the ribs, and are covered by the costal pleura ; the last two or three are placed on the sides of the bodies of the corresponding vertebræ. The ganglia are small, and of a greyish colour, and are connected together by the intervening portions of the trunk. The first is larger than the others, and of an elongated form ; it is frequently blended with the inferior cervical ganglion.

Two rami communicantes, a white and a grey, connect each ganglion with its corresponding spinal nerve.

The *branches from the upper five ganglia* are very small ; they supply filaments to the thoracic aorta and its branches. On the aorta they form a delicate plexus (*plexus aorticus thoracalis*) together with filaments from the greater splanchnic nerve. Twigs from the second, third, and fourth ganglia enter the posterior pulmonary plexus ; others, from the second, third, fourth and fifth ganglia, pass to the deep cardiac plexus.*

The *branches from the lower seven ganglia* are large, and white in colour ; they distribute filaments to the aorta, and unite to form the greater, the lesser and the lowest splanchnic nerves.

The *greater splanchnic nerve* is of a considerable size, and consists mainly of medullated, preganglionic fibres ; it is formed by branches from the fifth to the ninth or tenth thoracic ganglia, but the fibres in the higher branches may be traced upwards in the sympathetic trunk as far as the first or second thoracic ganglion. It descends obliquely on the bodies of the vertebræ, perforates the crus of the diaphragm, and ends in the cœliac ganglion. A ganglion [*ganglion splanchnicum*] exists on this nerve opposite the eleventh or twelfth thoracic vertebra.

The *lesser splanchnic nerve* is formed by filaments from the ninth and tenth, sometimes the tenth and eleventh, thoracic ganglia, and from the trunk between the ganglia. It pierces the diaphragm with the preceding nerve, and joins the aorticorenal ganglion.

The *lowest splanchnic nerve* arises from the last thoracic ganglion. It gains the abdomen with the sympathetic trunk, and ends in the renal plexus.

The Lumbar Part of the Sympathetic System (fig. 999)

The lumbar part of each sympathetic trunk is situated in front of the vertebral column, along the medial margin of the psoas major. It consists usually of four lumbar ganglia, connected together by the intervening portions of the trunk. It is continuous above with the thoracic portion, deep to the medial arcuate ligament (medial lumbocostal arch) ; below with the pelvic portion, behind the common iliac artery.

Grey rami communicantes pass from all the ganglia to the lumbar spinal nerves. Many of these fibres travel in the femoral nerve and its saphenous branch and in the obturator nerve and are distributed at intervals to the femoral artery and its branches. The first and second, and sometimes the third, lumbar nerves send white rami communicantes to the corresponding ganglia. The rami communicantes are of considerable length, and accompany the lumbar arteries round the sides of the bodies of the vertebræ, deep to the fibrous arches which give origin to some of the fibres of the psoas major.

Of the *branches of distribution*, some pass in front of the aorta, and join the abdominal aortic plexus ; others run downwards and form plexuses around the common, the external and the internal iliac arteries ; while others cross in front of the common iliac arteries, and assist in forming the hypogastric plexus.

The Pelvic Part of the Sympathetic System (fig. 996)

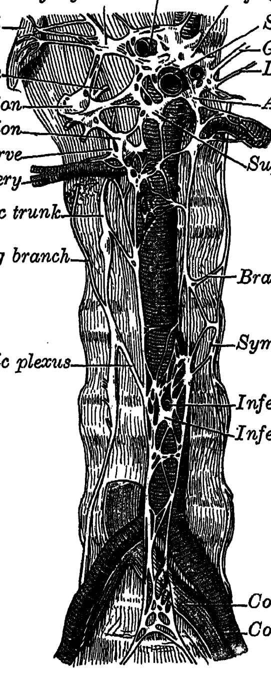
The pelvic part of each sympathetic trunk is situated in front of the sacrum, medial to, or overlapping, the anterior sacral foramina. It comprises four or five small sacral ganglia, connected by the intervening portions of the trunk. It is continuous above with the lumbar part, while below, the two pelvic sympathetic trunks converge, and unite on the front of the coccyx in a small ganglion, which is named the *ganglion impar*.

* Ionescu, D., and Enachescu, M., *Zeitschr. f. Anat. und Entwg.* Bd. 85, 1928.

Grey rami communicantes pass from the ganglia to the sacral and coccygeal nerves. Many of these fibres reach the medial popliteal (tibial) nerve and are distributed to the popliteal artery and its branches. No white rami communicantes pass to this part of the sympathetic trunk.

The *branches of distribution* communicate on the front of the sacrum with the corresponding branches from the opposite side; twigs from the first two ganglia join the pelvic plexuses, and others form a plexus on the median sacral artery. Filaments are distributed to the glomus coccygeum (coccygeal body) from the loop uniting the two trunks.

FIG. 999.—The abdominal portion of the sympathetic trunks, with the cœliac and aortic plexuses. (After Henle.)



The following facts concerning the course of the sympathetic nerve-fibres have been arrived at by experiments on lower animals, chiefly dogs, but they probably hold good for the human sympathetic system:

The preganglionic sympathetic fibres for the head and neck leave the spinal cord through the upper five thoracic nerves (chiefly through the second and third nerves). They ascend in the cervical part of the sympathetic trunk and end in the superior cervical ganglion. The fibres arising from the cells of this ganglion are vasoconstrictor for the blood-vessels, secretory for the salivary and sudoriferous glands, and dilator for the pupil.

The accelerator fibres of the heart leave mainly through the second and third thoracic nerves and pass to the *stellate*,* and the inferior and middle cervical ganglia. From the cells of these ganglia fibres are distributed to the heart. The *afferent* fibres from the heart run in the middle and inferior cervical cardiac and in the thoracic cardiac nerves. Having entered the sympathetic trunk, they pass to the posterior nerve-roots of the second to the fourth or fifth thoracic nerves.

Fibres leave the thoracic spinal nerves (mainly the lower six) and are conveyed through the splanchnic nerves to the cœliac ganglion, from the cells of which fibres pass to the blood-vessels and viscera of the abdominal cavity. Fibres from the lower thoracic and upper three or four lumbar nerves pass through the ganglia of the lumbar part of the sympathetic trunk to the inferior mesenteric ganglion; from this ganglion fibres are conveyed through the hypogastric and pelvic plexuses to the pelvic viscera.

* In the dog the upper four thoracic ganglia of the sympathetic trunk are fused into one mass which is named the *stellate* ganglion.

The constrictor fibres for the blood-vessels of the upper limbs leave the thoracic nerves from about the fourth to the tenth inclusive; those for the lower limbs through the lower two or three thoracic and upper three lumbar nerves; the former have their synapses in the stellate ganglion, the latter in the sixth and seventh lumbar and first sacral ganglia.

THE GREAT PLEXUSES OF THE SYMPATHETIC

The great plexuses of the sympathetic are aggregations of nerves and ganglia, situated in the thoracic, abdominal and pelvic cavities, and named the cardiac, cœliac and hypogastric plexuses. From the plexuses branches are given to the thoracic, abdominal and pelvic viscera.

The Cardiac Plexus (fig. 996)

The **cardiac plexus** is situated at the base of the heart, and is divided into a *superficial* and a *deep part*, which are, however, closely connected.

The **superficial part of the cardiac plexus** lies below the arch of the aorta, in front of the right pulmonary artery. It is formed by the cardiac branch of the superior cervical ganglion of the left sympathetic trunk, and the lower of the two cervical cardiac branches of the left vagus. A small ganglion, termed the *cardiac ganglion*, is usually found in this plexus, and is situated immediately below the arch of the aorta, on the right side of the ligamentum arteriosum. This ganglion is probably a part of the parasympathetic system and acts as a cell-station for vagal fibres only. The superficial part of the cardiac plexus gives branches (*a*) to the deep part of the plexus; (*b*) to the right coronary plexus; and (*c*) to the left anterior pulmonary plexus.

The **deep part of the cardiac plexus** is situated in front of the bifurcation of the trachea, above the point of division of the pulmonary trunk, and behind the aortic arch. It is formed by the cardiac nerves derived from the cervical and upper thoracic ganglia of the sympathetic trunk, and the cardiac branches of the vagus and recurrent laryngeal nerves. The only cardiac nerves which do not join the deep part of the cardiac plexus are those which pass to the superficial part of the plexus.

The branches from the *right half* of the deep part of the cardiac plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the right anterior pulmonary plexus, and are then continued onwards to form part of the right coronary plexus; those behind the pulmonary artery distribute a few filaments to the right atrium, and are then continued onwards to form part of the left coronary plexus.

The *left half* of the deep part of the cardiac plexus is connected with the superficial part of the plexus, and gives filaments to the left atrium, and to the left anterior pulmonary plexus, and is then continued to form the greater part of the left coronary plexus.

The **left coronary plexus** is larger than the anterior, and accompanies the left coronary artery; it is formed chiefly by filaments prolonged from the left half of the deep part of the cardiac plexus, and by a few from the right half. It gives branches to the left atrium and ventricle.

The **right coronary plexus** is formed partly from the superficial and partly from the deep parts of the cardiac plexus. It accompanies the right coronary artery, and gives branches to the right atrium and ventricle.

The sympathetic cardiac nerves are the accelerator nerves of the heart.

The *efferent* sympathetic fibres arise in the upper thoracic segments of the spinal cord, down to and including the fifth, emerge in the corresponding anterior nerve-roots and travel via the white rami communicantes to the sympathetic trunk, in which many of them ascend to the cervical ganglia before being relayed. The *afferent* sympathetic fibres run in the cardiac branches of the middle and inferior cervical ganglia and the thoracic cardiac nerves and reach the spinal cord through the posterior nerve-roots of T. 2 to T. 5.

The fibres derived from the upper thoracic segments of the spinal cord are distributed to the ascending aorta, the pulmonary trunk and the ventricles; those from the lower segments supply the atria.

The Cœliac Plexus (figs. 996, 999, 1000)

The **cœliac** or **solar plexus**, the largest of the three great sympathetic plexuses, is situated at the level of the upper part of the first lumbar vertebra, and is composed of a dense network of nerve-fibres which unite together two large ganglia, termed the cœliac ganglia. It surrounds the cœliac artery and the root of the superior mesenteric artery. It lies behind the stomach and the omental bursa, in front of the crura of the diaphragm and the commencement of the abdominal aorta, and between the suprarenal glands. The plexus and the ganglia receive the greater and lesser splanchnic nerves of both sides and some filaments from the right vagus, and give off numerous secondary plexuses along the neighbouring arteries.

The *cœliac ganglia* are two large irregularly-shaped masses, not unlike lymph glands in appearance, placed, one on each side of the median plane, in front of the crura of the diaphragm and medial to the suprarenal glands, that on the right side being placed behind the inferior vena cava. The upper part of each ganglion is joined by the greater splanchnic nerve, while the lower part, which is more or less detached and is often named the *aorticorenal* ganglion, receives the lesser splanchnic nerve and gives off the greater part of the renal plexus.

The secondary plexuses springing from or connected with the cœliac plexus are the following:

Phrenic.	Splenic.	Suprarenal.	Testicular (or ovarian).
Hepatic.	Left gastric.	Renal.	Superior mesenteric.
	Abdominal aortic.	Inferior mesenteric.	

The **phrenic plexus** accompanies the corresponding (inferior) phrenic artery to the diaphragm, some filaments passing to the suprarenal gland. It arises from the upper part of the cœliac ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point of junction of the right phrenic plexus with the phrenic nerve there is a small ganglion (*ganglion phrenicum*). This plexus distributes some branches to the inferior vena cava, and to the suprarenal and hepatic plexuses.

The **hepatic plexus**, the largest offset from the cœliac plexus, receives filaments from the left and right vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying upon its branches, and upon those of the portal vein, in the substance of the liver. Branches from this plexus accompany all the branches of the hepatic artery. The plexus exercises a controlling and regulating influence over both carbohydrate and protein metabolism in the liver. Its vagal constituents are believed to be motor to the musculature of the gall-bladder and bile ducts and inhibitory to the sphincter of the bile duct. A considerable plexus accompanies the gastroduodenal artery and is continued as the *right gastro-epiploic plexus* on the right gastro-epiploic artery along the greater curvature of the stomach, where it unites with offshoots from the splenic plexus.

The **splenic plexus** is formed by branches from the cœliac plexus, left cœliac ganglion and right vagus nerve. It accompanies the splenic artery to the spleen, giving off, in its course, subsidiary plexuses along the various branches of the artery. The terminal branches supply the unstriped muscle of the splenic capsule and trabeculæ.

The **left gastric plexus** accompanies the left gastric artery along the lesser curvature of the stomach, and joins with the gastric branches of the vagus nerves. The gastric sympathetic nerves are motor to the pyloric sphincter but inhibitory to the muscular coats of the stomach.

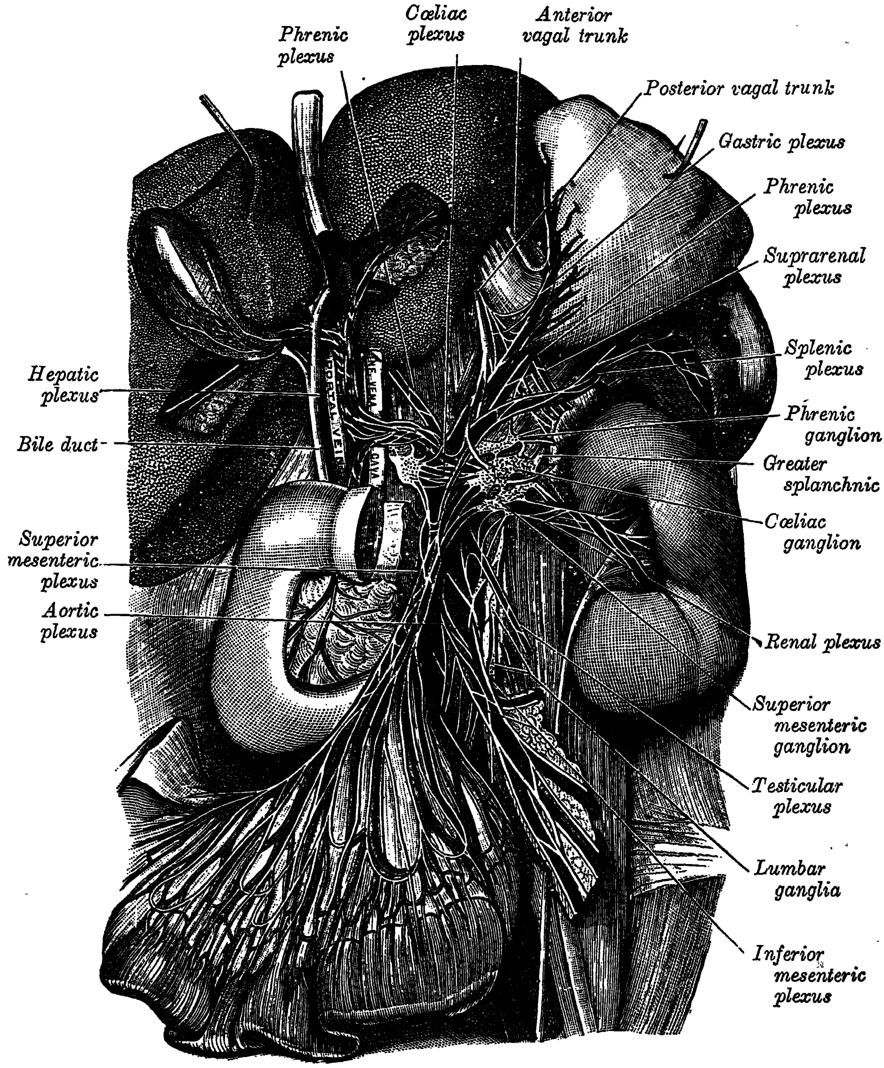
The **suprarenal plexus** is formed by branches from the cœliac plexus, from the cœliac ganglion, and from the phrenic and greater splanchnic nerves, a ganglion being formed at the point of junction with the latter nerve. The plexus supplies the suprarenal gland, and is distributed chiefly to its medullary portion; its branches are remarkable for their large size in comparison with that of the organ they supply.

The **renal plexus** is formed by filaments from the cœliac plexus, the aorticorenal ganglion, and the aortic plexus. It is joined also by the lowest splanchnic nerve and by branches from the vagus.* The nerves from these sources, fifteen

* O. Renner, *Die Innervation der Niere. Die Lebensnerven* (L. R. Müller), Berlin, 1924.

or twenty in number, have a few ganglia developed upon them. They accompany the branches of the renal artery into the kidney; some filaments are distributed to the testicular plexus and to the ureter, and, on the right side, to the inferior vena cava. The available evidence suggests strongly that the renal sympathetic nerves are entirely vasomotor in function.

FIG. 1000.—The cœliac ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (From Toldt's *Atlas*, published by Messrs. Redman, Ltd., London.)



The **testicular plexus** is derived from the renal plexus, and receives twigs from the aortic plexus. It accompanies the testicular artery to the testis. In the female the **ovarian plexus** arises from the renal plexus, and, accompanying the ovarian artery, is distributed to the ovary and the fundus of the uterus.

The sympathetic nerves to the intestine are motor to the ileocolic sphincter but inhibitory to the muscular coats of the gut. In addition, they convey vasoconstrictor fibres.

The **superior mesenteric plexus** is a continuation of the lower part of the cœliac plexus, and receives a branch from the junction of the right vagus nerve with the latter plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses which are distributed to the parts supplied by the artery, viz. pancreatic

branches to the pancreas ; jejunal and ileal branches to the small intestine ; ileocolic, right colic, and middle colic branches, which supply the corresponding parts of the large intestine. The nerves composing this plexus are white in colour and firm in texture ; the *superior mesenteric ganglion* is situated in the upper part of the plexus close to the origin of the superior mesenteric artery.

The **abdominal aortic plexus** is formed by branches from the cœliac plexus and ganglia, and receives filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus parts of the testicular, the inferior mesenteric, the iliac and the hypogastric plexuses arise ; it also distributes filaments to the inferior vena cava.

The **inferior mesenteric plexus** is derived chiefly from the aortic plexus. It surrounds the inferior mesenteric artery, and just below the origin of this vessel the *inferior mesenteric ganglion* is situated. The plexus divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery ; thus the left colic plexuses supply the descending and pelvic parts of the colon ; and the superior rectal plexus supplies the rectum and joins in the pelvis with branches from the pelvic plexuses. The colic sympathetic nerves are inhibitory to the muscular coats of the colon and rectum.

The Hypogastric Plexus (fig. 996)

The **hypogastric plexus** is situated in front of the left common iliac vein, the last lumbar vertebra and the promontory of the sacrum, between the two common iliac arteries. It is formed by the union of numerous filaments—the so-called " presacral nerves "—which descend on each side from the aortic plexus, and from the lumbar ganglia. It divides below into two portions which are named the *right* and *left pelvic plexuses*.

The Pelvic Plexuses (fig. 996)

The two **pelvic plexuses** supply the viscera of the pelvic cavity, and are situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. Each is formed by a continuation of the hypogastric plexus, and by a few filaments from the first two ganglia of the sacral part of the sympathetic trunk. The parasympathetic visceral branches of the second and third sacral nerves [the pelvic splanchnics] join the sympathetic nerves of the pelvic plexuses, and minute ganglia are found at the points of junction. From the pelvic plexuses numerous branches are distributed to the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The **middle rectal plexus** arises from the upper part of the pelvic plexus ; it supplies the rectum, and joins with branches of the superior rectal plexus.

The **vesical plexus** arises from the fore parts of the pelvic plexuses. The nerves composing it are numerous and, as it is a mixed sympathetic and parasympathetic plexus, contain a large proportion of medullated preganglionic nerve-fibres. They accompany the vesical arteries, and are distributed to the sides and fundus of the bladder. Numerous filaments also pass to the vesiculæ seminales and vasa deferentia ; those accompanying the vasa deferentia join, on the spermatic cord, with branches from the testicular plexuses. The vesical sympathetic nerves convey motor fibres to the sphincter and inhibitory fibres to the muscular coats of the bladder.

The **prostatic plexus** is continued from the lower parts of the pelvic plexuses. The nerves composing it are of large size. They are distributed to the prostate, vesiculæ seminales, and the corpora cavernosa and corpus spongiosum of the penis. The nerves supplying the corpora cavernosa consist of two sets, the lesser and greater cavernous nerves, which arise from the fore part of the prostatic plexus, and, after joining with branches from the pudendal nerve, pass forwards below the pubic arch.

The *lesser cavernous nerves* perforate the fibrous covering of the penis, near its root, and are distributed to its erectile tissue.

The *greater cavernous nerve* passes forwards along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa.

The **vaginal plexus** arises from the lower parts of the pelvic plexuses. It is distributed to the walls of the vagina and to the erectile tissue of the vestibule. The nerves composing this plexus contain, like the vesical, a large proportion of preganglionic parasympathetic nerve-fibres.

The **uterine plexus** accompanies the uterine artery along the side of the uterus, between the layers of the broad ligament, and communicates with the ovarian plexus. Its fibres are chiefly distributed to the neck, and the lower part of the body, of the uterus. A collection of small ganglia which together form the *uterine cervical ganglion* is situated at the side of the neck of the uterus.

Applied Anatomy.—Little is known as to the connexion between the numerous microscopical alterations (pigmentation, atrophy, hæmorrhage, fibrosis) that have been described in the sympathetic nervous system, and the functional changes that ensue therefrom. Grosser lesions due to stabs, bullet-wounds, or the pressure of new growths, may cause either irritative or paralytic symptoms. In *paralysis* of the cervical sympathetic on one side, the pupil is small and does not dilate when shaded or on the instillation of cocaine, although it contracts still further when brightly illuminated; it also loses the ciliospinal reflex, failing to dilate when the skin of the neck is pinched. The palpebral fissure narrows from paralysis of the involuntary muscle of the eyelid, and the eyeball sinks backwards into the orbit—enophthalmos. The superficial vessels of the face and scalp are at first dilated, but later they contract. Anidrosis, or absence of sweating, is often noted on the affected side. *Irritation* of the cervical sympathetic produces signs mainly the converse of those described above. We have no definite knowledge of the signs and symptoms that follow lesions of the thoracic or lumbar parts of the sympathetic system. It is likely, however, that a number of nervous disorders characterised by persistent vascular disturbances, such as dilatation of the vessels with throbbing, flushing, sweating, and localised œdema, or contraction of the vessels with pallor, chilliness, pain, and malnutrition of the affected parts, are due to implication of the sympathetic nervous system.

The operation of *periarterial sympathectomy* has been introduced of recent years in an attempt to deprive an artery of its sympathetic innervation, particularly in cases of intermittent claudication. It consists in the removal of a complete ' cuff ' of the tunica adventitia, in which the vascular nerves lie, but, although good results have followed in many cases, there is no anatomical basis for the operation. The aortic plexus is continued along the large branches of the aorta, and this source of supply may be cut off completely by the procedure, but it does not constitute the exclusive supply of the large arteries. Numerous branches of sympathetic origin join the vessels from the nerves which run close to them in their course. For example, the median nerve in the arm supplies numerous filaments to the brachial artery, and the femoral, saphenous and obturator nerves in the thigh give branches to the femoral artery. On this account the removal of a ' cuff ' of the tunica adventitia can only produce a local denervation of the vessel.

Complete removal of the cervical ganglia and the cervical part of the sympathetic trunk has been carried out in cases of bronchial asthma with varying success. In view of the fact that the bronchoconstrictors are supplied by the vagus (p. 1074), it would appear that the operation can only be expected to produce beneficial results when the condition is due to reflexes of peripheral origin. In such cases the removal of the cervical sympathetic trunk eliminates some of the afferent impulses.

The whole of the sympathetic innervation of the upper limb can be cut off by the excision of the first and second thoracic ganglia, and the portion of the trunk which connects them. This operation has been carried out with successful results in cases of Raynaud's disease affecting the upper limbs. Although the bilateral excision of the first and second thoracic ganglia cuts off a large part of the sympathetic innervation of the heart, the cardiac rhythm is not greatly disturbed. The operation is performed through a dorsal, vertical incision and involves the excision of the vertebral end of the second rib and the transverse process of the second thoracic vertebra.

Recently, the lumbar part of the sympathetic trunk and its rami have been subjected to operation in cases of Hirschsprung's disease, or congenital megalocolon. On the grounds that the dilated condition of the gut is attributable to overaction of the inhibitory influence of the sympathetic, the white ramus communicans of the first lumbar ganglion (and sometimes that of the second as well) and the medial branches of the lumbar ganglia are divided and the trunk itself is cut through below the fourth lumbar ganglion. Similar operations have been performed for spastic conditions of the vessels of the lower limb.

Division of the ' presacral nerves ' has recently been carried out for pain associated with disease of the pelvic organs on the assumption that the afferent fibres concerned reach the spinal cord by this route. A similar operation has been performed to hasten the onset of ' automatic bladder ' in lesions of the spinal cord.

THE ORGANS OF THE SENSES AND THE SKIN

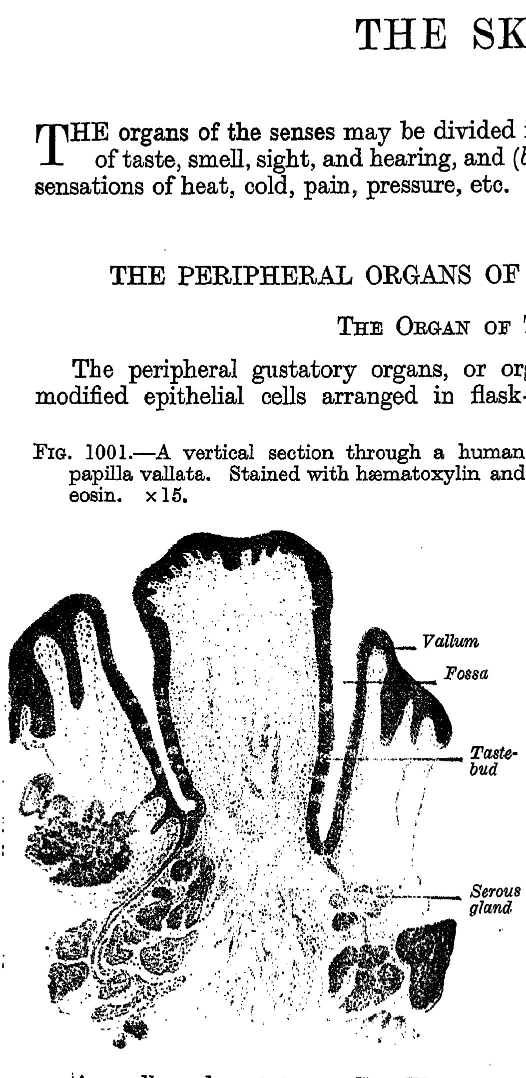
THE organs of the senses may be divided into (*a*) those of the special senses of taste, smell, sight, and hearing, and (*b*) those associated with the general sensations of heat, cold, pain, pressure, etc.

THE PERIPHERAL ORGANS OF THE SPECIAL SENSES

The Organ of Taste

The peripheral gustatory organs, or organs of taste, consist of certain modified epithelial cells arranged in flask-shaped groups termed *gustatory calyculi* or *taste-buds*, which are found on the tongue and adjacent parts. They occupy nests in the stratified epithelium (fig. 1001), and are very numerous on the sides of the papillæ vallatæ and less so on the walls surrounding the papillæ. They are found also in the epithelial covering of the sides and posterior part of the tongue. They are very plentiful over the folia linguæ, just in front of the lingual attachment of the palato-glossal arch. They are present also on the under surface of the soft palate, and on the posterior surface of the epiglottis.

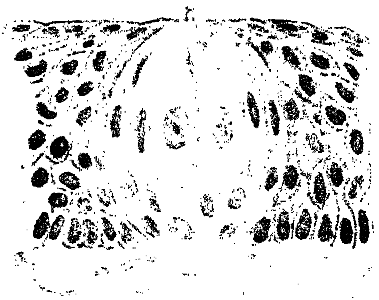
Fig. 1001.—A vertical section through a human papilla vallata. Stained with hæmatoxylin and eosin. ×15.



Structure.—Each taste-bud is flask-shaped (fig. 1002), its broad base resting on the corium, and its neck opening between the cells of the epithelium by an orifice termed the *gustatory pore*. The bud consists of supporting cells and gustatory cells. The *supporting cells* are mostly arranged like the staves of a cask, and form a complete envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The *gustatory cells* occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near its centre. The peripheral process of the cell ends at the gustatory pore in a fine hair-like filament, named the *gustatory hair*. The central process passes towards the deep part of the bud, and there ends in a single or branched extremity. The nerve-fibres, after losing their medullary sheaths, enter the taste-bud, and end in fine fibrils between the gustatory cells; other nerve-fibrils end between the epithelial cells which surround the taste-bud, but these are believed to be nerves of ordinary sensation and not gustatory.

Nerves of taste.—The chorda tympani nerve, derived from the facial nerve (p. 1061), and distributed with the lingual nerve, is the nerve of taste for the anterior two-thirds of the tongue; the glossopharyngeal is the nerve of taste for the posterior one-third of the tongue and for the soft palate. The internal laryngeal branch of the vagus innervates the taste-buds in the epiglottis.

Fig. 1002.—A section through a taste-bud from the human tongue. Stained with hæmatoxylin and eosin. × 450.



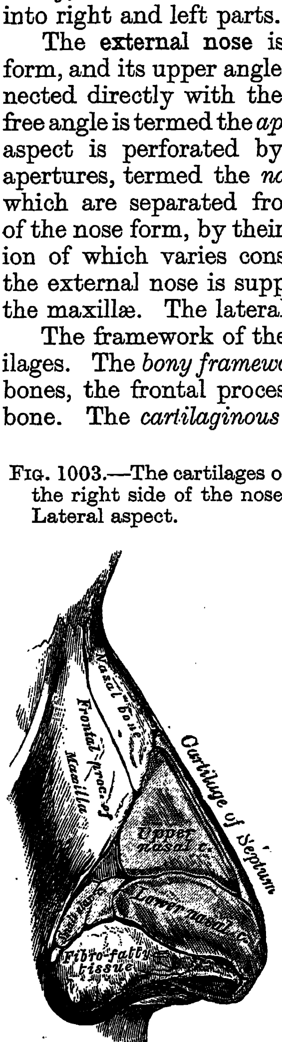
The Organ of Smell

The peripheral olfactory organ consists of the *external nose*, and the *nasal cavity*, which is divided by a septum into right and left parts.

The **external nose** is pyramidal in form, and its upper angle, or *root*, is connected directly with the forehead; its free angle is termed the *apex*. Its inferior aspect is perforated by two elliptical apertures, termed the *nares* or *nostrils*, which are separated from each other by the septum. The lateral surfaces of the nose form, by their union in the medial plane, the *dorsum nasi*, the direction of which varies considerably in different individuals; the upper part of the external nose is supported by the nasal bones and the frontal processes of the maxillæ. The lateral surfaces end below in the rounded *alæ nasi*.

The framework of the external nose is composed of bones and hyaline cartilages. The *bony framework*, which supports its upper part, consists of the nasal bones, the frontal processes of the maxillæ, and the nasal part of the frontal bone. The *cartilaginous framework* consists of the septal cartilage, the upper and lower nasal cartilages, and the small cartilages of the ala (figs. 1003-1005). These are connected to one another and to the bones by the continuity of the perichondrium and the periosteum.

Fig. 1003.—The cartilages of the right side of the nose. Lateral aspect.



The *septal cartilage* (figs. 1005, 1006), somewhat quadrilateral in form, and thicker at its margins than at its centre, forms almost the whole of the septum between the anterior parts of the nasal cavity. The upper part of its anterosuperior margin is connected to the posterior border of the internasal suture; the middle part is continuous with the upper nasal cartilages; the lower part is attached to these cartilages by the perichondrium. Its antero-inferior border is connected on each side to the septal process (medial crus) of the lower nasal cartilage. Its postero-superior border is joined to the perpendicular plate of the ethmoid bone, and its postero-inferior border is attached to the vomer and to the nasal crest of the maxillæ. The cartilage of the septum may extend backwards (especially in children) as a narrow process, termed the *sphenoidal process*, for some distance between the vomer and the perpendicular plate of the ethmoid bone. The anterior-inferior part of the nasal septum is freely movable, and hence is named the *septum mobile nasi*; it is not formed by the cartilage of the septum, but by the septal processes of the lower nasal cartilages and by the skin.

The *upper nasal cartilage* (lateral cartilage) (fig. 1003) is situated below the inferior margin of the nasal bone, and is triangular in shape. Its anterior margin is thicker than the posterior, and its upper part is continuous with the cartilage of the septum, but its lower part is separated from this cartilage by a narrow fissure; its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the lower nasal cartilage.

THE ORGANS OF THE SENSES AND THE SKIN

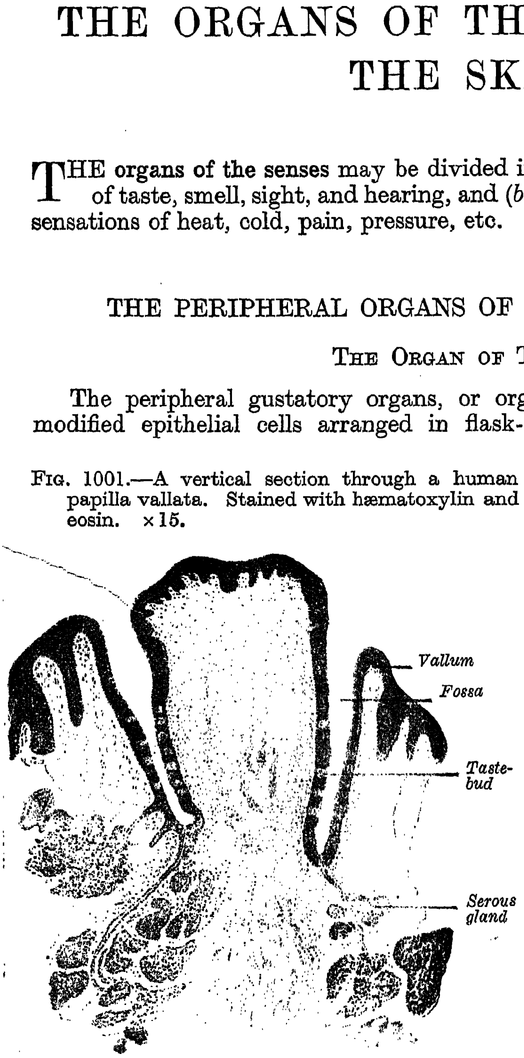
THE organs of the senses may be divided into (*a*) those of the special senses of taste, smell, sight, and hearing, and (*b*) those associated with the general sensations of heat, cold, pain, pressure, etc.

THE PERIPHERAL ORGANS OF THE SPECIAL SENSES

The Organ of Taste

The peripheral gustatory organs, or organs of taste, consist of certain modified epithelial cells arranged in flask-shaped groups termed *gustatory calyculi* or *taste-buds*, which are found on the tongue and adjacent parts. They occupy nests in the stratified epithelium (fig. 1001), and are very numerous on the sides of the papillæ vallatæ and less so on the walls surrounding the papillæ. They are found also in the epithelial covering of the sides and posterior part of the tongue. They are very plentiful over the folia linguæ, just in front of the lingual attachment of the palatoglossal arch. They are present also on the under surface of the soft palate, and on the posterior surface of the epiglottis.

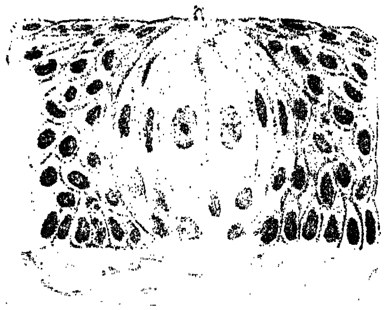
Fig. 1001.—A vertical section through a human papilla vallata. Stained with hæmatoxylin and eosin. ×15.



Structure.—Each taste-bud is flask-shaped (fig. 1002), its broad base resting on the corium, and its neck opening between the cells of the epithelium by an orifice termed the *gustatory pore*. The bud consists of supporting cells and gustatory cells. The *supporting cells* are mostly arranged like the staves of a cask, and form a complete envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The *gustatory cells* occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near its centre. The peripheral process of the cell ends at the gustatory pore in a fine hair-like filament, named the *gustatory hair*. The central process passes towards the deep part of the bud, and there ends in a single or branched extremity. The nerve-fibres, after losing their medullary sheaths, enter the taste-bud, and end in fine fibrils between the gustatory cells; other nerve-fibrils end between the epithelial cells which surround the taste-bud, but these are believed to be nerves of ordinary sensation and not gustatory.

Nerves of taste.—The chorda tympani nerve, derived from the facial nerve (p. 1061), and distributed with the lingual nerve, is the nerve of taste for the anterior two-thirds of the tongue; the glossopharyngeal is the nerve of taste for the posterior one-third of the tongue and for the soft palate. The internal laryngeal branch of the vagus innervates the taste-buds in the epiglottis.

FIG. 1002.—A section through a taste-bud from the human tongue. Stained with hæmatoxylin and eosin. × 450.



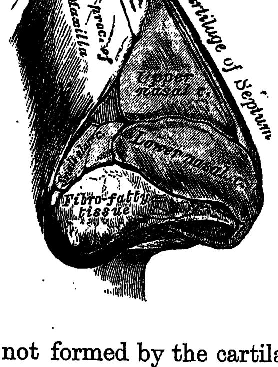
The Organ of Smell

The peripheral olfactory organ consists of the *external nose*, and the *nasal cavity*, which is divided by a septum into right and left parts.

The **external nose** is pyramidal in form, and its upper angle, or *root*, is connected directly with the forehead; its free angle is termed the *apex*. Its inferior aspect is perforated by two elliptical apertures, termed the *nares* or *nostrils*, which are separated from each other by the septum. The lateral surfaces of the nose form, by their union in the medial plane, the *dorsum nasi*, the direction of which varies considerably in different individuals; the upper part of the external nose is supported by the nasal bones and the frontal processes of the maxillæ. The lateral surfaces end below in the rounded *alæ nasi*.

The framework of the external nose is composed of bones and hyaline cartilages. The *bony framework*, which supports its upper part, consists of the nasal bones, the frontal processes of the maxillæ, and the nasal part of the frontal bone. The *cartilaginous framework* consists of the septal cartilage, the upper and lower nasal cartilages, and the small cartilages of the ala (figs. 1003-1005). These are connected to one another and to the bones by the continuity of the perichondrium and the periosteum.

FIG. 1003.—The cartilages of the right side of the nose. Lateral aspect.



The *septal cartilage* (figs. 1005, 1006), somewhat quadrilateral in form, and thicker at its margins than at its centre, forms almost the whole of the septum between the anterior parts of the nasal cavity. The upper part of its anterosuperior margin is connected to the posterior border of the internasal suture; the middle part is continuous with the upper nasal cartilages; the lower part is attached to these cartilages by the perichondrium. Its antero-inferior border is connected on each side to the septal process (medial crus) of the lower nasal cartilage. Its postero-superior border is joined to the perpendicular plate of the ethmoid bone, and its postero-inferior border is attached to the vomer and to the nasal crest of the maxillæ. The cartilage of the septum may extend backwards (especially in children) as a narrow process, termed the *sphenoidal process*, for some distance between the vomer and the perpendicular plate of the ethmoid bone. The anterior-inferior part of the nasal septum is freely movable, and hence is named the *septum mobile nasi*; it is not formed by the cartilage of the septum, but by the septal processes of the lower nasal cartilages and by the skin.

The *upper nasal cartilage* (lateral cartilage) (fig. 1003) is situated below the inferior margin of the nasal bone, and is triangular in shape. Its anterior margin is thicker than the posterior, and its upper part is continuous with the cartilage of the septum, but its lower part is separated from this cartilage by a narrow fissure; its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the lower nasal cartilage.

The *lower nasal cartilage* (greater alar cartilage) (figs. 1003, 1004) is a thin, flexible plate which is situated below the upper nasal cartilage, and is bent acutely around the anterior part of the naris. The medial part of the plate is narrow, and is termed the *septal process*. It is loosely connected by fibrous tissue to that of the opposite cartilage, and to the anterō-inferior part of the septal cartilage, thus helping to form the movable, lower part of the nasal septum (septum mobile nasi). The upper border of the lateral part of the lower nasal cartilage is attached by fibrous tissue to the lower border of the upper nasal cartilage. Its posterior, narrow end is connected with the frontal process of the maxilla by a tough fibrous membrane, in which three or four small cartilaginous plates, termed the *small cartilages of the ala* (fig. 1003), are found. Its lower, free edge falls short of the lateral margin of the naris, the lower part of ala nasi being formed by fatty and fibrous tissue covered with skin. In front, the lower nasal cartilages are separated by a notch which corresponds with the apex of the nose.

FIG. 1004.—The cartilages of the nose. Inferior aspect.

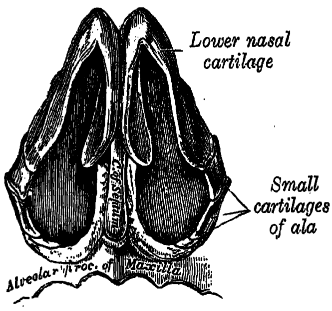


FIG. 1005.—The bones and cartilages of the septum of the nose. Right surface.

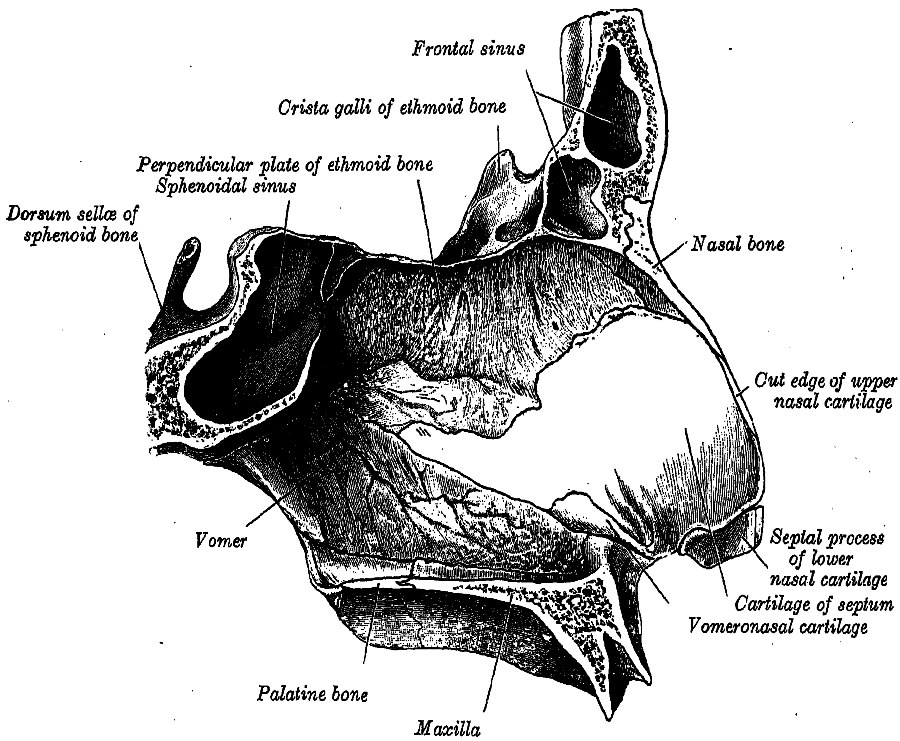


The *muscles* acting on the external nose have been described on p. 527.

The *skin* of the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but over the tip and alæ it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

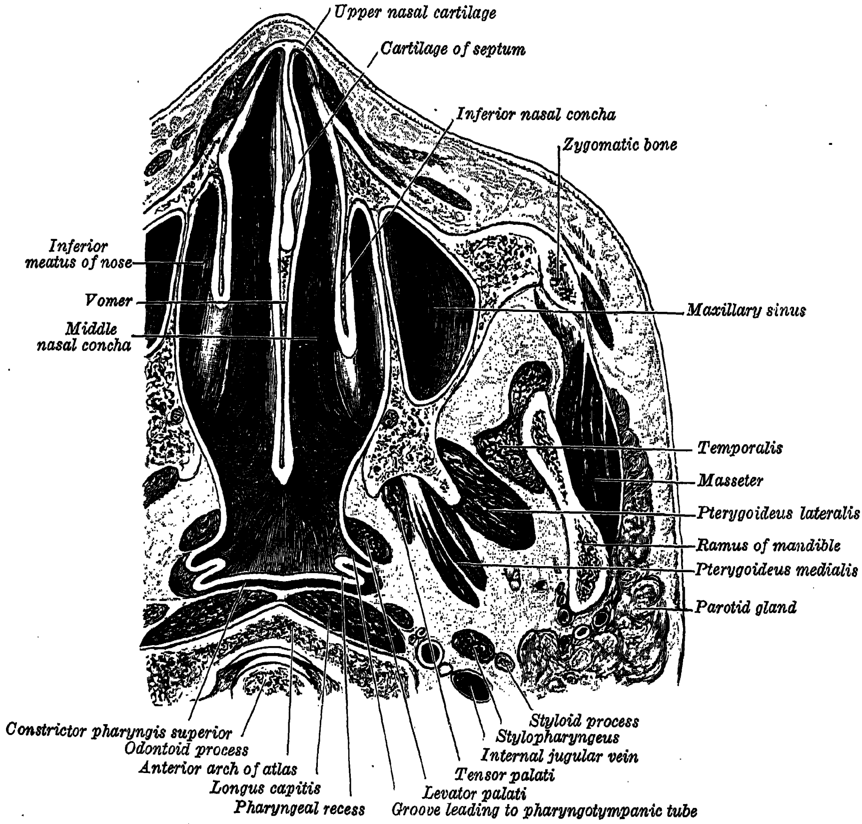
The *arteries* of the external nose are the alar and septal branches of the facial (external maxillary) artery, which supply the ala and lower part of the septum; and the dorsal

nasal branch of the ophthalmic artery and the infra-orbital branch of the maxillary artery, which supply the lateral aspects and the dorsum. The *veins* end in the anterior facial and ophthalmic veins.

The *nerves* for the muscles of the nose are derived from the facial nerve, while the skin receives branches from the ophthalmic nerve, through its infratrochlear branch and the external nasal nerve (p. 1045), and from the infra-orbital branch of the maxillary nerve.

Nasal cavity.—The nasal cavity is subdivided into right and left halves by the nasal septum (fig. 1006). They open on the face through the nares, and communicate behind with the nasal part of the pharynx through the posterior

FIG. 1006.—A transverse section through the anterior part of the head at a level just below the apex of the odontoid process. Viewed from below.



nasal apertures. The *nares* are somewhat pear-shaped apertures, each measuring from 1·5 cm. to 2 cm. anteroposteriorly, and from 0·5 cm. to 1 cm. transversely at its widest part. The *posterior nasal apertures* are two oval openings each measuring about 2·5 cm. in the vertical, and 1·25 cm. in the transverse direction.

For the description of the bony boundaries of the nasal cavity, see p. 273.

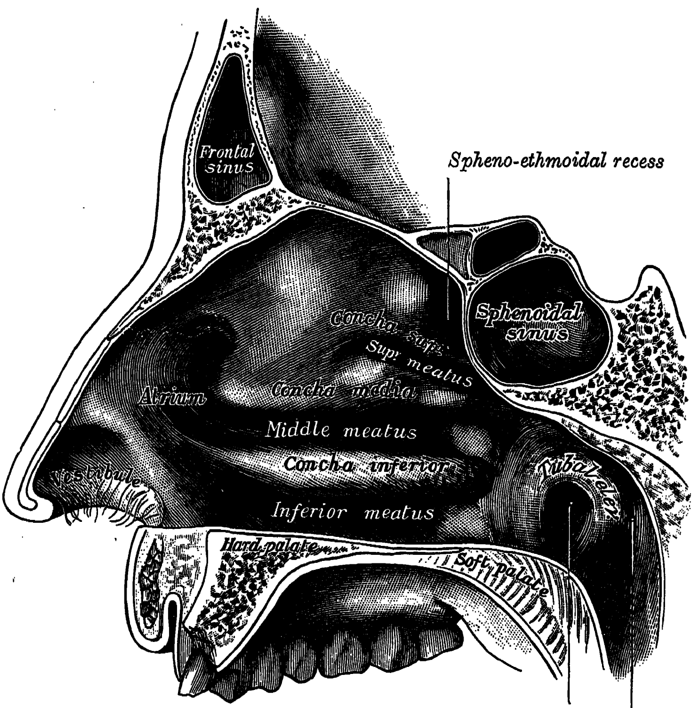
Inside the aperture of the nostril there is a slight dilatation, termed the *vestibule* (fig. 1007), bounded laterally by the ala and the lateral part of the lower nasal cartilage, and medially by the septal process of the same cartilage; it extends as a small recess towards the apex of the nose. The vestibule is lined with skin, and coarse hairs and sebaceous glands are found in its lower part; the hairs (vibrissæ) curve downwards and forwards to the naris, and tend to arrest the passage of foreign substances carried with the current of inspired air. The vestibule is limited above and behind by a curved elevation, named the *limen nasi*, along which the skin of the vestibule is continuous with the mucous membrane of the nasal cavity.

Each half of the nasal cavity, above and behind the vestibule, is divided into two parts: an *olfactory* region, limited to the superior nasal concha and

the opposed part of the septum, and a *respiratory* region, which comprises the rest of the cavity.

Lateral wall (figs. 1007, 1008).—The lateral wall is marked by three elevations, formed by the superior, middle and inferior nasal conchæ, and below and lateral to each concha by the corresponding nasal passage or meatus. Above the superior concha a triangular fossa, named the *spheno-ethmoidal recess*, receives the opening of the sphenoidal sinus. The *superior meatus* is a short oblique passage extending about half-way along the upper border of the middle concha; the posterior ethmoidal sinuses open, usually by two apertures, into the front part of this meatus. The *middle meatus*, deeper in front than behind, is below

FIG. 1007.—The lateral wall of the right half of the nasal cavity. Medial aspect.

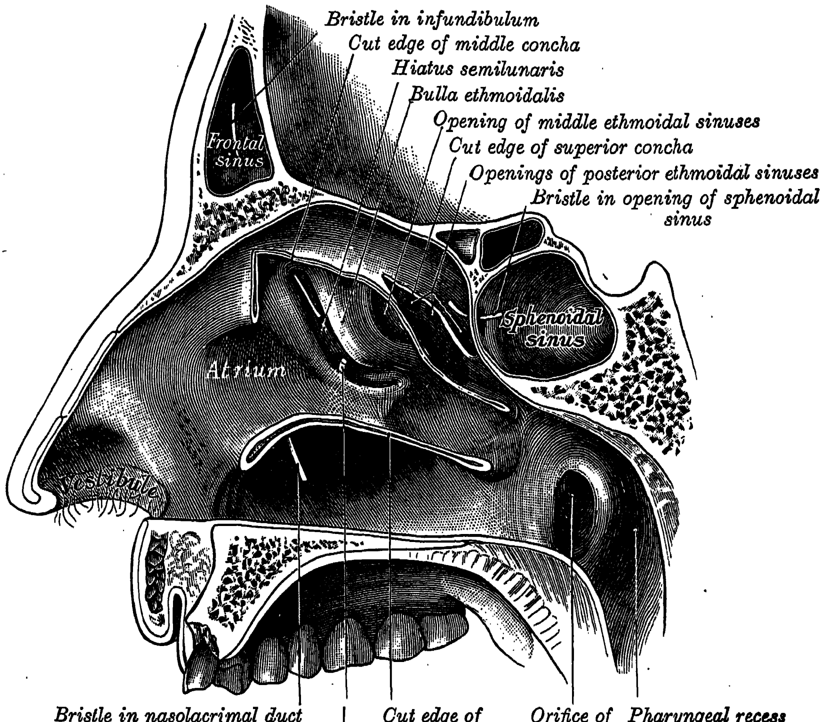


and lateral to the middle concha, and is continued anteriorly into a shallow depression situated above the vestibule and named the *atrium* of the middle meatus. Above the atrium an ill-defined curved ridge, termed the *agger nasi*, runs forwards and downwards from the upper end of the anterior free border of the middle concha; it is better developed in the new-born child than in the adult. When the middle concha is raised or removed the lateral wall of this meatus is displayed fully. A rounded elevation, termed the bulla ethmoidalis, and, below and extending upwards in front of it, a curved cleft, termed the hiatus semilunaris, form the principal features of this wall. The *bulla ethmoidalis* is caused by the bulging of the middle ethmoidal sinuses, which open on or immediately above it, and the size of the bulla varies with that of its contained sinuses. The *hiatus semilunaris*, which is bounded inferiorly by a sharp concave ridge produced by the uncinate process of the ethmoid bone, leads forwards and upwards into a curved channel, which is named the *ethmoidal infundibulum*. The anterior ethmoidal sinuses open into the front part of the infundibulum, which in rather more than 50 per cent. of subjects is continuous with the frontonasal duct or passage leading from the frontal sinus. The frontonasal duct frequently opens directly into the anterior end of the middle meatus. The opening of the maxillary sinus is situated below the bulla ethmoidalis, and is usually hidden by the flange-like lower (or medial) edge of

the hiatus semilunaris; in a coronal section of the nose this opening is seen to be placed near the roof of the sinus (fig. 1011). An accessory opening of the maxillary sinus is frequently present below and behind the hiatus semilunaris. The *inferior meatus* is below and lateral to the inferior nasal concha; the naso-lacrimal duct opens into this meatus under cover of the anterior part of the inferior concha.

Nasal septum (fig. 1005).—The nasal septum is frequently more or less deflected from the median plane, thus lessening the size of one half of the nasal cavity and increasing that of the other; ridges or spurs of bone sometimes

FIG. 1008.—The lateral wall of the right half of the nasal cavity; the three nasal conchæ have been removed.



project from the septum to one or other side. Immediately over the incisive canal at the lower edge of the cartilage of the septum a depression is sometimes seen; it points downwards and forwards, and occupies the position of a canal which connected the nasal with the buccal cavity in early fœtal life. In the septum close to this recess a minute orifice may be discerned; it leads backwards into a blind pouch—the rudimentary *vomeronasal organ of Jacobson*—which is supported by a strip of cartilage, named the *subvomerine* (vomeronasal) *cartilage*. This organ is well developed in many of the lower animals, where it apparently plays a part in the sense of smell, since it is supplied by twigs of the olfactory nerve and is lined with epithelium similar to that in the olfactory region of the nose.

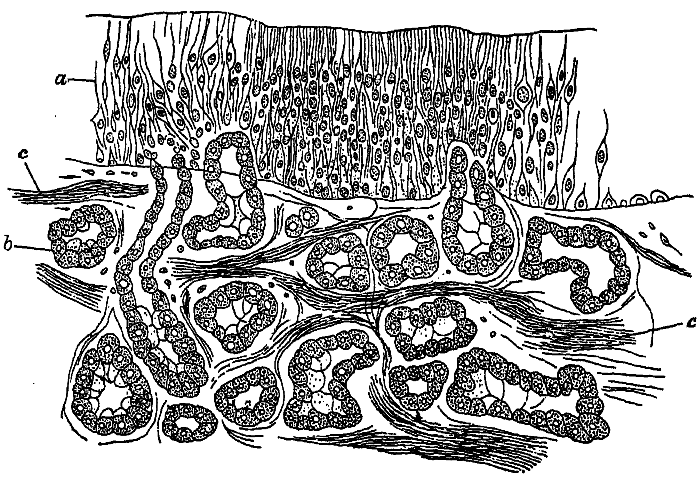
The *roof* of the nasal cavity is narrow from side to side, except at its posterior part, and may be divided, from behind forwards, into sphenoidal, ethmoidal and frontonasal parts, corresponding to the bones which enter into its formation (pp. 273 and 277). The ethmoidal part is almost horizontal, but the frontonasal and sphenoidal parts slope downwards and forwards and downwards and backwards, respectively. The cavity is therefore deepest where its roof is formed by the cribriform plate of the ethmoid bone.

The *floor* is concave from side to side, flat and almost horizontal antero-posteriorly; its anterior three-fourths are formed by the palatine process of the maxilla, its posterior one-fourth by the horizontal part of the palatine bone.

The **nasal mucous membrane** lines the nasal cavities with the exception of the vestibules, and is intimately adherent to the periosteum or perichondrium. It is continuous with the mucous membrane of the nasal part of the pharynx through the posterior nasal apertures; with the conjunctiva, through the naso-lacrimal duct and lacrimal canaliculi; and with the mucous membranes of the sphenoidal, ethmoidal, frontal and maxillary sinuses, through the openings of these sinuses.

The mucous membrane is thickest and most vascular over the nasal conchæ, especially at their extremities. It is also thick over the nasal septum, but very thin in the meatuses, on the floor of the nasal cavity, and in the various sinuses.

FIG. 1009.—A section through the olfactory mucous membranes. (Cadiat.)



a. Epithelium. *b.* Nasal glands. *c.* Nerve-bundles.

Owing to the thickness of the membrane, the nasal cavity is much narrower, and the middle and inferior nasal conchæ larger and more prominent than they appear in the skeleton; for the same reason the various apertures communicating with the meatuses are also considerably narrowed.

Structure of the mucous membrane.—The epithelium of the mucous membrane differs in its characteristics according to the functions of the part of the nose in which it is found. In the *respiratory region* it is columnar and ciliated. Goblet or mucous cells are interspersed among the columnar cells, while smaller pyramidal cells are found between the bases of the latter. Beneath the epithelium and its basement-membrane there is a fibrous layer infiltrated with lymph corpuscles, forming in many parts a diffuse adenoid tissue, and under this a nearly continuous layer of mucous and serous glands, the ducts of which open upon the surface. In the *olfactory region* (fig. 1009) the mucous membrane is yellowish in colour and the epithelial cells are of two kinds, supporting cells and olfactory cells. The *supporting cells* contain oval nuclei, which are situated in the deeper parts of the cells and constitute the zone of oval nuclei; the superficial part of each cell is columnar, and contains granules of yellow pigment, while its deep part is prolonged as a delicate process which ramifies, and communicates with similar processes from neighbouring cells so as to form a network in the mucous membrane. Lying between the deep processes of the supporting cells there are a number of bipolar nerve-cells—the *olfactory cells*—each consisting of a small amount of granular protoplasm with a large spherical nucleus, and possessing two processes; the superficial process runs between the columnar epithelial cells, and ends at the surface of the mucous membrane in one or more fine, hair-like processess, called the *olfactory hairs*; the deep or central process is frequently beaded, and is continued as an olfactory nerve-fibre (p. 1036). Beneath the epithelium, and extending through the thickness of the mucous membrane there is a layer of tubular, often branched, glands, termed the *nasal glands*, similar in structure to serous glands.

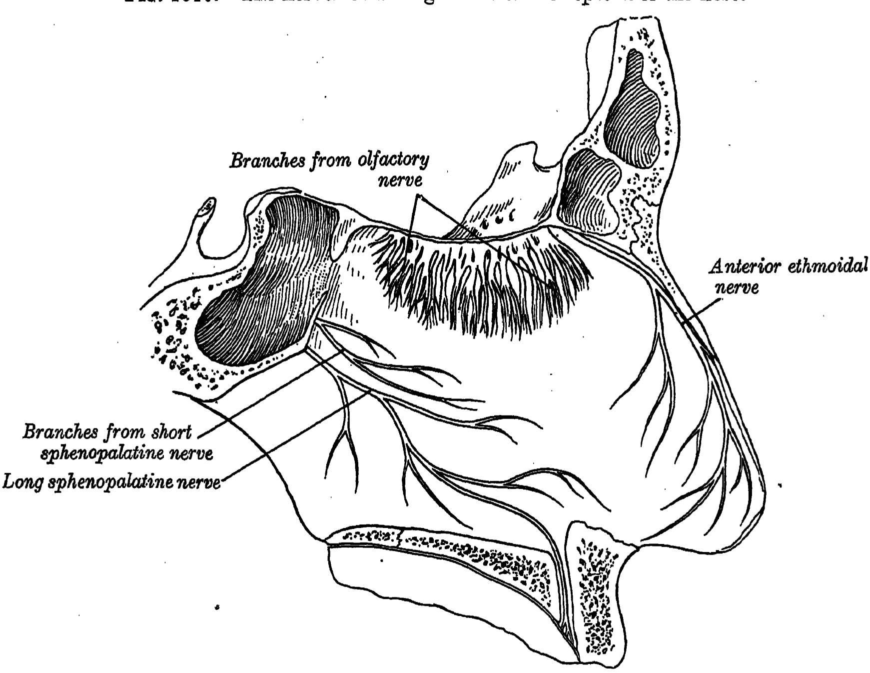
Vessels and Nerves.—The *arteries* of the nasal cavity are the anterior and posterior ethmoidal branches of the ophthalmic artery, which supply the ethmoidal and frontal

sinuses, and the roof of the nose; the sphenopalatine branch of the (internal) maxillary artery, which supplies the mucous membrane covering the conchæ, the meatuses, and septum; the septal ramus of the superior labial branch of the facial (external maxillary) artery; the infra-orbital and inferior dental branches of the maxillary artery, which supply the lining membrane of the maxillary sinus; and the pharyngeal branch of the same artery, which is distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform network, beneath and in the substance of the mucous membrane.

The *veins* form a close cavernous plexus beneath the mucous membrane. This plexus is especially marked over the lower part of the septum and over the middle and inferior conchæ. Some of the veins open into the sphenopalatine vein; others join the anterior facial vein; some accompany the ethmoidal arteries, and end in the ophthalmic veins; a few communicate with the veins on the orbital surface of the frontal lobe of the brain, through the foramina in the cribriform plate of the ethmoid bone. When the foramen cæcum is patent it transmits a vein from the nasal cavity to the superior sagittal sinus.

The *lymph vessels* are described on p. 855.

FIG. 1010.—The nerves of the right side of the septum of the nose.



The *nerves* of ordinary sensation (figs. 943, 1010) are: the anterior ethmoidal branch of the nasociliary nerve, filaments from the anterior superior dental branch of the maxillary nerve, the nerve of the pterygoid canal, the long sphenopalatine (nasopalatine) nerve, the greater palatine (anterior palatine) and nasal branches of the sphenopalatine ganglion.

The anterior ethmoidal branch of the nasociliary nerve distributes filaments to the anterior parts of the septum and lateral wall. Filaments from the anterior superior dental nerve supply the inferior meatus and inferior concha. The nerve of the pterygoid canal supplies the upper and posterior parts of the septum, and superior concha; and the upper nasal branches from the sphenopalatine ganglion have a similar distribution. The long sphenopalatine (nasopalatine) nerve supplies the middle of the septum. The greater palatine nerve supplies the lower nasal branches to the middle and inferior conchæ.

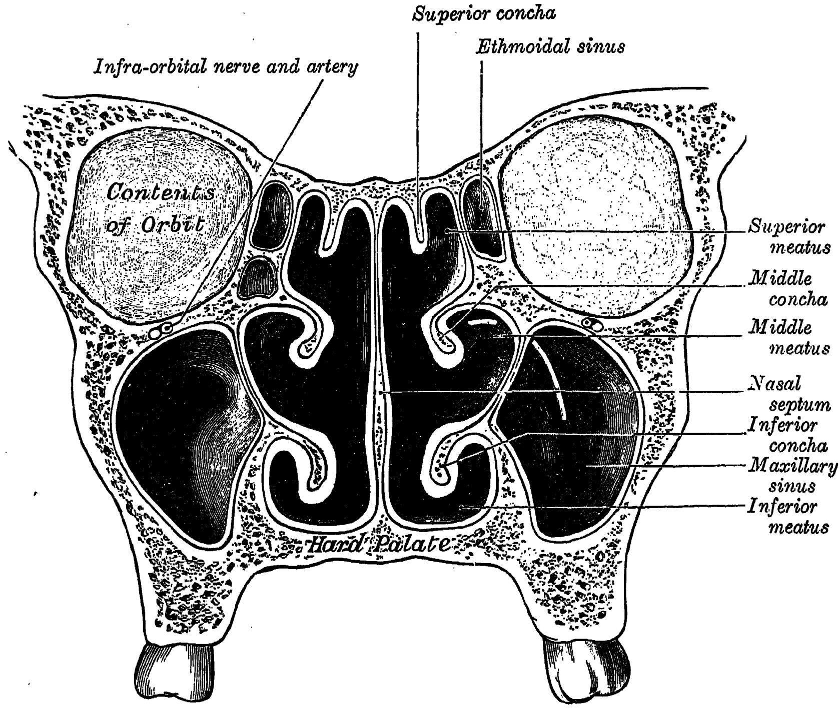
The *olfactory nerves* are distributed to the olfactory region. Their fibres arise from the bipolar olfactory cells and are destitute of medullary sheaths. They unite in fasciculi which cross one another in various directions, and thus give rise to the appearance of a plexus in the mucous membrane (fig. 1010) and then ascend in grooves or canals in the ethmoid bone; they pass into the skull through the foramina in the cribriform plate of the ethmoid and enter the under surface of the olfactory bulbs, in which they ramify and form synapses with the dendrites of the mitral cells (fig. 934). Closely associated with the olfactory nerves are the *nervi terminales* (p. 1037).

THE PARANASAL SINUSES (figs. 1006, 1007, 1008, 1011)

The paranasal sinuses are the frontal, ethmoidal, sphenoidal and maxillary; they vary in size and form in different individuals, and are lined with mucous membrane continuous with that of the nasal cavity.

The **frontal sinuses**, two in number, are situated behind the superciliary arches; they are rarely symmetrical, because the septum between them frequently deviates from the median plane. Their average measurements are as follows: height, 3·16 cm.; breadth, 2·58 cm.; depth from before backwards, 1·8 cm. Each opens into the anterior part of the corresponding middle meatus of the nose through the frontonasal duct, which traverses the anterior part of the labyrinth of the ethmoid. Small at birth, they are generally fairly well

FIG. 1011.—A coronal section through the nasal cavity.



developed between the seventh and eighth years, but only reach their full size after puberty.

The **ethmoidal sinuses** consist of numerous thin-walled cavities situated in the ethmoidal labyrinth, and completed by the frontal, maxillary, lacrimal, sphenoidal and palatine bones. They lie between the upper parts of the nasal cavity and the orbits, and are separated from the latter by the orbital plates of the ethmoid bone. On each side they are arranged in three groups—anterior, middle and posterior. The anterior and middle groups open into the middle meatus of the nose, the former by way of the ethmoidal infundibulum, the latter on or above the ethmoidal bulla. The posterior air-sinuses open into the superior meatus under cover of the superior nasal concha; sometimes one or more opens into the sphenoidal sinus. The ethmoidal sinuses begin to develop during fœtal life.

The **sphenoidal sinuses**, two in number, are placed behind the upper part of the nasal cavity, and are contained within the body of the sphenoid bone. They are related, above, to the optic chiasma, and the hypophysis cerebri; on each side, to the internal carotid artery and the cavernous sinus. They vary in size and shape, and, owing to the lateral displacement of the intervening septum,

are rarely symmetrical. Frequently one sinus is much the larger of the two and extends across the median plane behind the sinus of the opposite side. The following are their average measurements: vertical height, 2 cm.; transverse breadth, 1·8 cm.; anteroposterior depth, 2·1 cm. When exceptionally large they may extend into the roots of the pterygoid processes or greater wings, and may invade the basilar part of the occipital bone. Each sinus communicates with the spheno-ethmoidal recess by an aperture in the upper part of its anterior wall. They are present as minute cavities at birth, but their main development takes place after puberty.

The **maxillary sinuses**, which are the largest accessory air-sinuses of the nose, are pyramidal cavities in the bodies of the maxillæ. The base of each is formed by the lateral wall of the nasal cavity; the apex extends into the zygomatic process of the maxilla. The roof or orbital wall is frequently ridged by the infra-orbital canal, while the floor is formed by the alveolar process and is usually about 1·25 cm. below the level of the floor of the nose; several conical elevations corresponding with the roots of the first and second molar teeth project into the floor, which is sometimes perforated by one or more of these roots. The size of the maxillary sinus varies in different skulls, and even on the two sides of the same skull; when large, its apex may invade the zygomatic bone. The following measurements are those of an average-sized air-sinus: vertical height opposite the first molar tooth, 3·5 cm.; transverse breadth, 2·5 cm.; anteroposterior depth, 3·2 cm. It communicates with the lower part of the hiatus semilunaris through an opening in the anterosuperior part of its base (fig. 1011); a second orifice is frequently seen in, or immediately behind, the hiatus. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the fourth month of fœtal life, but does not reach its full size until after the eruption of the permanent teeth.*

Applied Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the external nose, an aperture only being present, or perfect development on one side, and suppression or malformation on the other. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis; or imperfect development of the nasal bones in cases of congenital syphilis; or a lateral deviation of the nose after fracture.

The septum of the nose may be displaced or may deviate from the median plane as a result of an injury or of some congenital defect. Sometimes the deviation may be so great that the septum may come into contact with the lateral wall of the nasal cavity, producing complete unilateral obstruction.

Suppuration in the paranasal sinuses of the nose is of frequent occurrence, and in connexion with this the situations at which the various sinuses normally communicate with the nasal cavity, are important: thus one finds they fall into two main groups: (1) anterior, opening into the middle meatus, and draining the maxillary, the frontal, and the anterior ethmoidal sinuses; and (2) posterior, opening into the superior meatus and spheno-ethmoidal recess, and draining the posterior ethmoidal and sphenoidal sinuses. Suppuration in the anterior group is the more common, and the pus can be seen running down over the anterior end of the inferior concha, whereas in the case of the posterior group, the pus does not come forwards, but runs back into the nasopharynx over the posterior end of the middle concha. Again, it is of importance to notice that the middle meatus is of such a form that pus running down from the frontal sinus is directed by the hiatus semilunaris into the opening of the maxillary sinus, so that the latter sinus may, in some cases, act as a secondary reservoir for pus discharged from the frontal sinus. All the paranasal sinuses can be and are infected from the nasal cavity, but it should be noted that in the case of the maxillary sinus, the infection is frequently conveyed in another way, and that is from the teeth. This sinus is the one most frequently the seat of chronic suppuration and it often requires drainage; this can be carried out by removing bone from the lateral wall of the inferior meatus of the nose. Simple drainage, however, is not usually sufficient, and more extensive operations have often to be performed.

The Organ of Sight

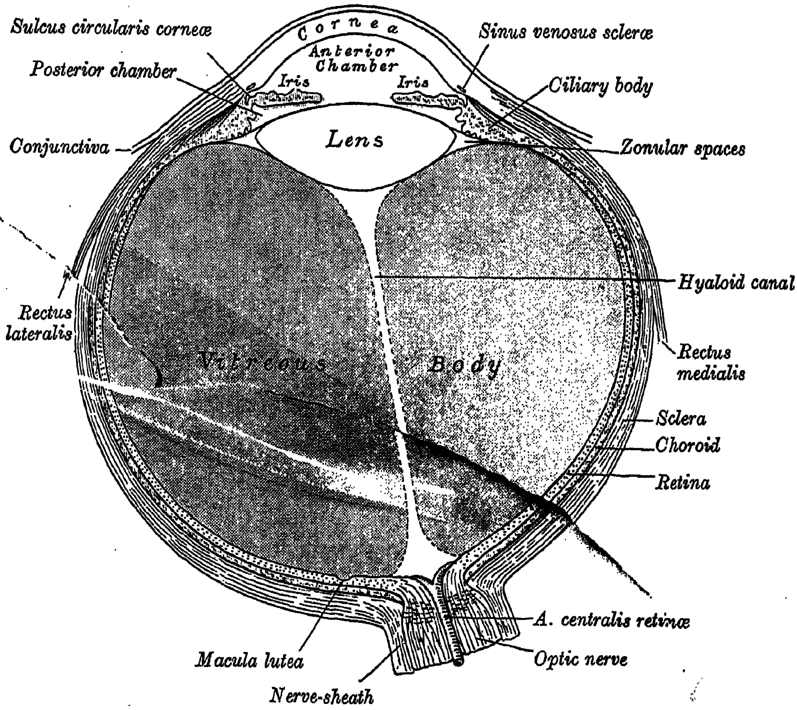
The eyeball (bulbus oculi) is the peripheral organ of sight, and is situated in the cavity of the orbit, the walls of which serve to protect it from injury. Certain accessory structures, viz. the muscles, fasciæ, eyebrows, eyelids,

* The measurements of the paranasal sinuses supplied in the text are those given by A. Logan Turner, *Accessory Sinuses of the Nose*, 1901.

conjunctiva and lacrimal apparatus, are intimately associated with the eyeball and will be described in the same section.

The eyeball is imbedded in the fat of the orbit, but is separated from it by a thin membranous sac, termed the *fascial sheath of the eyeball* (p. 1182). It is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere; it is transparent, and its arc forms about one-sixth of the circumference. It is more prominent than the posterior segment, which is one of a larger sphere, and is opaque, and forms about five-sixths of the whole circumference of the eyeball. The term *anterior pole* is applied to the central point of the anterior curvature of the eyeball, and that of *posterior pole* to the central point of its posterior curvature; a line joining the two poles forms the *optic axis*. The axes of the two eyeballs are nearly parallel, and therefore do not correspond with the axes of the orbits which are directed forwards and laterally. The optic nerves follow the direction of the axes of the orbits, and

Fig. 1012.—A horizontal section through the eyeball.



therefore are not parallel; *each nerve enters its eyeball 3 mm. to the nasal side of the posterior pole.* The vertical diameter (23·5 mm.) of the eyeball is rather less than the transverse and anteroposterior diameters (24 mm.); the anteroposterior diameter at birth is about 17·5 mm. and at puberty from 20 to 21 mm. In the female all three diameters are rather less than in the male.

The eyeball is composed of three coats, which enclose three refracting media.

The Coats of the Eye (fig. 1012)

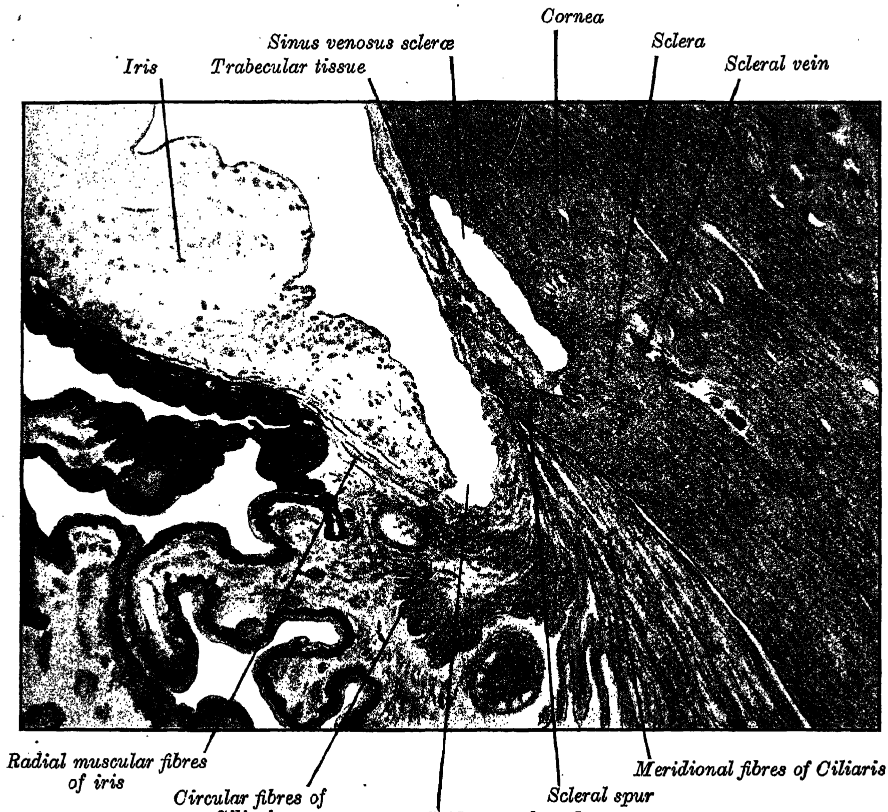
From without inwards the three coats are: (1) the fibrous coat, consisting of the *sclera* behind and the *cornea* in front; (2) the vascular, pigmented coat, comprising, from behind forwards, the *choroid, ciliary body* and *iris*; and (3) the nervous coat, termed the *retina*.

I. The Fibrous Coat

The fibrous coat of the eyeball (fig. 1012) consists of an opaque, posterior part, named the sclera, and a transparent, anterior part, named the cornea.

The **sclera**, so named from its density and hardness, is a firm membrane which serves to maintain the form of the eyeball. It is thickest (about 1 mm.) behind, near the entrance of the optic nerve, and thinnest (0·4 mm.) at a distance of about 6 mm. behind the sclerocorneal junction. Its *external surface* is white, and is in contact with the inner surface of the fascial sheath of the eyeball (p. 1182); it is smooth, except where the tendons of the orbital muscles are inserted into it; its anterior part is covered by the conjunctival membrane. Its *inner surface* is brown, and is marked by grooves in which the ciliary nerves and vessels are lodged; it is separated from the outer surface of the choroid by an extensive *perichoroidal space*, which is traversed by an exceedingly fine cellular tissue, termed the *suprachoroid lamina*. Behind, it is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater. Where the optic nerve pierces the sclera, the latter has the appearance of a cribriform plate and is named the *lamina cribrosa scleræ* (fig. 1022); the minute orifices in this lamina serve for the transmission of the nerve-bundles, and the fibrous septa between the orifices are continuous with the supporting tissue of the nerve. One opening, larger than the rest, and occupying the centre of the lamina, transmits the central artery and vein of the retina. Around the lamina cribrosa scleræ numerous small apertures are present for the transmission of the ciliary vessels and nerves, and about midway between these and the sclerocorneal junction there are four or five large apertures for the transmission of veins [*venæ vorticosæ*]. In front, the sclera is directly continuous with the cornea, the line of union being termed the *sclerocorneal junction*. In the substance of the sclera close to this junction is a circular canal, termed the *sinus venosus scleræ*. In a meridional section through the sclerocorneal junction, this sinus presents the appearance of a cleft, the outer wall of which consists

FIG. 1013.—A general view of the iridocorneal angle. Enlarged. (After Thomson.)



of the firm tissue of the sclera, while its inner wall is formed by a triangular mass of trabecular tissue (fig. 1013); the apex of the mass is directed forwards and is continuous with the posterior elastic lamina of the cornea. The sinus is lined with endothelium, and communicates internally with the anterior chamber of the eye, and is continuous externally with the anterior ciliary veins.

Structure.—The sclera is formed of white fibrous tissue intermixed with fine elastic fibres; flattened connective tissue corpuscles, some of which are pigmented, are contained in cell-spaces between the fibres. The fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. Its *vessels* are not numerous; its capillaries are small, and unite at long and wide intervals. Its *nerves* are derived from the ciliary nerves, but their exact mode of ending is not known.

The **cornea** (fig. 1012) is the anterior, projecting and transparent part of the external coat; it is almost circular in outline, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects as a flattened dome in front of the sclera. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, being more pronounced in youth than in old age. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in diameter. Immediately in front of the sclerocorneal junction the cornea bulges inwards as a thickened rim, and behind this rim there is a distinct furrow between the attachment of the iris and the sclerocorneal junction. This furrow has been named by Arthur Thomson * the *sulcus circularis corneæ*; it is bounded externally by the trabecular tissue already described as forming the inner wall of the sinus venosus scleræ. Between this tissue and the anterior surface of the attached margin of the iris there is an angular recess, named the *iridocorneal angle* (iridial angle) of the eye (fig. 1013). A projecting rim of scleral tissue which appears in a meridional section as a small triangular area, termed the *scleral spur*, is situated between the iridocorneal angle and the sinus venosus scleræ (fig. 1013). Its base is continuous with the inner surface of the sclera immediately to the outer side of the iridocorneal angle and its apex is directed forwards and inwards. The bundles of trabecular tissue just referred to are attached to the anterior sloping margin of this spur; the meridional fibres of the Ciliaris muscle arise from its posterior aspect.

Structure (fig. 1014).—The cornea consists from before backwards of four layers, viz.: (1) the corneal epithelium, continuous with that of the conjunctiva; (2) the substantia propria; (3) the posterior elastic lamina; and (4) the mesothelium of the anterior chamber.

The *corneal epithelium* covers the front of the cornea and consists of several layers of cells. The cells of the deepest layer are columnar; then follow two or three layers of polyhedral cells, the majority of which are prickle-cells similar to those found in the germinative zone of the epidermis (p. 1219). Lastly, there are three or four layers of squamous cells, with flattened nuclei.

The *substantia propria* is fibrous, tough, unyielding and perfectly transparent. It is composed of about sixty flattened, superimposed lamellæ. These lamellæ are made up of bundles of modified connective tissue, the fibres of which are continuous with those of the sclera. The fibres of each lamella are for the most part parallel with one another, but at right angles to those of adjacent lamellæ. Fibres, however, frequently pass from one lamella to the next.

Between the lamellæ there is a small amount of ground-substance, in which spaces are found, which are termed the *corneal spaces*. These are stellate in shape and communicate with one another by numerous offsets. Each contains a cell, named the *corneal corpuscle*, resembling in form the space in which it is lodged, but not entirely filling it.

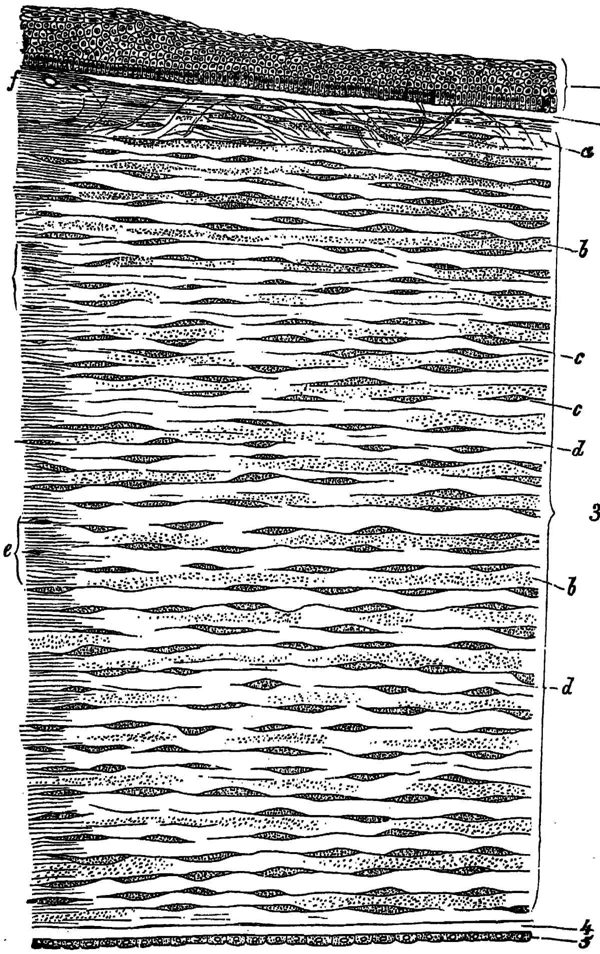
The layer immediately beneath the corneal epithelium presents certain characteristics which have led some anatomists to regard it as a distinct membrane, and it has been named the *anterior elastic lamina*. It consists of extremely closely interwoven fibrils, similar to those found in the substantia propria, but contains no corneal corpuscles.

The *posterior elastic lamina* covers the posterior surface of the substantia propria, and is a thin, elastic, transparent, homogeneous membrane, which is not rendered opaque by water, alcohol, or acids. When stripped from the substantia propria it curls up, and rolls upon itself, with the attached surface innermost.

* *Atlas of the Eye*, Clarendon Press, Oxford, 1912.

At the margin of the cornea the posterior elastic lamina breaks up into fibres which form the trabecular tissue on the inner wall of the sinus venosus scleræ (p. 1165); the spaces between the trabeculæ are termed the *spaces of the iridocorneal angle*; they communicate with the sinus venosus scleræ and with the anterior chamber. Some of the fibres of this trabecular tissue are continued into the substance of the iris, forming the *pectinate ligament of the iris*; others are connected with the fore-part of the sclera and choroid.

Fig. 1014.—A vertical section through the human cornea near its margin. Magnified. (Waldeyer.)



1. Epithelium. 2. Anterior elastic lamina. 3. Substantia propria. 4. Posterior elastic lamina. 5. Endothelium of the anterior chamber. *a.* Oblique fibres in the anterior layer of the substantia propria. *b.* Lamellæ the fibres of which are cut across producing a dotted appearance. *c.* Corneal corpuscles appearing fusiform in section. *d.* Lamellæ the fibres of which are cut longitudinally. *e.* Transition to the sclera, with more distinct fibrillation, and surmounted by a thicker epithelium. *f.* Small blood-vessels cut across near the margin of the cornea.

The *endothelium of the anterior chamber* covers the posterior surface of the posterior elastic lamina, is reflected on to the front of the iris, and also lines the spaces of the iridocorneal angle; it consists of a layer of polygonal, flattened, nucleated cells.

Vessels and Nerves.—The cornea is a non-vascular structure, the capillary vessels of the conjunctiva and sclera ending in loops at its circumference. Lymph vessels have not yet been demonstrated in it, but are probably represented by the channels in which the nerves run; these channels are lined by an endothelium. The *nerves* are numerous and are derived from the ciliary nerves. Around the periphery of the cornea they form an *annular plexus*, from which fibres enter the substantia propria. They lose their medullary sheaths and ramify throughout the substantia propria in a delicate network, and their terminal filaments form a firm and closer plexus beneath the corneal epithelium. This is termed the

subepithelial plexus, and from it fine, varicose fibrils are given off which ramify between the epithelial cells, forming an *intra-epithelial plexus*.

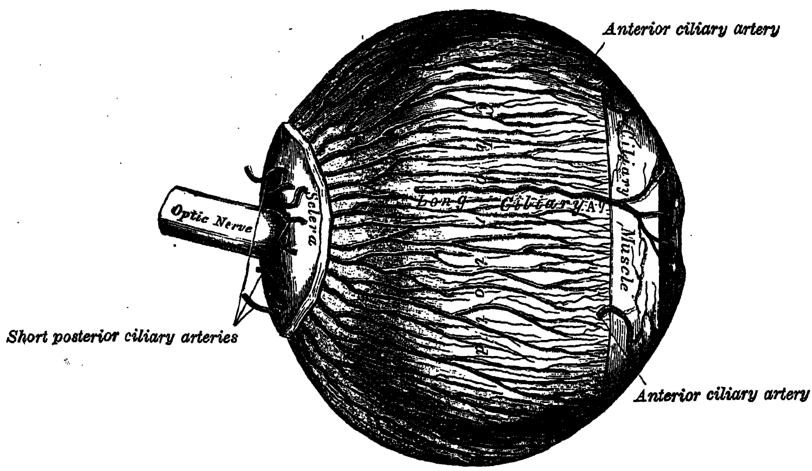
II. The Vascular Coat (figs. 1015 to 1020)

The vascular coat of the eye is formed from behind forwards by the choroid, the ciliary body and the iris.

The choroid covers the inner surface of the sclera, and extends as far forwards as the ora serrata of the retina. The ciliary body connects the choroid with the circumference of the iris. The iris is a circular diaphragm behind the cornea, and presents near its centre the rounded aperture of the *pupil*.

The choroid is a thin, highly vascular membrane, of a dark brown or chocolate colour, investing the posterior five-sixths of the eyeball; it is pierced

Fig. 1015.—The arteries of the choroid and iris. The greater part of the sclera has been removed. (Enlarged.)



behind by the optic nerve, and in this situation is firmly adherent to the sclera. It is thicker behind than in front. Its outer surface is loosely connected with the sclera by the suprachoroid lamina; its inner surface is attached to the pigmented layer of the retina.

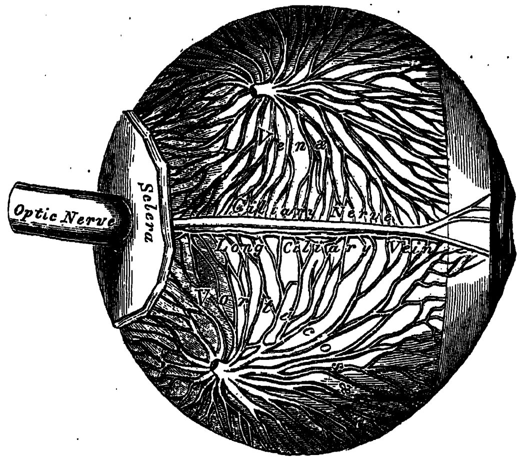
Structure.—The choroid consists mainly of a dense capillary plexus, and of small arteries and veins carrying blood to and from it. On its external surface there is a thin membrane, termed the *suprachoroid lamina*, which is composed of delicate non-vascular lamellæ, each lamella consisting of a network of fine elastic fibres, among which are branched pigment-cells. The spaces between the lamellæ are lined by mesothelium, and open freely into the perichoroidal lymph space, which, in its turn, communicates with the periscleral space at the points where the vessels and nerves are transmitted through the sclera.

The *choroid proper* lies internal to this lamina. It consists of two layers: an outer, composed of small arteries and veins, with pigment-cells interspersed between them; and an inner, consisting of a capillary plexus. The outer layer or *vascular lamina* consists, in part, of the larger branches of the short posterior ciliary arteries, which run forwards between the veins before they bend inwards to end in the capillaries, but is formed principally of veins, named, from their arrangement, the *venæ vorticosæ* (fig. 1016); these converge to four or five equidistant trunks, which pierce the sclera about midway between the sclero-corneal junction and the entrance of the optic nerve. Interspersed between the vessels there are dark star-shaped pigment-cells, the processes of which communicate with those of neighbouring cells, and form a delicate network or stroma, which loses its pigmentary character towards the inner surface of the choroid. The inner layer, or *choriocapillary lamina*, consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels; the network is closer and finer in the posterior than in the anterior part of the choroid. About 1·25 cm. behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. These laminæ are connected by a *stratum intermedium* consisting

of fine elastic fibres. On the inner surface of the choriocapillary lamina is a very thin, structureless, or faintly fibrous membrane, called the *basal lamina*; it is closely connected with the stroma of the choroid, and separates it from the pigmented layer of the retina.

Tapetum.—This name is often applied to the outer and posterior part of the choroid, which in many animals presents an iridescent appearance.

FIG. 1016.—The veins of the choroid. (Enlarged.)

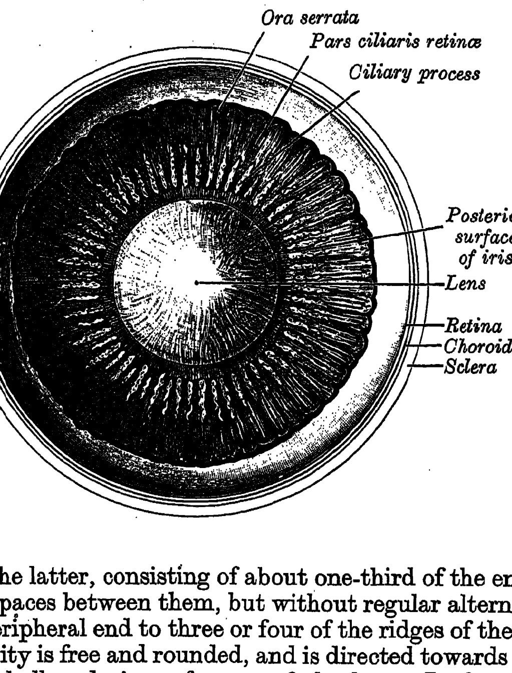


The **ciliary body** comprises the ciliary ring, the ciliary processes and the Ciliaris muscle.

The *ciliary ring* [orbiculus ciliaris] is a zone of about 4 mm. in width, directly continuous with the anterior part of the choroid; it presents numerous ridges arranged in a radial manner, but has no choriocapillary lamina.

The *ciliary processes* are formed by the inward folding of the various layers of the choroid (i.e. the choroid proper and the basal lamina), and are received between corresponding foldings of the suspensory ligament of the lens. They are arranged in a circle, and form a sort of frill behind the iris, round the margin of the lens (fig. 1017). They vary from sixty to eighty in number, lie side by side, and may be divided into large and small processes; the former are about

FIG. 1017.—The interior of the anterior half of the eyeball.



2·5 mm. long, and the latter, consisting of about one-third of the entire number, are situated in the spaces between them, but without regular alternation. Each is attached by its peripheral end to three or four of the ridges of the ciliary ring; the opposite extremity is free and rounded, and is directed towards the posterior chamber of the eyeball and circumference of the lens. In front, the ciliary processes are continuous with the periphery of the iris. Their posterior surfaces are connected with the suspensory ligament of the lens.

Structure.—The ciliary processes (figs. 1017, 1018) are similar in structure to the choroid, but the vessels are larger and have chiefly a longitudinal direction. Their posterior surfaces

are covered by the *ciliary part of the retina,* continued forwards from the nervous part of the retina, and consisting of an outer layer of cubical pigment-cells, and an inner layer of columnar cells which are not pigmented. In the stroma of the ciliary processes there are also stellate pigment-cells, but these are not so numerous as in the choroid itself.

The *Ciliaris muscle* consists of unstriped fibres; it forms a greyish, semi-transparent, circular band, about 6 mm. broad, on the outer surface of the fore-part of the choroid. It consists of meridional and circular fibres. The *meridional* fibres, much the more numerous, arise from the posterior margin of the scleral spur (p. 1166); they run backwards, and are attached to the ciliary processes and ring. The *circular* fibres are internal to the meridional ones, and in a meridional section appear as a triangular zone behind the irido-corneal angle and close to the circumference of the iris; they are well developed in hypermetropic, but are rudimentary or absent in myopic, eyes. The Ciliaris muscle is the chief agent in accommodation, i.e. in adjusting the eye to the vision of near objects. When it contracts, it draws forwards the ciliary processes, relaxes the suspensory ligament of the lens, and thus allows the lens to become more convex.

Fig. 1018.—The vessels of the choroid, ciliary processes and iris, of a child. (Arnold.) ×10.

a. Capillary network of the anterior part of the choroid, ending at *b*, the ora serrata. *c.* Arteries supplying the ciliary processes *d*, and passing into the iris *e*. *f.* The capillary network close to the pupillary margin of the iris.

The iris has received its name from the various colours it presents in different individuals. It is a thin, circular, contractile disc, suspended in the aqueous humour between the cornea and the lens, and perforated a little to the nasal side of its centre by the circular aperture of the *pupil.* Its periphery is continuous with the ciliary body, and is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament; its flattened surfaces look forwards and backwards, the anterior towards the cornea, the posterior towards the ciliary processes and lens. The iris divides the space between the lens and the cornea into an anterior and a posterior chamber (fig. 1012). The *anterior chamber* of the eye is bounded in front by the posterior surface of the cornea, behind by the front of the iris, and, opposite the pupil, by the central part of the front of the lens. The *posterior chamber* is a narrow chink behind the iris, and in front of the lens and its suspensory ligament. In the adult the two chambers communicate through the pupil, but in the fœtus up to the seventh month they are separated by the *pupillary membrane* (p. 1171).

The colour of the iris is produced by the reflection of light from dark pigment-cells underlying a translucent tissue, and is therefore determined by the amount of the pigment and its distribution throughout the texture of the iris. The number and the situation of the pigment-cells differ in different irises. In the albino pigment is absent; in the various shades of blue eyes the pigment-cells are confined to the posterior surface of the iris, whereas in grey, brown, and black eyes pigment is found also in the cells of the stroma and in those of the endothelium on the front of the iris.

Structure.—The iris is composed of the following structures:

1. In the front there is a layer of flattened endothelial cells, placed on a delicate hyaline basement-membrane. This layer of cells is continuous with the endothelium covering the posterior elastic lamina of the cornea, and in individuals with dark-coloured irises the cells contain pigment-granules.

2. The *stroma* of the iris consists of connective tissue fibres and cells. A few fibres at the circumference of the iris have a circular direction; but the majority are arranged radially, forming, by their interlacement, delicate meshes, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue there

are numerous branched cells with fine processes. In dark eyes many of these cells contain pigment-granules, but in blue eyes and the eyes of albinos they are unpigmented.

3. The *muscular fibres* are involuntary, and consist of circular and radiating fibres. The *circular fibres* form the Sphincter pupillæ; they are arranged in a band about 1 mm. wide which surrounds the margin of the pupil, towards the posterior surface of the iris; those near the free margin of the band are closely aggregated; those near the periphery are somewhat separated and form incomplete circles. The *radiating fibres* form the Dilatator pupillæ and lie close to the posterior surface of the iris; they converge from the circumference towards the centre, and blend with the circular fibres near the margin of the pupil.

4. The posterior surface of the iris is of a deep purple tint, being covered by two layers of pigmented epithelial cells, continuous at the periphery of the iris with the ciliary part of the retina. This pigmented epithelium is often named the *pars iridica retinæ.*

Episcleral vessels. *o*. Recurrent artery of the choroid. *p*. Circulus arteriosus major (in section). *q*. Vessels of iris. *r*. Vessels of ciliary process. *s*. Branch from ciliary muscle to vorticose vein. *t*. Branch from ciliary muscle to anterior ciliary vein. *u*. Sinus venosus scleræ. *v*. Capillary loop at margin of cornea.

Vessels and Nerves.—The *arteries of the iris* are derived from the long posterior and the anterior ciliary arteries, and from the vessels of the ciliary processes. Each of the two long ciliary arteries, on reaching the attached margin of the iris, divides into an upper and a lower branch; these anastomose with corresponding branches of the artery from the opposite side and with the anterior ciliary arteries, and form a vascular circle (*circulus arteriosus major*). From this circle vessels converge to the free margin of the iris, and there communicate and form a second circle (*circulus arteriosus minor*) (fig. 1020).

The *nerves of the choroid and iris* are the long and short ciliary nerves; the former are branches of the nasociliary nerve, the latter of the ciliary ganglion. They pierce the sclera around the entrance of the optic nerve, run forwards in the perichoroidal space, and supply the blood-vessels of the choroid and the ciliary muscle. After reaching the iris they form a plexus around its attached margin; from this non-medullated fibres are derived which end in the Sphincter and Dilatator pupillæ. Other fibres from the plexus end in a network on the anterior surface of the iris. The fibres derived through the motor (parasympathetic) root of the ciliary ganglion from the oculomotor nerve supply the Sphincter pupillæ and the Ciliaris muscle; the sympathetic fibres in the long ciliary nerves supply the Dilatator pupillæ.

Membrana pupillaris.—In the fœtus, the pupil is closed by a delicate, vascular membrane, termed the *pupillary membrane* (p. 128). The vessels of this membrane are partly derived from those of the margin of the iris and partly from those of the capsule of the lens; they end in loops a short distance from the centre of the membrane, which is thus left free from blood-vessels. About the sixth month of fœtal life the membrane begins to disappear by absorption from the centre towards the circumference, and at birth only a few fragments are present; in exceptional cases it persists.

III. The Retina (fig. 1012)

The retina is a delicate, nervous membrane, which is specially adapted for the reception of light stimuli. Its outer surface is in contact with the choroid; its inner with the hyaloid membrane of the vitreous body. Posteriorly it is continuous with the optic nerve; it gradually diminishes in thickness from behind forwards and, just behind the ciliary body, it presents a jagged margin named the *ora serrata*. Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forwards over the back of the ciliary processes and iris, forming the *ciliary* and *iridial parts of the retina*. This forward prolongation consists of the pigmented layer of the retina together with

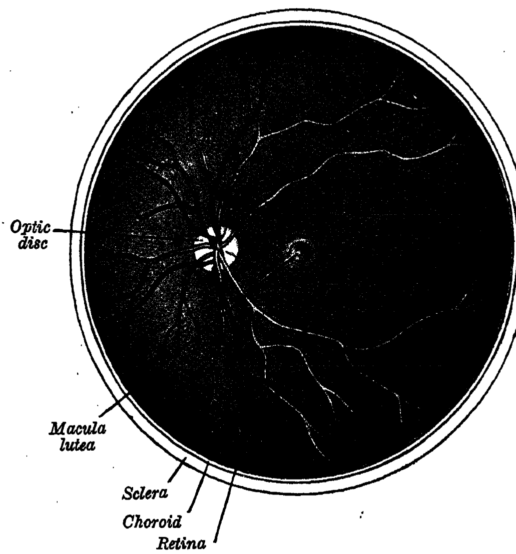
a stratum of columnar epithelium; in the pars iridica retinæ both layers of epithelium are cubical and pigmented. The retina is soft, translucent, and of a purple tint in the fresh state, owing to the presence of a colouring material, named *rhodopsin*, or *visual purple*; but it soon becomes clouded, opaque, and bleached when exposed to light. Near the centre of the posterior part of the retina there is an oval, yellowish area, named the *macula lutea*, where the visual sense is most perfect; it shows a central depression, termed the *fovea centralis* (fig. 1021). At the fovea centralis the retina is exceedingly thin, and the dark colour of the choroid is distinctly seen through it. About 3 mm. to the nasal side of the macula lutea the optic nerve pierces the retina at the *optic disc*, which has a diameter of about 1·5 mm. The circumference of the disc is slightly raised, while the central part presents a depression. The centre of the disc is pierced by the central artery and vein of the retina (fig. 1012). The optic disc is insensitive to light, and is termed the 'blind spot.'

Structure (figs. 1023, 1024).— The retina consists of an outer pigmented layer and an inner nervous stratum or retina proper.

The **pigmented layer** is a single stratum of cells. When viewed from the outer surface these cells are smooth and hexagonal in shape; when seen in section each cell consists of an outer non-pigmented part containing a large oval nucleus, and an inner pigmented portion which extends as a series of straight thread-like processes between the rods (fig. 1024), the amount of pigment between the rods being greater when the eye has been exposed to light. In the eyes of albinos the cells of the layer are destitute of pigment.

Fig. 1021.—The interior of the posterior half of the left eyeball.



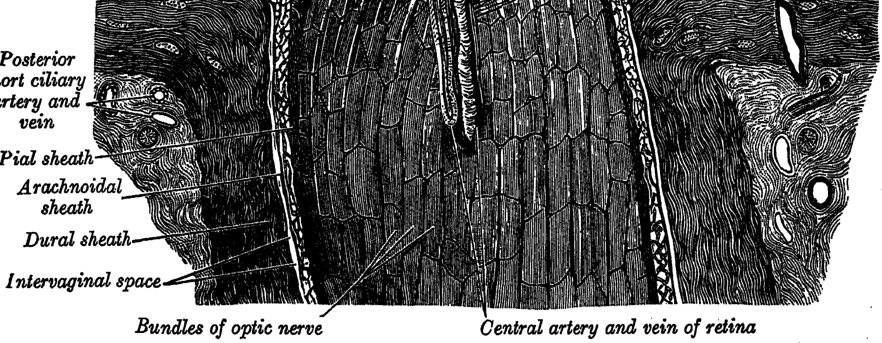
The veins are darker in appearance than the arteries.

Retina proper.—The nervous structures of the retina proper are supported by a series of non-nervous, or sustentacular, fibres, and, when examined microscopically by means of sections made perpendicular to the surface of the retina, are found to comprise seven layers, named from within outwards as follows:

1. Stratum opticum.
2. Ganglionic layer.
3. Inner plexiform layer.
4. Inner nuclear layer.
5. Outer plexiform layer.
6. Outer nuclear layer.
7. Layer of rods and cones.

1. The *stratum opticum* or *layer of nerve-fibres* is formed by the expansion of the fibres of the optic nerve; it is thickest near the optic disc, gradually diminishing towards the ora serrata. As the nerve-fibres pass through the lamina cribrosa scleræ (p. 1165), they lose

Fig. 1022.—A horizontal section through the terminal portion of the optic nerve and its entrance into the eyeball. (From Toldt's *Atlas*, published by Messrs. Rebman, Ltd., London.)



their medullary sheaths and are continued onwards through the choroid and retina as simple axis-cylinders. When they reach the internal surface of the retina they radiate from their point of entrance over this surface, grouped in bundles which communicate with

one another and form an intricate network. Most of the fibres are centripetal and are the continuations of the axis-cylinder processes of the cells of the ganglionic layer, but a few are centrifugal; these originate in the brain and ramify in the inner plexiform and inner nuclear layers of the retina, where they end.

Fig. 1023.—A section through the retina. (Magnified.)

2. The *ganglionic layer* consists of a single layer of large nerve-cells, except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, the rounded internal surface of each resting on, and sending an axon into, the stratum opticum. From the opposite end numerous dendrites extend into the inner plexiform layer, where they form flattened arborisations at different levels. The ganglion-cells vary much in size, and the dendrites of the smaller ones as a rule arborise in the inner plexiform layer as soon as they enter it; while those of the larger cells ramify close to the inner nuclear layer.

3. The *inner plexiform layer* is made up of a dense reticulum of minute fibrils formed by the interlacement of the dendrites of the ganglion-cells with the processes of the cells of the inner nuclear layer; within this reticulum a few branched cells are imbedded.

4. The *inner nuclear layer* is made up of a number of closely packed cells, of which there are three varieties, viz. bipolar cells, horizontal cells and amacrine cells.

The *bipolar cells,* by far the most numerous, are divisible into rod- and cone-bipolars. They are round or oval in shape, and each is prolonged into an inner and an outer process. The inner processes of the *rod-bipolars* run through the inner plexiform layer and arborise around the outer parts of the cell-bodies of the ganglionic layer; their outer processes end in the outer plexiform layer in tufts of fibrils around the button-like ends of the inner processes of the rod-granules. The inner processes of the *cone-bipolars* ramify in the inner plexiform layer in contact with the dendrites of the ganglionic cells; their outer processes pass into the outer plexiform layer, where they divide and form arborisations with the expanded foot-plate of the inner processes of the cone-granules.

The *horizontal cells* lie in the outer part of the inner nuclear layer and possess somewhat flattened cell-bodies. Their dendrites divide into numerous branches in the outer plexiform layer, while their axons run horizontally for some distance and finally ramify in the same layer.

The *amacrine cells* are placed in the inner part of the inner nuclear layer, and were so named under the supposition that they were destitute of axons. It is now known that some, at least, possess axons. Their dendrites undergo extensive ramification in the inner plexiform layer.

5. The *outer plexiform layer* is much thinner than the inner; but, like it, consists of a dense network of minute fibrils derived from the processes of the horizontal cells, and the outer processes of the rod- and cone-bipolar cells of the preceding layer, which arborise around the enlarged ends of the rod-fibres and the branched foot-plate of the cone-fibres.

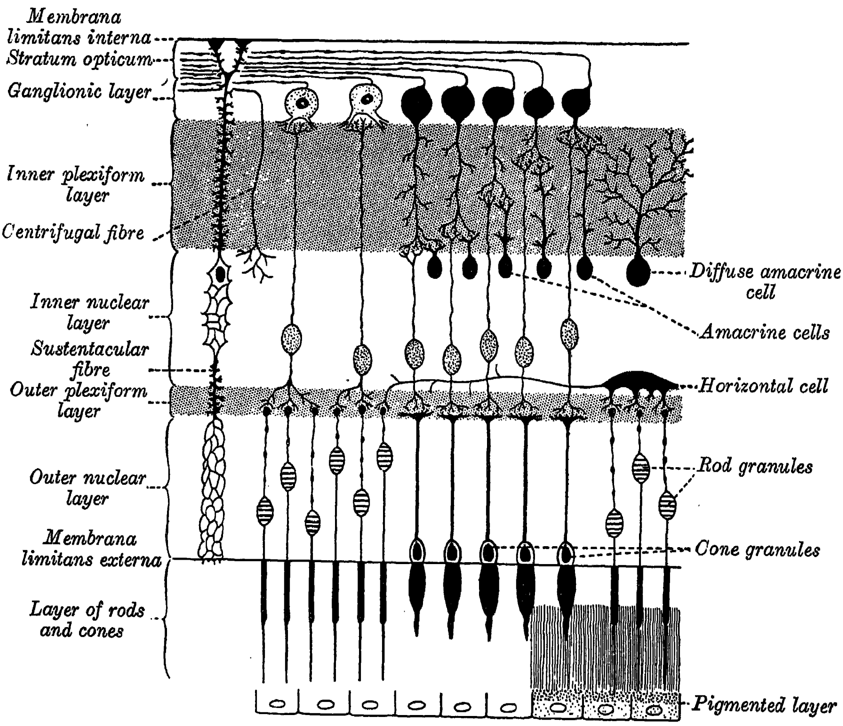
6. The *outer nuclear layer.*—Like the inner nuclear layer, this contains several strata of oval cells; they are of two kinds, viz. rod-granules and cone-granules, the former being connected with the rods, the latter with the cones, of the next layer. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer ; in some animals they present a cross-striped appearance. A fine process is prolonged from each extremity of each cell; the outer process is continuous with a rod of the layer of rods and cones ; the inner process ends in the outer plexiform layer in an enlarged extremity and is imbedded in the tuft into which the outer processes of the rod-bipolar cells break up ; in its course it presents numerous varicosities. The *cone-granules,* fewer in number than the rod-granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of the layer of rods and cones. Each contains a spheroidal nucleus which almost completely fills the granule. From the inner extremity of each cone-granule a thick process passes into the outer plexiform layer, and there expands into a pyramidal enlargement or foot-plate, from which are given off numerous fine fibrils that come in contact with the outer processes of the cone-bipolars.

7. The *layer of rods and cones.*—The elements composing this layer are of two kinds, *rods* and *cones,* the former being much more numerous than the latter except in the macula lutea. The *rods* are cylindrical, of nearly uniform thickness, and are arranged perpendicularly to the surface. Each rod consists of two segments, an outer and an inner, of about equal lengths. The segments differ from each other as regards refraction and in their behaviour towards colouring reagents ; the inner segment is stained by carmine, iodine,

etc.; the outer segment is not stained by these reagents, but is coloured yellowish-brown by osmic acid. The outer segment is marked by transverse striæ, and tends to break up into a number of thin superimposed discs; it also exhibits faint longitudinal markings. The inner part of the inner segment is indistinctly granular; the outer part is longitudinally striated, being composed of fine, highly refracting fibrils. The visual purple or rhodopsin is found only in the outer segments of the rods.

The *cones* are conical, their broad ends resting upon the membrana limitans externa, the pointed extremities being turned to the choroid. Like the rods, each is made up of two segments, outer and inner; the outer segment is a short conical process, which, like the outer segment of a rod, exhibits transverse striæ. The inner segment resembles the inner segment of a rod in structure, presenting an outer striated and an inner granular part, but differs from it in size and shape, being flask-shaped. The optical characters of the two portions are identical with those of the rods.

FIG. 1024.—A plan of the retinal neurones. (After Ramón y Cajal.)



Supporting framework of the retina.—The nervous layers of the retina are connected together by a supporting framework, formed by the *sustentacular fibres* (fig. 1024); these fibres pass through all the nervous layers, except that of the rods and cones. Each fibre begins on the inner surface of the retina by an expanded, often forked, base, which sometimes contains a spheroidal body, staining deeply with hæmatoxylin; the edges of the bases of adjoining fibres are united to form the *membrana limitans interna*. As the sustentacular fibres pass through the stratum opticum and the ganglionic layer they send off a few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the bipolar cells, while in the outer nuclear layer they form a network and unite to form the *membrana limitans externa* at the bases of the rods and cones. At the level of the inner nuclear layer each sustentacular fibre contains a clear oval nucleus.

Structure of the macula lutea and fovea centralis.—At the fovea centralis there are no rods, and the cones are longer and thinner than in other parts of the retina. The nerve-fibre layer disappears at the margin of the fovea, and the other retinal layers are extremely thin. The pigment-cells are large and well-marked. At the circumference of the fovea the retina rapidly increases in thickness, so that this part of the macula lutea has a greater depth than any other part of the retina. All the layers are involved in this increase, but especially the ganglionic layer, in which the cells are six to eight deep. The yellow colour

of the macula seems to imbue all the layers except that of the rods and cones; it is deepest towards the centre of the macula, and does not appear to be due to pigment-cells, but simply to a staining of the constituent parts.

At the *ora serrata* the nervous layers of the retina end abruptly, and the retina is continued onwards as a single layer of columnar cells along with the pigmented layer. This double layer is known as the *ciliary part of the retina*, and can be traced forwards from the ciliary processes on to the back of the iris, where it is termed the *iridial part of the retina* (p. 1172).

The *central artery of the retina* (fig. 1021) and its accompanying vein pierce the lower and medial surface of the optic nerve, and enter the bulb of the eye at the centre of the optic disc. The artery immediately bifurcates into an upper and a lower branch, and each of these again divides into a nasal and a temporal branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forwards, dividing dichotomously. From those branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives two small branches (superior and inferior macular arteries) from the temporal branches, and small twigs directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the arteria centralis retinæ do not anastomose with each other—in other words, they are terminal arteries. In the fœtus, a small vessel, termed the hyaloid artery, passes forwards as a continuation of the central artery of the retina through the vitreous humour to the posterior surface of the capsule of the lens.

The Refracting Media of the Eye

The refracting media of the eye are the aqueous humour, the vitreous body and the lens.

I. The Aqueous Humour

The **aqueous humour** fills the anterior and posterior chambers of the eyeball (fig. 1012). It is small in quantity, has an alkaline reaction, and is a dilute saline solution, derived from the blood plasma. It is secreted into the posterior chamber from the vessels of the iris and the ciliary processes. It escapes from the iridocorneal angle of the anterior chamber into the anterior ciliary veins, through the spaces of the angle and the sinus venosus scleræ.

Applied Anatomy.—Interference with the resorption of the aqueous humour into the sinus venosus scleræ results in increase of the intra-ocular tension—the condition known as glaucoma. The optic disc becomes cupped and, owing to degenerative changes in the nervous elements of the retina produced by pressure, blindness eventually results. The operation of iridectomy, performed in the earlier stages of the disease, re-establishes the flow of the aqueous humour from the posterior chamber to the anterior, in cases where the disease is due to adhesions between the iris and the lens.

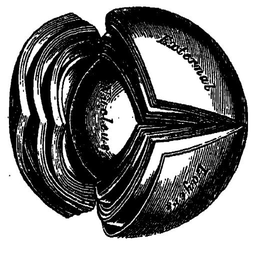
II. The Vitreous Body

The **vitreous body** (fig. 1012) occupies about four-fifths of the eyeball. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, termed the *hyaloid fossa*, for the reception of the lens. It is transparent, of the consistence of thin jelly, and is enclosed in a delicate transparent membrane, named the *hyaloid membrane*. It has been supposed by Hannover, that from the surface of the hyaloid membrane numerous thin lamellæ are prolonged inwards in a radiating manner, forming spaces in which the jelly is contained. In the adult, these lamellæ cannot be detected even after careful microscopical examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the vitreous body. The *hyaloid canal*, which is filled with lymph and lined by a prolongation of the hyaloid membrane, runs forward through the vitreous body from the entrance of the optic nerve to the posterior surface of the lens. In the embryonic vitreous body this canal conveyed the hyaloid artery from the central artery of the retina to the back of the lens.

The vitreous body consists of 98·6 per cent. water, with some salts and a little protein.

The *hyaloid membrane* envelops the vitreous body. The portion in front of the ora serrata is thickened by the accession of radial fibres and is termed the *zonula ciliaris*. Here it presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they adhere, as is shown by the fact that when they are removed some of their pigment remains attached to the zonula. The zonula ciliaris splits into two layers, one of which is thin and lines the hyaloid fossa of the vitreous body; the other, named the *suspensory ligament of the lens*, is thicker and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the meridional fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, named the *spatia zonularia*, which encircles the equator of the lens; it can be easily inflated through a fine blowpipe inserted under the suspensory ligament.

Fig. 1025.—The lens, hardened and divided. (Enlarged.)



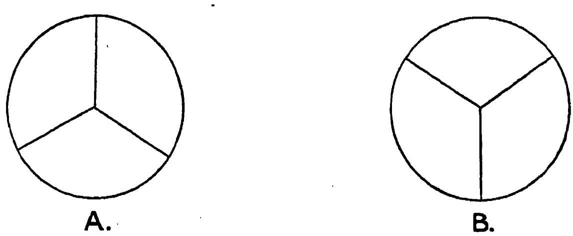
No blood-vessels penetrate the vitreous body; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. The Lens

The lens (fig. 1012), enclosed in its capsule, is situated immediately behind the iris, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* is a transparent, structureless membrane which closely surrounds the lens, and is thicker in front than behind. It is brittle but highly elastic, and when it is ruptured the edges roll up with the outer surface innermost. The lens rests, behind, in the hyaloid fossa on the fore-part of the vitreous body; in front, it is in contact with the free border of the iris, but recedes from it at the circumference, thus forming the posterior chamber of the eye; it is retained in its position chiefly by the suspensory ligament already described.

Fig. 1026.—A diagram showing the direction and arrangement of the radiating lines on the fœtal lens. a. On the back. b. On the front.

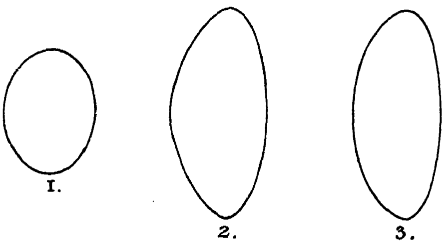


The *lens* is a transparent, biconvex body, the convexity of its anterior being less than that of its posterior surface. The central points of these surfaces are termed respectively the *anterior* and *posterior poles*; a line connecting the poles constitutes the *axis* of the lens, while the marginal circumference is termed the *equator*.

Structure.—The lens is made up of soft cortical substance and a firm, central part, the so-called nucleus (fig. 1025). Faint sutural lines [radii lentis] radiate from the poles to the

equator. In the adult there may be six or more of these lines, but in the fœtus there are only three, and these diverge in a Y-shaped manner at angles of 120°; on the anterior surface the Y is upright (fig. 1026, B); on the posterior surface the Y is inverted (fig. 1026, A).* These lines correspond with the free edges of septa composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened it is seen to consist of a series of concentrically arranged laminæ, each of which is interrupted at the septa referred to. Each lamina is built up of a number of ribbon-like lens-fibres, the edges of which are more or less serrated—the serrations fitting between those of neighbouring fibres, while the ends of the fibres come into apposition at the septa. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole; they are arranged in such a way that those which begin near the pole on

FIG. 1027.—Profile views of the lens at different periods of life.

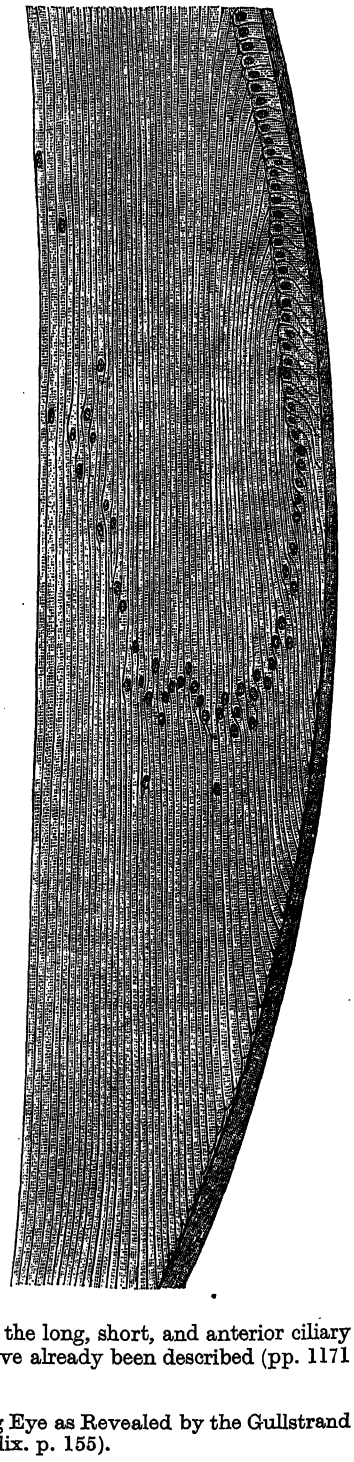


1. In the fœtus. 2. In adult life. 3. In old age.

one surface of the lens end near the peripheral extremity of the plane on the other, and vice versa. The fibres of the outer layers of the lens are nucleated, and together form a nuclear layer, most distinct towards the equator. The anterior surface of the lens is covered by a layer of transparent, nucleated columnar epithelium. At the equator the cells become elongated, and their gradual transition into lens-fibres can be traced (fig. 1028).

In the fœtus, the lens is nearly spherical and has a slightly reddish tint; it is soft and breaks down readily on the slightest pressure. A small branch (hyaloid artery) from the central artery of the retina runs forwards through the vitreous body to the posterior part of the capsule of the lens, where its branches radiate, forming a plexiform network which covers the posterior surface of the capsule, and is continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. *In the adult*, the lens is colourless, transparent, firm in texture and devoid of vessels. *In old age*, it becomes flattened on both surfaces, slightly opaque, of an amber tint and increased in density (fig. 1027).

FIG. 1028.—A section through the margin of the lens, showing the transition of the columnar epithelium into the lens-fibres. (Babuchin.)



Vessels and Nerves.—The *arteries* of the eyeball are the long, short, and anterior ciliary arteries, and the central artery of the retina. They have already been described (pp. 1171 and 1176).

* Consult an article on "The Anatomy of the Living Eye as Revealed by the Gullstrand Slit-lamp," by Ida C. Mann (*Journal of Anatomy*, vol. lix. p. 155).

The *ciliary veins* are seen on the outer surface of the choroid, and are named, from their arrangement, the *venæ vorticosæ*; they converge to four or five equidistant trunks, which pierce the sclera midway between the sclerocorneal junction and the optic disc. Another set of veins accompanies the anterior ciliary arteries. All these veins open into the ophthalmic veins.

The *ciliary nerves* are derived from the nasociliary nerve and from the ciliary ganglion.

Applied Anatomy.—In the condition termed cataract the lens gradually becomes opaque and blindness ensues. In such cases sight may be restored by extraction of the lens and the provision of suitable glasses.

The Accessory Organs of the Eye

The accessory organs of the eye include the orbital muscles, the fasciæ, the eyebrows, the eyelids, the conjunctiva and the lacrimal apparatus.

The Orbital Muscles

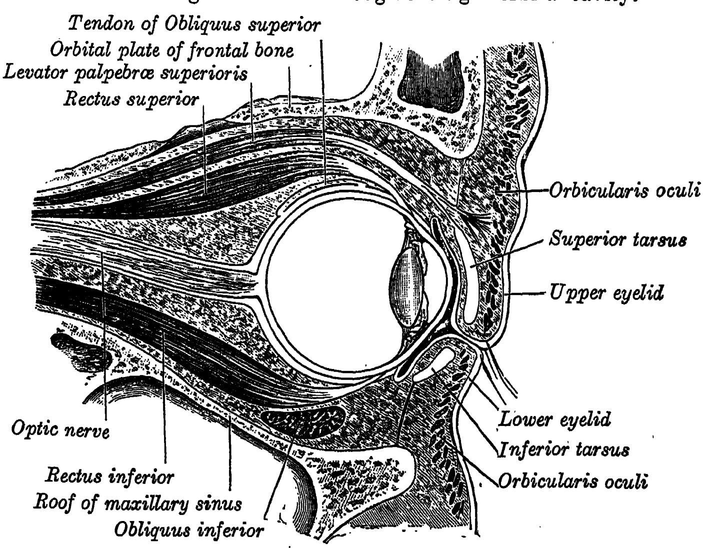
The orbital muscles are the:

Levator palpebræ superioris.	Rectus medialis.
Rectus superior.	Rectus lateralis.
Rectus inferior.	Obliquus superior.

Obliquus inferior.

The **Levator palpebræ superioris** (figs. 1029, 1030) is thin and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid bone, above and in front of the optic foramen, from which it is separated by

Fig. 1029.—A sagittal section through the right orbital cavity.



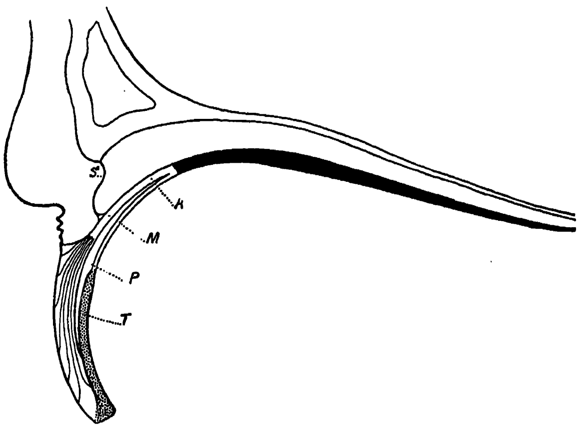
the origin of the Rectus superior. At its origin, it is narrow and tendinous but soon becomes broad and fleshy, the medial margin of the muscle being almost straight, while the lateral margin is concave. The muscle ends anteriorly in a wide aponeurosis which splits into two lamellæ. Some of the fibres of the superficial lamella are attached to the anterior surface of the superior tarsus (p. 1185), while others radiate and pass through the overlying Orbicularis oculi to the skin of the upper eyelid. The deep lamella consists of non-striped muscular fibres *; it is attached directly to the upper margin of the superior tarsus and is covered by conjunctiva on its inferior surface.

The fascial sheaths of the Levator palpebræ superioris and Rectus superior fuse. Where the two muscles separate to reach their insertions, the fascia between them forms a thick

* A layer of non-striped muscle is also present in the lower eyelid; it unites the inferior tarsus to the Obliquus inferior.

mass which is fixed to the superior conjunctival fornix and is described as an additional insertion of the Levator palpebræ superioris. When traced laterally the aponeurosis of the Levator palpebræ superioris passes between the lacrimal gland and its palpebral process, and is fixed to a tubercle on the zygomatic bone, just within the orbital margin (p. 326). When traced medially the aponeurosis loses its tendinous nature as it passes over and comes into close contact with the reflected tendon of the Obliquus superior, whence it can be

FIG. 1030.—A diagram of the Levator palpebræ superioris, showing its connexions. (From Whitnall's *Anatomy of the Human Orbit*, Oxford Medical Publications.)

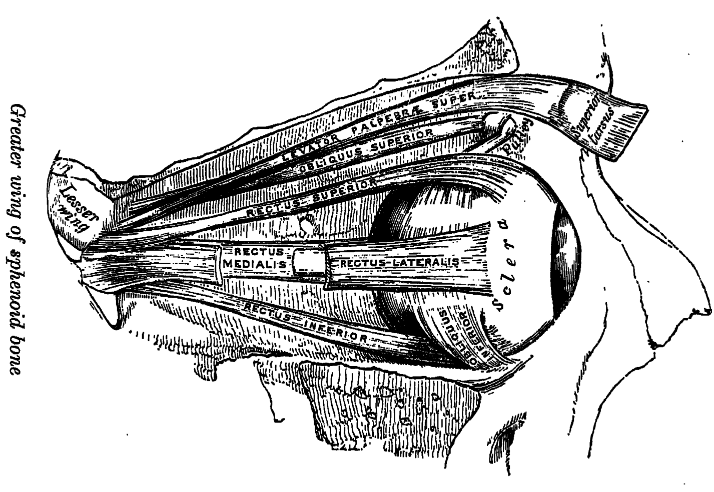


A, Superficial lamella of aponeurosis: *M*, Deep lamella (Müller's muscle); *P*, Interval between superficial and deep lamellæ of aponeurosis; *T*, Tarsus; *S*, Orbital septum.

followed with difficulty towards the medial palpebral ligament in the form of loose strands of connective tissue. When the Levator palpebræ contracts the upper eyelid is raised, but the lateral and medial parts of the aponeurosis are stretched and limit the action of the muscle; the elevation of the upper eyelid is checked also by the orbital septum.

The **four Recti** (figs. 1031, 1032) arise from a fibrous ring which surrounds the upper, medial, and lower margins of the optic foramen (fig. 1032), and is termed

FIG. 1031.—The muscles of the right orbit. Lateral aspect.

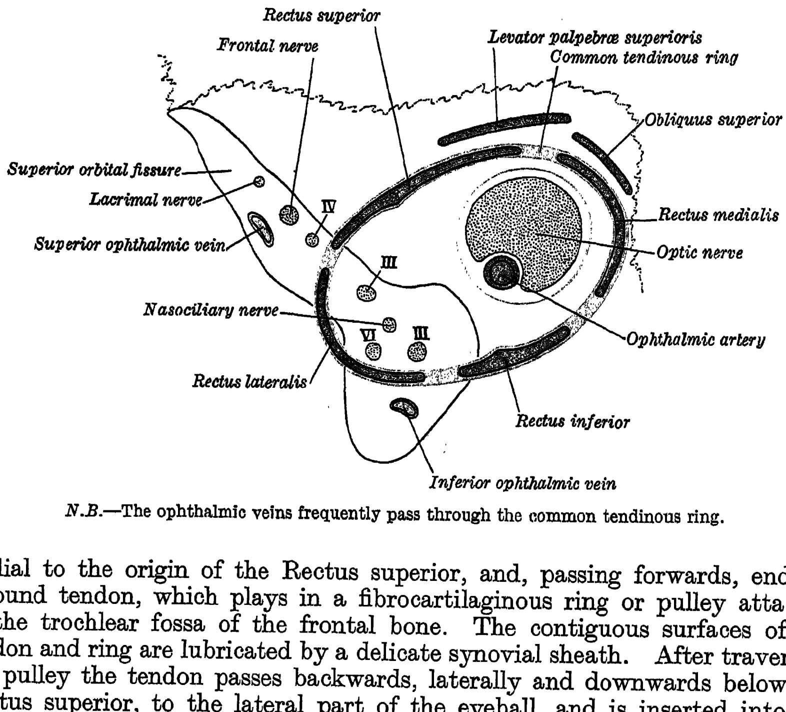


the *common tendinous ring* (annulus tendineus communis); the fibrous ring is continued across the lower and medial part of the superior orbital fissure and is attached to a tubercle on the margin of the greater wing of the sphenoid bone. The ring is closely adherent to the sheath of the optic nerve and to the surrounding periosteum; within it are (1) the optic foramen transmitting the optic nerve and ophthalmic artery, and (2) the medial part of the superior orbital

fissure which transmits the two divisions of the oculomotor nerve, the nasociliary nerve, and the abducent nerve. The superior ophthalmic vein may pass through, or above, the ring; the inferior ophthalmic vein through, or below, the ring. Two specialised parts of this fibrous ring may be made out: a lower, which gives origin to the Rectus inferior, a part of the Rectus medialis, and the lower fibres of the Rectus lateralis; and an upper, which gives origin to the Rectus superior, the other part of the Rectus medialis, and the upper fibres of the Rectus lateralis; a second small tendinous head of origin of the Rectus lateralis arises from the orbital surface of the greater wing of the sphenoid bone, lateral to the tendinous ring. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion into the sclera, about 6 mm. from the margin of the cornea.*

The **Obliquus superior** is a fusiform muscle, placed at the upper and medial side of the orbit. It arises above the optic foramen, superior and

FIG. 1032.—Scheme to show the common tendinous ring, the origins of the Recti, and the relative positions of the nerves entering the orbital cavity through the superior orbital fissure. (Modified from a figure in Whitnall's *Anatomy of the Human Orbit*, Oxford Medical Publications.)



N.B.—The ophthalmic veins frequently pass through the common tendinous ring.

medial to the origin of the Rectus superior, and, passing forwards, ends in a round tendon, which plays in a fibrocartilaginous ring or pulley attached to the trochlear fossa of the frontal bone. The contiguous surfaces of the tendon and ring are lubricated by a delicate synovial sheath. After traversing the pulley the tendon passes backwards, laterally and downwards below the Rectus superior, to the lateral part of the eyeball, and is inserted into the sclera, behind the equator of the eyeball, and between the Rectus superior and Rectus lateralis.

The **Obliquus inferior** is a thin, narrow muscle, placed near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla lateral to the nasolacrimal groove. Passing laterally, backwards and upwards, at first between the Rectus inferior and the floor of the orbit, and then between the eyeball and the Rectus lateralis, it is inserted into the lateral part of the sclera between the Rectus superior and Rectus lateralis, near to, but somewhat behind, the insertion of the Superior oblique muscle.

Nerves.—The Levator palpebræ superioris, the Obliquus inferior, and the Recti superior, inferior et medialis are supplied by the oculomotor nerve; the Obliquus superior, by the trochlear nerve; the Rectus lateralis, by the abducent nerve.

* The average distances of the insertions of the Recti from the margin of the cornea are: Rectus medialis, 5·5 mm.; Rectus inferior, 6·5 mm.; Rectus lateralis, 6·9 mm.; Rectus superior, 7·7 mm.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis oculi. The four Recti are attached to the eyeball in such a manner that, acting singly, they will turn its corneal surface either upwards, downwards, medially, or laterally, as expressed by their names. The movement produced by the Rectus superior and by the Rectus inferior is not quite a simple one, for inasmuch as each passes obliquely laterally and forwards to the eyeball, the elevation or depression of the cornea is accompanied by a certain deviation medially, with a slight amount of rotation. These latter movements are corrected by the oblique muscles. The obliquus inferior rotates the eyeball so as to turn its corneal surface upwards and laterally. When the eye is directed upwards, it corrects the medial deviation caused by the Rectus superior. The obliquus superior rotates the eyeball so as to turn its corneal surface downwards and laterally. When the eye is directed downwards, the superior oblique corrects the medial deviation caused by the Rectus inferior. The contraction of the Rectus lateralis or Rectus medialis, on the other hand, produces a purely horizontal movement. If any two neighbouring Recti of one eye act together they carry the globe of the eye in the diagonal of these directions, viz. upwards and medially, upwards and laterally, downwards and medially, or downwards and laterally. Sometimes the corresponding Recti of the two eyes act in unison, and at other times the opposite Recti act together. Thus, in turning the eyes to the right, the Rectus lateralis of the right eye acts in unison with the Rectus medialis of the left eye ; but if both eyes are directed to an object in the median plane at a short distance, the two medial Rectus muscles act in unison. The movement of circumduction, as in looking round a room, is performed by the successive actions of the four Recti. The Oblique muscles rotate the eyeball on its transverse and vertical axes, the superior directing the cornea downwards and laterally, and the inferior directing it upwards and laterally ; in addition, the oblique muscles rotate the globe of the eye round its anteroposterior axis ; these movements are required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye.

A thin layer of non-striped muscle, named the *Orbitalis muscle*, bridges the inferior orbital fissure.

The **fascial sheath of the eyeball** (fascia bulbi) (figs. 1033, 1034) is a thin membrane which envelops the eyeball from the optic nerve to the sclerocorneal junction, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is separated from the outer surface of the sclera by the *episcleral space* ; this space is traversed by delicate bands of connective tissue which extend between the fascia and the sclera. The fascia is perforated behind by the ciliary vessels and nerves, and fuses with the sheath of the optic nerve and with the sclera around the entrance of the optic nerve. In front it blends with the sclera just behind the sclerocorneal junction. It is perforated by the tendons of the orbital muscles, and is reflected on each as a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle ; that on the Inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the Recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Rectus superior blends with the tendon of the Levator palpebræ superioris ; that of the Rectus inferior is attached to the inferior tarsus. The expansions from the sheaths of the Recti medialis et lateralis are strong and triangular in shape, and are attached to the lacrimal and zygomatic bones respectively ; as they probably check the actions of these two Recti they have been named the *medial* and *lateral check ligaments*. Lockwood * described a thickening of the lower part of the fascial sheath of the eyeball, which he named the *suspensory ligament of the eye* ; it is slung like a hammock below the eyeball, being expanded in the centre, and narrow at its extremities ; it is formed by the union of the margins of the sheath of the Rectus inferior with the medial and lateral check ligaments.

The **orbital fascia** forms the periosteum of the orbit, but is loosely connected to the bones. Behind, it is united with the dura mater and with the sheath of

* C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx.

FIG. 1033.—A scheme of the fascia of the orbit (the muscle-sheaths and the fascial sheath of the eyeball) in sagittal section. (From Whitnall's *Anatomy of the Human Orbit*; Oxford Medical Publications.)

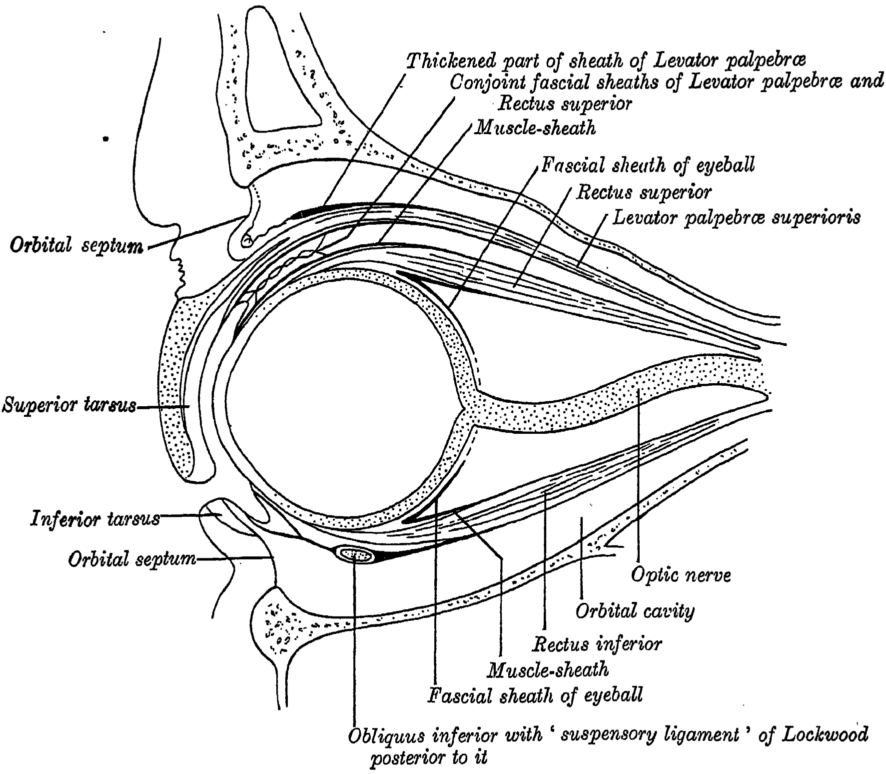


FIG. 1034.—A schematic view of a horizontal section through the right orbit to illustrate the fascia of the orbit. (From Whitnall's *Anatomy of the Human Orbit*; Oxford Medical Publications.)

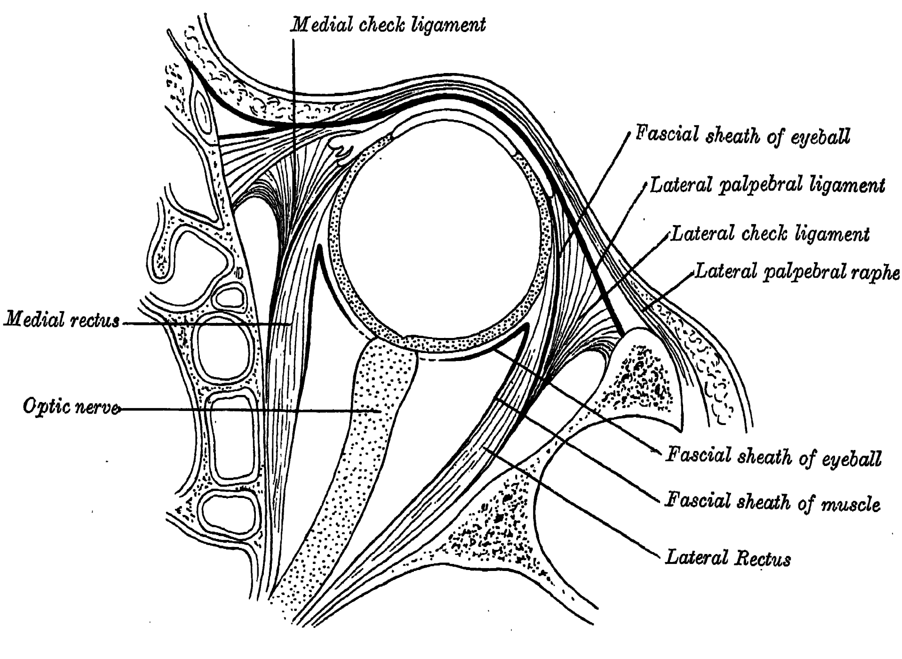
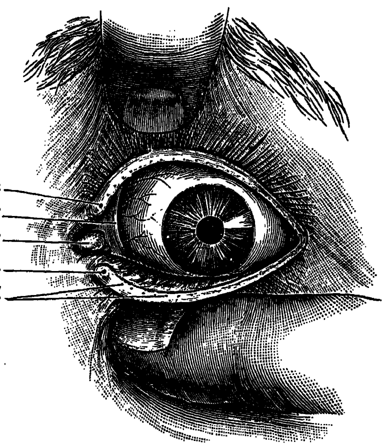


the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a stratum which assists in forming the orbital septum. From it two processes are given off : one holds the pulley of the Superior oblique muscles in position, the other, named the *lacrimal fascia,* forms the roof and lateral wall of the sulcus in which the lacrimal sac is lodged (p. 1189).

Applied Anatomy.—The positions and exact areas of insertion of the tendons of the Recti medialis and lateralis into the globe of the eye should be carefully examined from the front, as the surgeon is often required to divide one or other of the muscles for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned medially, and the condition may require the division of the Rectus medialis. In the divergent form, which is more rare, the eye is turned laterally, the Rectus lateralis being especially implicated. If the deformity produced in either case be marked, it may be remedied by division of one or the other muscle.

FIG. 1035.—The front of the left eye with the eyelids separated to show the plica semilunaris, caruncula lacrimalis and puncta lacrimalia.



The converse operation is that of *advancement,* in which either the Rectus medialis or Rectus lateralis (depending on the form of strabismus) is shortened. The muscle is exposed in a similar manner ; its tendon is divided, and sutured to the globe of the eye in front of its previous site of attachment.

Removal of the eyeball is effected by dividing the conjunctiva all round with scissors at its attachment to the cornea, after which each ocular muscle in turn is picked up on a blunt hook and divided close to the sclera. The optic nerve is then divided with curved scissors passed to the back of the orbit; it should be remembered that the perineural sheaths from the meninges are opened by this procedure.

The **eyebrows** are two arched eminences of skin, which surmount the orbits and support numerous short, thick hairs directed obliquely on the surface. Fibres of the Orbicularis oculi, Corrugator and frontal belly of the Occipitofrontalis are inserted into the skin of the eyebrows.

The **eyelids** or **palpebræ** are two thin, movable folds, placed in front of the eye, and protecting it, by their closure, from injury. The upper eyelid is the larger and more movable, and is furnished with an elevator muscle [the Levator palpebræ superioris] (p. 1179) ; the two eyelids unite with each other at their extremities. When the eyelids are open, an elliptical space, termed the *palpebral fissure* [*rima palpebrarum*], is left between their margins ; the extremities of the fissure are called the angles of the eye.

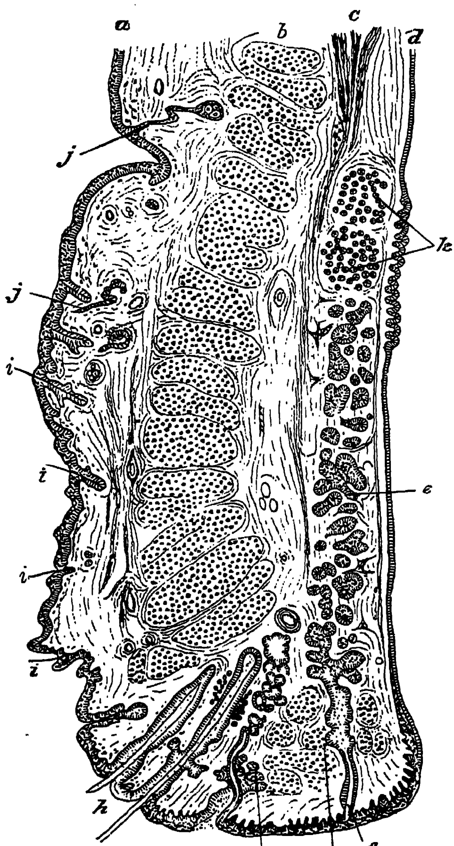
The *lateral angle of the eye* is more acute than the medial, and lies in close contact with the eyeball. The *medial angle* is prolonged for a short distance towards the nose, and is about 6 mm. away from the eyeball ; the two eyelids are here separated by a triangular space, named the *lacus lacrimalis,* in which a small reddish body, termed the *caruncula lacrimalis,* is situated (fig. 1035). On the margin of each eyelid, at the basal angles of the lacus lacrimalis, there is a small conical elevation, termed the *lacrimal papilla,* the apex of which is pierced by the commencement of the lacrimal canaliculus. This minute orifice (fig. 1035) is known as the *punctum lacrimale.*

The *eyelashes* are attached to the free edges of the eyelids from the lateral angle of the eye to the lacrimal papillæ. They are short, thick, curved hairs, arranged in double or triple rows : those of the upper eyelid, more numerous and longer than those of the lower, curve upwards ; those of the lower eyelid curve downwards so that the upper and lower eyelashes do not interlace when

the lids are closed. A number of enlarged and modified sudoriferous glands, termed *ciliary glands*, are arranged in several rows close to the free margin of each lid and open near the attachments of the eyelashes.

Structure of the eyelids.—From without inwards, each eyelid consists of: skin, subcutaneous areolar tissue, fibres of the Orbicularis oculi, tarsus and orbital septum, tarsal glands and conjunctiva. The upper eyelid has, in addition, the aponeurosis of the Levator palpebræ superioris (fig. 1036).

FIG. 1036.—A sagittal section through the upper eyelid. (After Waldeyer.)



a. Skin. b. Orbicularis oculi. b'. Ciliary bundle of the Orbicularis oculi. c. Levator palpebræ superioris. d. Conjunctiva. e. Tarsal glands embedded in the tarsal plate. f. Opening of a tarsal gland. g. Sebaceous gland. h. Eyelashes. i. Small hairs of the skin. j. Sweat gland. k. Posterior tarsal glands.

The *skin* is extremely thin, and continuous at the margins of the eyelids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, and seldom contains any fat.

The *palpebral fibres of the Orbicularis oculi* are thin, pale in colour and parallel with the palpebral fissure.

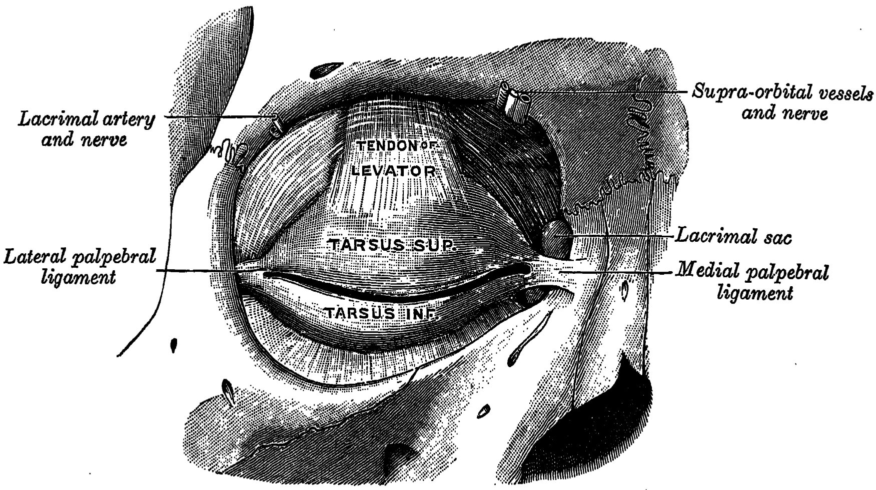
The *tarsi* (fig. 1037) are two thin elongated plates of dense connective tissue, about 2·5 cm. long; one is placed in each eyelid and contributes to its form and support. The *tarsus of the upper eyelid*, the larger, is of a semioval form, about 10 mm. in height at the centre, and gradually narrowing towards its extremities. The lowest fibres of the superficial lamella of the aponeurosis of the Levator palpebræ superioris are attached to its anterior surface, and the deep lamella of the same aponeurosis is inserted into its upper margin (p. 1179). The *tarsus of the lower eyelid*, the smaller, is a narrow plate, the vertical diameter of which is about 5 mm. The free or ciliary margins of the tarsi are thick and straight. The attached or orbital margins are connected to the circumference of the orbit by the orbital septum. The lateral ends of the tarsi are attached by a band, named the *lateral palpebral ligament*, to a tubercle on the zygomatic bone, just within the orbital margin; this ligament is separated from the more superficially placed lateral palpebral raphe (p. 527) by a few lobules of the lacrimal gland. The medial ends of the tarsi are attached by a strong tendinous band, named the *medial palpebral ligament*; to the upper part of the lacrimal crest, and to the adjoining part of the frontal process of the maxilla in front of this crest; the lower edge of this ligament is separated from the lacrimal sac by some fibres of the Orbicularis oculi.

The *orbital septum* is a weak membranous sheet, attached to the edge of the orbit, where it is continuous with the periosteum. In the upper eyelid it blends with the superficial lamella of the aponeurosis of the Levator palpebræ superioris, and in the lower eyelid with the anterior surface of the tarsus. It is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp, by the aponeurosis of the Levator palpebræ superioris, and by the palpebral process of the lacrimal gland.

The *tarsal glands* (fig. 1038) are situated between the tarsi and the conjunctiva, and may be distinctly seen through the latter on everting the eyelids; they present an appearance like parallel strings of pearls. There are about thirty in the upper eyelid, and somewhat fewer in the lower. They are im-

bedded in grooves on the deep surfaces of the tarsi and correspond in length with the breadth of these plates; they are, consequently, longer in the upper

FIG. 1037.—The tarsi and their ligaments. Anterior aspect. (Testut.)



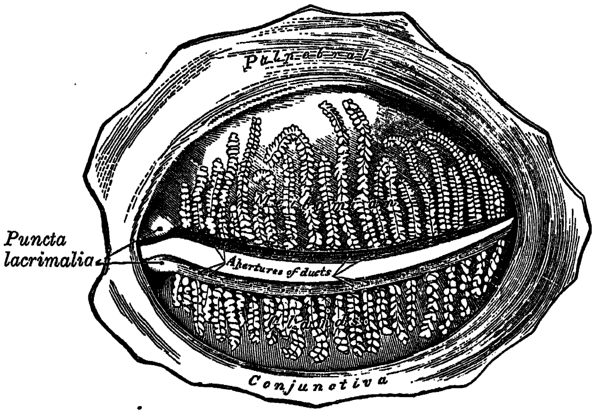
than in the lower eyelid. Their ducts open on the free margins of the lids by minute foramina.

Structure.—The tarsal glands are modified sebaceous glands, each consisting of a straight tube or follicle, with numerous small lateral diverticula. The tubes are supported by a basement-membrane and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells.

The **conjunctiva** is the mucous membrane which lines the inner surfaces of the eyelids, and is reflected over the fore part of the sclera and the cornea.

The *palpebral portion* is thick, opaque and highly vascular, and has numerous subepithelial connective tissue papillæ, its deeper part containing a considerable amount of lymphoid tissue. At the margins of the lids it is continuous with the skin, with the lining epithelium of the ducts of the tarsal glands, and, through the lacrimal canaliculi, with the lining membrane of the lacrimal sac and nasolacrimal duct. The line of reflection of the conjunctiva from the eyelids on to the eyeball is named the *conjunctival fornix*, and its different parts are known as the superior and inferior fornices; the ducts of the lacrimal gland open into the lateral part of the superior fornix. Upon the *sclera* the conjunctiva is loosely connected to the eyeball; it is thin, transparent, destitute of papillæ, and only slightly vascular. Upon the *cornea*, the conjunctiva consists only of epithelium, constituting the epithelium of the cornea, already described (p. 1166). The epithelium of the palpebral conjunctiva is columnar, that of the

FIG. 1038.—The tarsal glands of the eyelids. Posterior aspect.



ocular conjunctiva and the cornea is stratified squamous. Glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, chiefly near the medial angle of the eye.

The *lacrimal caruncle* (fig. 1035) is a small, reddish, conical body situated in the lacus lacrimalis at the medial angle of the eye; it consists of a small island of skin, and contains sebaceous and sudoriferous glands; a few slender hairs are attached to its surface. Lateral to the caruncula there is a semilunar fold of conjunctiva [the *plica semilunaris*], the concavity of which is directed towards the cornea.

Vessels and Nerves.—The eyelids receive their blood-supply from the medial palpebral branches of the ophthalmic artery and from the lateral palpebral branches of the lacrimal artery (p. 722).

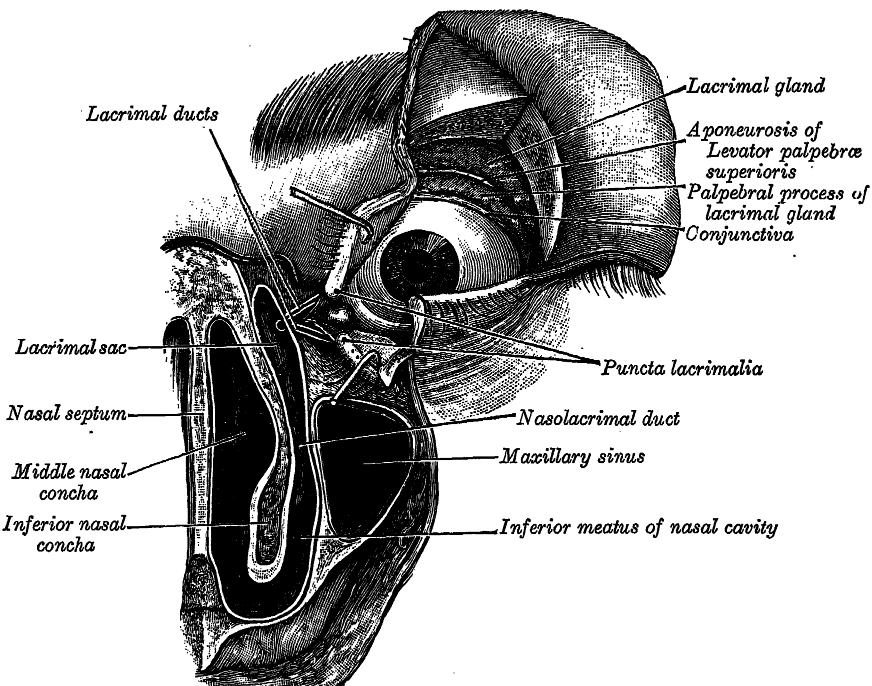
The upper half of the conjunctiva is supplied by the ophthalmic division of the trigeminal nerve, and the lower half by the maxillary division. Many of the nerves to the conjunctiva end in bulbous corpuscles (p. 1216).

The lymph vessels of the eyelids and the conjunctiva are described on p. 853.

The Lacrimal Apparatus (figs. 1039 to 1041)

The lacrimal apparatus consists of (*a*) the lacrimal gland, which secretes the tears, and its excretory ducts which convey the fluid to the surface of the eye; (*b*) the lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct, by which the fluid is conveyed into the cavity of the nose.

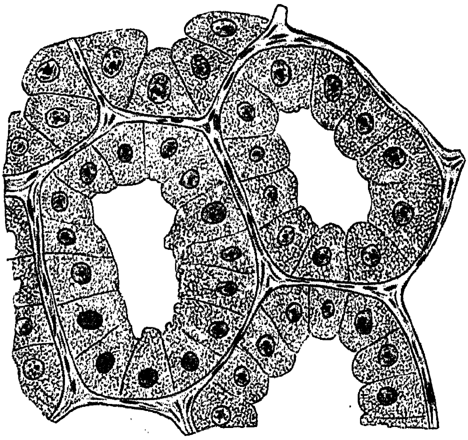
Fig. 1039.—The left lacrimal apparatus. Exposed from the front.



The lacrimal gland (fig. 1039) is lodged in the lacrimal fossa, on the medial side of the zygomatic process of the frontal bone. It is about the size and shape of an almond, and its inferolateral aspect sends a *palpebral process* into the lateral part of the upper eyelid. The gland and its process are continuous with each other around the lateral edge of the aponeurosis of the Levator palpebræ superioris. The *lacrimal gland* is connected to the periosteum of the orbit by a few fibrous bands; its *palpebral process* lies below the aponeurosis of the

Levator palpebræ superioris, and projects into the posterior part of the upper eyelid, where it lies upon and is adherent to the conjunctiva. The ducts of the glands, from six to twelve in number, run obliquely beneath the conjunctiva for a short distance, and open along the lateral part of the superior conjunctival fornix.

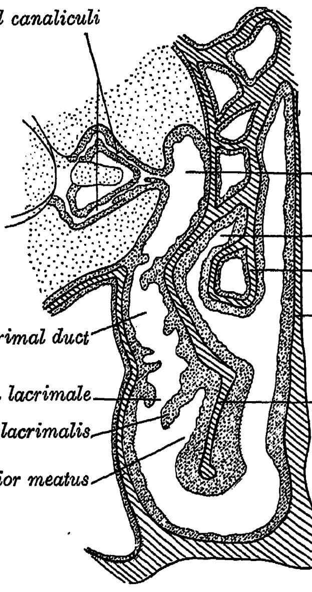
Fig. 1040.—A transverse section through a portion of the lacrimal gland of a cat. ×250.



Many, small, accessory lacrimal glands are present in and near the conjunctival fornices; they are more numerous in the upper lid than in the lower. Their existence may explain why the conjunctiva does not dry up after extirpation of the lacrimal gland proper.

Structure of the lacrimal gland (fig. 1040).—In structure the lacrimal resembles the salivary glands (p. 1270), but there are no crescents of Gianuzzi. It is a compound racemose gland, the alveoli of which are lined with columnar cells resting on a basement-membrane. The cells contain oval nuclei, and in the resting condition are crowded with small, clear vacuoles, which disappear when the gland secretes actively; protoplasmic granules are also present. The excretory ducts are lined with columnar epithelial cells, but these cells do not show the rod-like structures of the corresponding cells in the salivary glands.

Fig. 1041.—Sketch from a coronal section through the right half of the nasal cavity, viewed from the front, to show the relation of the lacrimal passages to the maxillary and ethmoidal sinuses and the inferior nasal concha. The mucous membrane is coloured. (After Gerard, 1907; from Whitnall's *Anatomy of the Human Orbit*; Oxford Medical Publications.)



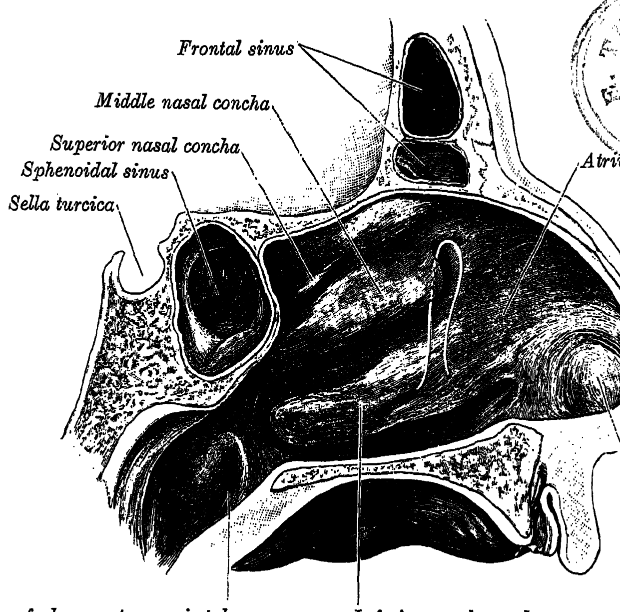
The **lacrimal canaliculi** (lacrimal ducts), one in each eyelid, are about 10 mm. long; they commence at the *puncta lacrimalia* (figs. 1035, 1039, 1041). The *superior canaliculus*, smaller and shorter than the inferior, at first ascends, and then bends at an acute angle, and passes medially and downwards to the lacrimal sac. The *inferior canaliculus* at first descends, and then runs almost horizontally to the lacrimal sac. At the angles they are dilated into *ampullæ*. The mucous lining of the ducts is covered with stratified squamous epithelium, placed on a basement-membrane, and outside the latter there is a layer of striped muscular fibres, continuous with the lacrimal part of the Orbiculari oculi; at the base of each lacrimal papilla the muscular fibres are circularly arranged and form a kind of sphincter.

The **lacrimal sac** (fig. 1041) is the upper end of the nasolacrimal duct, and is lodged in a fossa formed by the lacrimal bone, the frontal process of the maxilla and the lacrimal fascia. It measures about 12 mm. in length; its upper, closed end is flattened from side to side, but its lower part is rounded,

and is continued into the nasolacrimal duct; the openings of the lacrimal canaliculi are situated in its lateral wall.

Relations.—A layer of fascia, continuous with the periosteum of the orbit and named the *lacrimal fascia*, passes from the lacrimal crest of the maxilla to the crest of the lacrimal bone, and forms the roof and lateral wall of the fossa in which the lacrimal sac is lodged; between the fascia and the lacrimal sac there is a minute plexus of veins. The lacrimal fascia separates the sac from the medial palpebral ligament in front, and from the lacrimal part of the

FIG. 1042.—A sagittal section through the anterior part of the head of an adult female. Left half viewed from within to show the left lateral nasal wall. The relative positions of the fossa for the lacrimal sac and the nasolacrimal duct are indicated by the white line. × about ⅜. (From Whitnall's *Anatomy of the Human Orbit*; Oxford Medical Publications.)



Orbicularis oculi behind. The lower half of the fossa which lodges the lacrimal sac is related medially to the anterior part of the middle meatus of the nasal cavity; the upper half is related to the anterior ethmoidal sinuses.*

Structure.—The lacrimal sac consists of a fibro-elastic coat, lined internally by mucous membrane; the latter is continuous, through the lacrimal canaliculi, with the conjunctiva, and through the nasolacrimal duct with the mucous membrane of the nasal cavity.

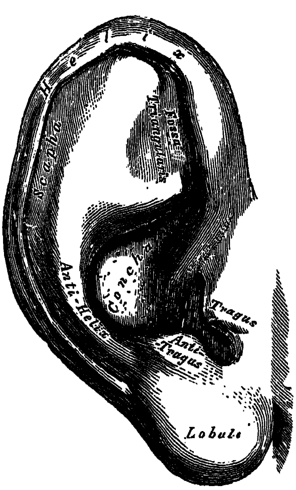
The tears pass from the superolateral to the inferomedial angle of the conjunctival sac, where they enter the puncta lacrimalia. They then traverse the lacrimal canaliculi and so reach the lacrimal sac. Their passage across the eyeball is effected by the movements of the eyelids and by capillarity.

The **nasolacrimal duct** (figs. 1041, 1042) is a membranous canal about 18 mm. long, which extends from the lower part of the lacrimal sac to the anterior part of the inferior meatus of the nose, where it ends in a somewhat expanded orifice. A fold of the mucous membrane forms an imperfect valve just above the opening and is known as the *lacrimal fold* [plica lacrimalis]. The duct is contained in an osseous canal, formed by the maxilla, the lacrimal bone and the inferior nasal concha; it is narrower in the middle than at either

* S. E. Whitnall (*Ophthalmic Review*, Nov. 1911) examined 100 skulls and found that in 14 the anterior ethmoidal air-sinuses came into relation only with the posterior wall of the fossa; in 32 they reached as far forward as the suture between the lacrimal bone and the maxilla; while in 54 one large irregular air-sinus extended forward as far as the anterior lacrimal crest.

end, and is directed downwards, backwards and a little laterally. The mucous lining of the lacrimal sac and nasolacrimal duct is covered with columnar epithelium which in places is ciliated.

FIG. 1043.—The right auricle. Lateral surface.



THE ORGAN OF HEARING

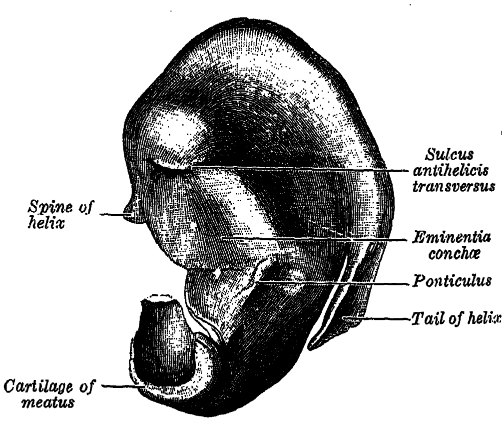
The ear or organ of hearing is divisible into three parts: the external ear, the middle ear or tympanic cavity, and the internal ear or labyrinth.

THE EXTERNAL EAR

The **external ear** consists of the expanded portion named the *auricle* and the *external auditory meatus.* The former projects from the side of the head and serves to collect the air-vibrations by which sound is produced; the latter leads inwards from the bottom of the auricle and conducts the vibrations to the tympanic cavity.

The **auricle** (fig. 1043) is of an oval form, with its larger end directed upwards. Its lateral surface is irregularly concave, looks slightly forwards, and presents numerous eminences and depressions. The prominent rim of the auricle is called the *helix*; where the helix turns downwards posteriorly, a small tubercle termed the *auricular tubercle,* is frequently seen; this tubercle is very evident about the sixth month of fœtal life, when the whole auricle has a close resemblance to that of some of the adult monkeys. Another curved prominence, parallel with and in front of the posterior part of the helix, is called the *antihelix*; this divides above into two crura, between which is a triangular depression, named the *triangular fossa.* The narrow curved depression between the helix and the antihelix is called the *scaphoid fossa*; the antihelix partly encircles a deep, capacious cavity, named the *concha of the auricle,* which is incompletely divided into two parts by the *crus* or anterior end of the helix. Below the crus of the helix and in front of the concha, a small, curved flap, termed the *tragus,* projects backwards over the orifice of the meatus. Opposite the tragus, and separated from it by the *intertragic notch,* there is a small tubercle, named the *antitragus.* The *lobule,* composed of fibrous and adipose tissues, and devoid of the firmness and elasticity of the rest of the auricle, lies below the antitragus.

FIG. 1044.—The cranial surface of the cartilage of the right auricle.



The cranial surface of the auricle presents elevations which correspond to the depressions on its lateral surface, and after which they are named, e.g. eminentia conchæ, eminentia triangularis, etc.

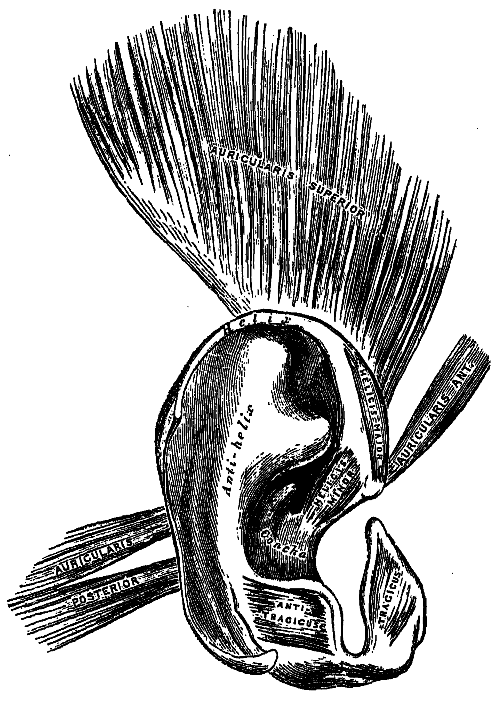
Structure.—The auricle is composed of a thin plate of elastic fibrocartilage, covered with skin, and connected with the surrounding parts by ligaments and muscles; it is continuous with the cartilaginous portion of the external auditory meatus, and the latter is joined to the margins of the bony meatus by fibrous tissue.

The *skin of the auricle* is thin, closely adherent to the cartilage, and covered with fine

hairs which are furnished with sebaceous glands; these glands are most numerous in the concha and scaphoid fossa. On the tragus and antitragus, and in the intertragic notch the hairs are strong and numerous. The skin of the auricle is continuous with that lining the external auditory meatus.

The *cartilage of the auricle* (figs. 1044, 1045) consists of a single piece; upon its surface the eminences and depressions above described are found. It is absent from the lobule; it is deficient, also, between the tragus and beginning of the helix, the gap being filled up by dense fibrous tissue. At the front part of the auricle, where the helix bends upwards, there is a small projection of the cartilage, called the *spine of the helix*, while in the lower part of the helix the cartilage is prolonged downwards as a tail-like process, named the *tail of the helix*; the latter is separated from the antihelix by the *fissura antitragohelicina*. The cranial surface of the cartilage exhibits a transverse furrow, named the *sulcus antihelicis transversus*, which corresponds with the inferior crus of the antihelix and separates the eminentia conchæ from the eminentia triangularis. The eminentia conchæ is crossed by a vertical ridge (*ponticulus*) which gives attachment to the Auricularis posterior muscle. In the cartilage of the auricle there are two fissures, one behind the crus helicis and another in the tragus.

FIG. 1045.—The muscles of the right auricle.



The *ligaments of the auricle* consist of two sets: (1) extrinsic, connecting it to the temporal bone; (2) intrinsic, connecting various parts of its cartilage together.

The *extrinsic ligaments* are two in number, anterior and posterior. The *anterior ligament* extends from the tragus and spine of the helix to the root of the zygomatic process of the temporal bone. The *posterior ligament* passes from the posterior surface of the concha to the lateral surface of the mastoid process.

The chief *intrinsic ligaments* are: (*a*) a strong fibrous band, stretching from the tragus to the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (*b*) a band between the antihelix and the tail of the helix. Other less important bands are found on the cranial surface of the auricle.

The *muscles of the auricle* (fig. 1045) consist of two sets: (1) the extrinsic, which connect it with the skull and scalp and move the auricle as a whole; and (2) the intrinsic, which extend from one part of the auricle to another.

The extrinsic muscles are the Auriculares anterior, superior et posterior.

The *Auricularis anterior*, the smallest of the three, is thin, fan-shaped, and its fibres are pale and indistinct. It arises from the lateral edge of the epicranial aponeurosis, and its fibres converge to be inserted into the spine of the helix.

The *Auricularis superior*, the largest of the three, is thin and fan-shaped. Its fibres arise from the epicranial aponeurosis, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the auricle.

The *Auricularis posterior* consists of two or three fleshy fasciculi, which arise by short aponeurotic fibres from the mastoid portion of the temporal bone, and are inserted into the ponticulus on the eminentia conchæ.

Nerve-supply.—The Auriculares anterior et superior are supplied by the temporal branches, and the Auricularis posterior by the posterior auricular branch, of the facial nerve.

Actions.—In man, these muscles possess very little action; the Auricularis anterior draws the auricle forwards and upwards; the Auricularis superior raises it slightly; and the Auricularis posterior draws it backwards.

The intrinsic muscles are the:

Helicis major.	Antitragicus.
Helicis minor.	Transversus auriculæ.
Tragicus.	Obliquus auriculæ.

The *Helicis major* is a narrow vertical band situated upon the anterior margin of the helix. It arises from the spine of the helix, and is inserted into the anterior border of the helix, where the latter is about to curve backwards.

The *Helicis minor* is an oblique fasciculus, covering the crus helicis.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

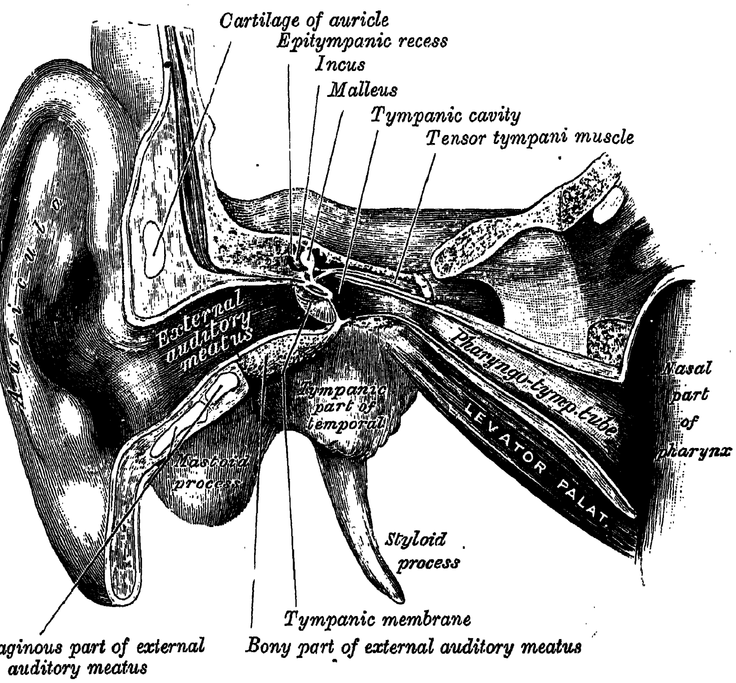
The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the tail of the helix and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the auricle. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the eminentia scaphæ.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and posterior parts of the eminentia conchæ to the eminentia triangularis.

Nerve-supply.—The intrinsic muscles on the lateral surface are supplied by the temporal branches of the facial nerve, the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

FIG. 1046.—The external and middle portions of the right ear, from the front.



The *arteries of the auricle* are: (*a*) the posterior auricular branch of the external carotid artery, which supplies three or four branches to the cranial surface; twigs from these reach the lateral surface, some by passing through the fissures of the auricular cartilage, and others by turning round the margin of the helix; (*b*) the anterior auricular branches of the superficial temporal artery, which are distributed to the lateral surface; and (*c*) a branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *sensory nerves* are: the great auricular and lesser occipital nerves, from the cervical plexus; the auriculotemporal branch of the mandibular nerve; and the auricular branch of the vagus nerve.

The **external auditory meatus** extends from the bottom of the concha to the tympanic membrane (figs. 1046, 1047). It is about 4 cm. long if measured from the tragus; from the bottom of the concha its length is about 2·5 cm. It forms an S-shaped curve, and is directed at first medially, forwards, and slightly upwards (*pars externa*); it then passes medially, backwards, and upwards (*pars media*), and lastly is carried medially, forwards, and slightly downwards (*pars interna*). It is an oval cylindrical canal, the greatest diameter of the oval being directed downwards and backwards at the external orifice, but nearly hori-

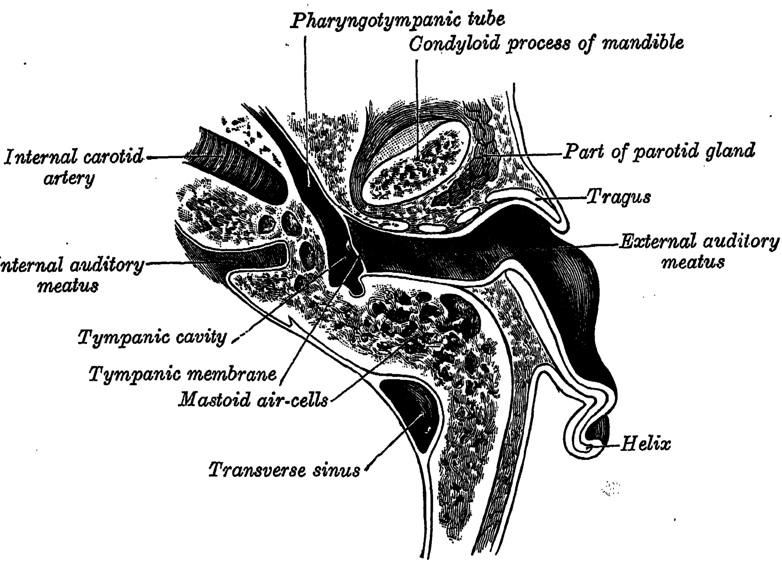
zontally at the medial end. It presents two constrictions, one near the medial end of the cartilaginous portion, and another, named the *isthmus*, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the medial end of the meatus, is obliquely directed; in consequence of this obliquity the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external auditory meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The *cartilaginous portion* is about 8 mm. long; it is continuous with the cartilage of the auricle and is fixed to the circumference of the osseous portion. The cartilage is deficient at the upper and posterior parts of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The *osseous portion* is about 16 mm. long, and is narrower than the cartilaginous portion. It is directed medially, forwards, and slightly downwards,

FIG. 1047.—A horizontal section through the left ear. Upper half of the section.



forming in its course a slight curve the convexity of which is upwards and backwards. Its medial end is smaller than the lateral end, and is sloped, the anterior wall projecting beyond the posterior for about 4 mm.; this end is marked, except at its upper part, by a narrow groove, named the *tympanic sulcus*, in which the circumference of the tympanic membrane is attached. Its lateral end is dilated, and rough in the greater part of its circumference for the attachment of the cartilaginous portion. The anterior and inferior parts of the osseous portion are formed by the tympanic part of the temporal bone, which, in the fœtus, exists as the tympanic ring (p. 301).

The skin which envelops the auricle is continued into the external auditory meatus and covers the outer surface of the tympanic membrane. It is thin and closely adherent to the cartilaginous and osseous parts of the tube. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus there are numerous *ceruminous glands*, which secrete the ear-wax; their structure resembles that of the sudoriferous glands (p. 1225).

Relations of the meatus.—The condyloid process of the mandible lies in front of the meatus, but the two are sometimes separated by a small portion of the parotid gland. The movements of the mandible influence to some extent the lumen of the cartilaginous portion. Above the osseous part is the middle cranial fossa; behind it are the mastoid air-cells, separated from the meatus by a thin layer of bone.

The *arteries* supplying the meatus are branches from the posterior auricular, (internal) maxillary, and temporal arteries.

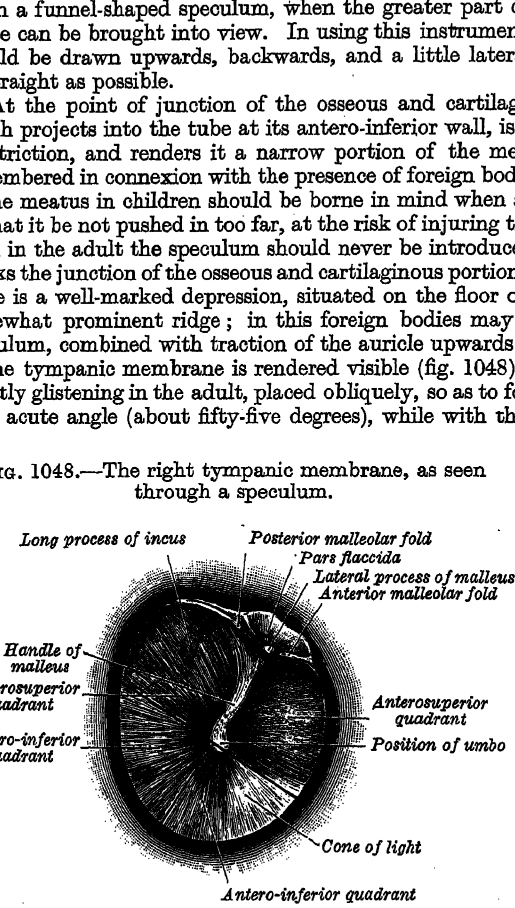
The *nerves* are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus nerve.

Applied Anatomy.—Malformations, such as imperfect development of the external parts, supernumerary auricle, or absence of the meatus, are occasionally met with.

The external auditory meatus can be examined most satisfactorily by light reflected down a funnel-shaped speculum, when the greater part of the canal and tympanic membrane can be brought into view. In using this instrument, it is advisable that the auricle should be drawn upwards, backwards, and a little laterally, so as to render the meatus as straight as possible.

At the point of junction of the osseous and cartilaginous portions an obtuse angle, which projects into the tube at its antero-inferior wall, is formed; this produces a sort of constriction, and renders it a narrow portion of the meatus—an important point to be remembered in connexion with the presence of foreign bodies in the meatus. The shortness of the meatus in children should be borne in mind when an aural speculum is introduced, so that it be not pushed in too far, at the risk of injuring the tympanic membrane; indeed even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. Just in front of the membrane there is a well-marked depression, situated on the floor of the meatus, and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upwards and backwards, the greater part of the tympanic membrane is rendered visible (fig. 1048). It is a pearly-grey membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about fifty-five degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. A reddish-yellow streak can be seen about midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upwards and forwards; this is the handle of the malleus, which is attached to the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, round prominence is plainly to be seen; this is the lateral or short process of the malleus, projecting against the membrane. The tympanic membrane does not present a plane surface; on the contrary, its centre is drawn inwards, on account of its connexion with the manubrium of the malleus.

Fig. 1048.—The right tympanic membrane, as seen through a speculum.



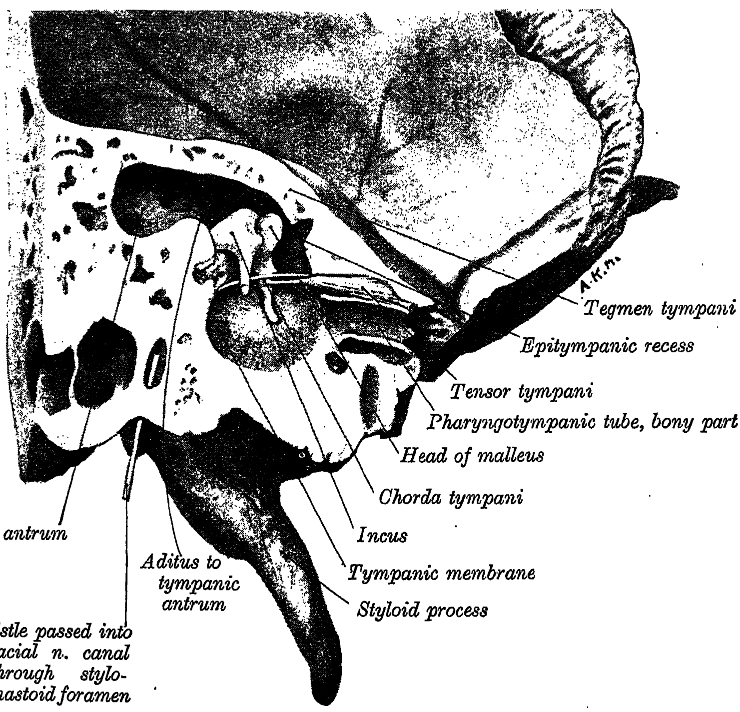
The connexions of the nerves of the meatus explain the occurrence of constant coughing and sneezing, from implication of the vagus, when there exists any source of irritation in the meatus; and the vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly people. No doubt also the association of earache with toothache or with cancer of the tongue is due to implication of the mandibular branch of the trigeminal nerve, which supplies the teeth and the tongue also. The upper half of the tympanic membrane is much more vascular than the lower half; for this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The Middle Ear, or Tympanic Cavity

The middle ear or tympanic cavity, is an irregular, laterally compressed space within the temporal bone. It is lined with mucous membrane (p. 1202) and filled with air, which is conveyed to it from the nasal part of the pharynx through the pharyngotympanic tube (auditory tube). It contains a chain of movable bones, which connect its lateral to its medial wall and transmit the vibrations of the tympanic membrane across the cavity to the internal ear.

The tympanic cavity consists of two parts: the *tympanic cavity proper*, opposite the tympanic membrane, and the *epitympanic recess*, above the level of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. Including the epitympanic recess, the vertical and anteroposterior diameters of the cavity are each about 15 mm. The transverse diameter measures about 6 mm. above and 4 mm. below; opposite the centre of the tympanic membrane it is only about 2 mm. The tympanic cavity is bounded laterally by the tympanic membrane; medially, by the lateral wall of the internal ear; it communicates, behind, with the tympanic antrum and through it with the mastoid air-cells, and in front with the pharyngotympanic tube (fig. 1046).

Fig. 1049.—An oblique section through the left temporal bone, to show the lateral wall of the middle ear, and the tympanic antrum.



The **roof** of the tympanic cavity is formed by a thin plate of bone, named the *tegmen tympani*, which separates the cranial and tympanic cavities, and forms the greater part of the anterior surface of the petrous portion of the temporal bone; it is prolonged backwards so as to roof the tympanic antrum, and forwards to cover the canal for the Tensor tympani muscle.

The **floor** is narrow, and consists of a thin, convex plate of bone which separates the tympanic cavity from the superior bulb of the internal jugular vein; in places this bony wall may be deficient, and then the tympanic cavity is separated from the vein by mucous membrane and fibrous tissue only. In the floor of the tympanic cavity, near the medial wall, there is a small aperture for the passage of the tympanic branch of the glossopharyngeal nerve.

The **lateral wall** of the tympanic cavity (fig. 1049) is formed mainly by the tympanic membrane, but partly by the ring of bone in which this membrane is attached. There is a deficiency or notch in the upper part of the ring, close to which are three small apertures, viz.: the anterior and posterior canaliculi for the chorda tympani nerve and the petrotympanic fissure.

The *posterior canaliculus for the chorda tympani nerve* is situated in the angle of junction between the posterior and lateral walls of the tympanic cavity

immediately behind the tympanic membrane and on a level with the upper end of the manubrium mallei; it leads into a minute canal, which descends in front of the canal for the facial nerve, and ends in that canal about 6 mm. above the stylomastoid foramen. Through it the chorda tympani nerve and a branch of the stylomastoid artery enter the tympanic cavity.

The *petrotympanic fissure* opens just above and in front of the ring of bone into which the tympanic membrane is inserted; in this situation it is a mere slit about 2 mm. in length. It lodges the anterior process and anterior ligament of the malleus, and transmits to the tympanic cavity the anterior tympanic branch of the (internal) maxillary artery.

The *anterior canaliculus for the chorda tympani nerve* is placed at the medial end of the petrotympanic fissure; through it the chorda tympani nerve leaves the tympanic cavity.

FIG. 1050.—The membranous wall of the right tympanic cavity. (Testut.)

The malleus has been resected immediately below its lateral process in order to show the malleolar folds and the pars flaccida.
1. Tympanic membrane. 2. Umbo. 3. Handle of malleus; 4. its cut surface. 5. Anterior malleolar fold. 6. Posterior malleolar fold. 7. Pars flaccida. 8, 9. Anterior and posterior recesses of tympanic membrane. 10. Fibrocartilaginous ring. 11. Petrotympanic fissure. 12. Pharyngotympanic tube. 13. Posterior canaliculus for chorda tympani. 14. Anterior canaliculus for chorda tympani. 15. Fossa incudis for short process of the incus. 16. Prominentia styloidea.

The **tympanic membrane** (figs. 1048, 1050) separates the tympanic cavity from the external auditory meatus. It is thin and semitransparent, nearly oval in form, somewhat broader above than below, and placed very obliquely, forming an angle of about fifty-five degrees with the floor of the meatus. Its longest diameter is downwards and forwards, and measures from 9 to 10 mm.; its shortest diameter from 8 to 9 mm. The greater part of its circumference is thickened, and forms a *fibrocartilaginous ring* which is fixed in the *tympanic sulcus* at the medial end of the meatus. This sulcus is deficient superiorly, and from the ends of the notch two bands, termed the *anterior* and *posterior malleolar folds*, are prolonged to the lateral process of the malleus. The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the *pars flaccida*; a small orifice is sometimes seen in it. The chief part of the membrane is taut and is named the *pars tensa*. The manubrium of the malleus is firmly attached to the inner surface of the tympanic membrane as far as its centre, which projects towards the tympanic cavity; the inner surface of the membrane is thus convex, and the point of greatest convexity is named the *umbo*. Although the membrane as a whole is convex on its inner surface, its radiating fibres (*vide infra*) are curved with their concavities directed inwards, and the membrane has a shape somewhat resembling that of a convolvulus flower.

Structure.—The tympanic membrane is composed of three strata: an outer (cuticular), an intermediate (fibrous), and an inner (mucous). The *cuticular layer* is derived from the skin which lines the external auditory meatus, and consists of stratified epithelium. The *fibrous stratum* consists of two layers: a superficial layer of radiate fibres which diverge from the manubrium of the malleus, and a deep layer of circular fibres, which are plentiful around the circumference, but sparse and scattered near the centre, of the membrane. Branched or dendritic fibres (Grüber) are also present, especially in the posterior half of the membrane. The *mucous layer* is a part of the mucous membrane of the tympanic cavity; it is thickest towards the upper part of the membrane, and is covered by a single layer of flattened cells. In the flaccid part of the tympanic membrane the fibrous stratum is replaced by loose connective tissue.

Vessels and Nerves.—The *arteries* of the tympanic membrane are derived from the deep auricular branch of the (internal) maxillary artery, which ramifies beneath the cuticular stratum; and from the stylomastoid branch of the posterior auricular artery, and tympanic branch of the maxillary artery, which are distributed to the mucous surface. The superficial *veins* open into the external jugular vein; those on the deep surface drain partly into the transverse sinus and veins of the dura mater, and partly into the plexus of veins on the pharyngotympanic (auditory) tube. The membrane receives its *nerve-supply* from the auriculotemporal branch of the mandibular nerve, the auricular branch of the vagus nerve, and the tympanic branch of the glossopharyngeal nerve.

The **medial wall** (fig. 1051) of the tympanic cavity is formed by the lateral wall of the internal ear. It presents for examination the promontory, the fenestra vestibuli, the fenestra cochleæ and the prominence of the facial nerve canal.

The *promontory* is a rounded prominence furrowed by small grooves which lodge the nerves of the tympanic plexus. It is formed by the projection outwards of the first turn of the cochlea. A minute spicule of bone frequently connects the promontory to the pyramid on the posterior wall.

The *fenestra vestibuli* is a reniform opening, situated above and behind the promontory, and leading from the tympanic cavity into the vestibule of the internal ear; its long diameter is horizontal, and its convex border is directed upwards. In the recent state it is occupied by the base of the stapes, the circumference of which is fixed to the margin of the fenestra by the annular ligament.

The *fenestra cochleæ* is situated below and a little behind the fenestra vestibuli, from which it is separated by the posterior part of the promontory. It lies completely under cover of the overhanging edge of the promontory, in a deep hollow or niche. It is placed very obliquely, and, in the macerated bone, opens upwards and forwards from the tympanic cavity into the scala tympani of the cochlea. In the recent state it is closed by the *secondary tympanic membrane*, which is somewhat concave towards the tympanic cavity and convex towards the cochlea, the membrane being bent so that its posterosuperior one-third forms an angle with its antero-inferior two-thirds. This membrane consists of three layers: an external, derived from the mucous lining of the tympanic cavity; an internal, from the lining membrane of the cochlea; and an intermediate, fibrous, layer.

The *prominence of the facial nerve canal* indicates the position of the upper part of the bony canal in which the facial nerve is contained; this canal, the wall of which may be partly deficient, traverses the medial wall of the tympanic cavity from before backwards, immediately above the fenestra vestibuli, and then curves downwards in the posterior wall.

The **posterior wall** of the tympanic cavity is wider above than below, and presents for examination the entrance to the tympanic antrum, the pyramid and the fossa incudis.

The *aditus to the tympanic antrum* is a large irregular aperture, which leads backwards from the epitympanic recess into the upper part of an air-sinus, named the *tympanic antrum* (p. 297). On the medial wall of the entrance to the antrum there is a rounded eminence, situated above and behind the prominence of the facial nerve canal; it corresponds with the position of the lateral semicircular canal.

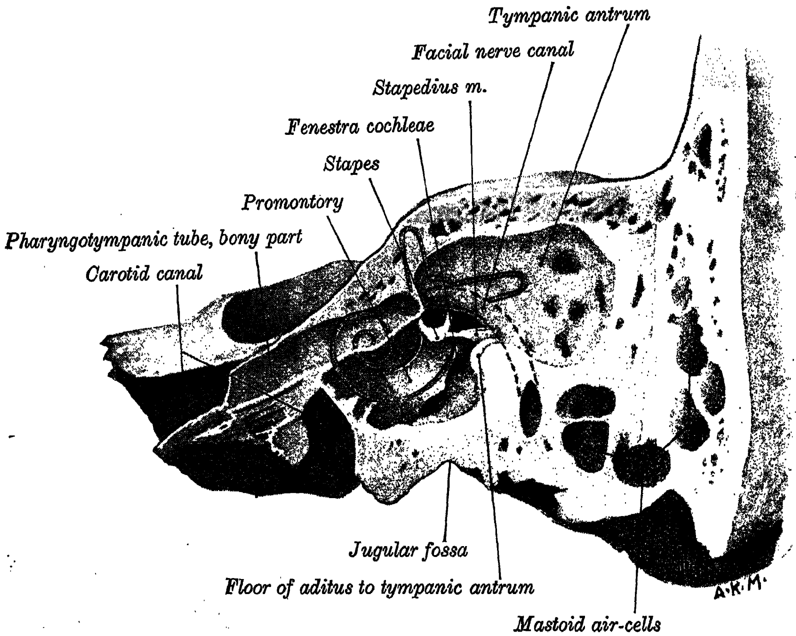
The *pyramid* is situated immediately behind the fenestra vestibuli, and in front of the vertical portion of the facial nerve canal; it is hollow, and contains the Stapedius muscle; its summit projects forwards towards the fenestra vestibuli, and is pierced by a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged downwards and backwards in front of the facial nerve canal, and communicates with the latter by a minute aperture which transmits a twig from the facial nerve to the Stapedius muscle.

The *fossa incudis* is a small depression in the lower and posterior part of the epitympanic recess; it lodges the short process of the incus, which is fixed to the fossa by ligamentous fibres.

The *tympanic antrum* is a small air-sinus in the posterior portion of the petrous part of the temporal bone, communicating with the epitympanic

recess through the aditus, which is placed in the *upper* part of its anterior wall. Its diameters do not often exceed 10 mm., but its topographical relations are of great importance to the surgeon. Its *lateral wall* is formed by the post-meatal process of the squamous part of the temporal bone and corresponds to the suprameatal triangle on the outer surface of the skull. This wall is only 2 mm. thick in the newly-born child but it usually averages 10-12 mm. in the adult. *Posteriorly* the antrum is related to the sigmoid sinus, but some of the mastoid air-cells may intervene between them. *Superiorly* the roof is formed by the tegmen tympani, which separates the antrum from the middle cranial

FIG. 1051.—An oblique section through the left temporal bone, to show the medial wall of the middle ear.



The cochlea and the superior and lateral semicircular canals are outlined in *blue*. Note the relationship of the first coil of the cochlea to the promontory, and the relationships of the facial nerve canal and the lateral semicircular canal to the medial wall of the aditus.

fossa and the temporal lobe of the brain. *Inferiorly* the floor shows a number of apertures which communicate with the mastoid air-cells. These air-cells vary considerably in number, size and form, and, like the tympanic antrum, are lined by mucous membrane continuous with that lining the tympanic cavity.

The **anterior wall** of the tympanic cavity is constricted owing to the approximation of the medial and lateral walls of the cavity. Its lower and larger part consists of a thin lamina of bone which forms the posterior wall of the carotid canal, and is perforated by the superior and inferior caroticotympanic nerves, and the tympanic branch of the internal carotid artery. At the upper part of the anterior wall there are two canals, placed one above the other; the higher is the *canal for the Tensor tympani muscle*, the lower, the *bony part of the pharyngotympanic* (*auditory*) *tube*. These canals incline downwards and forwards, and open in the angle between the squamous and petrous parts of the temporal bone; they are separated by a thin, bony septum. The canal for the Tensor tympani and the septum run backwards on the medial wall of the tympanic cavity, and end immediately above the fenestra vestibuli, where the posterior end of the septum is curved laterally to form a pulley, named the processus cochleariformis, over which the tendon of the Tensor tympani bends

in a lateral direction to reach its insertion into the upper part of the manubrium mallei.

The **pharyngotympanic tube** (auditory tube) is the channel through which the tympanic cavity communicates with the nasal part of the pharynx. Its length is about 36 mm., and its direction is downwards, forwards and medially, forming an angle of about 45° with the sagittal plane and one of about 30° with the horizontal plane, It is formed partly of bone, partly of cartilage and fibrous tissue (fig. 1046).

The *bony part* of the tube is about 12 mm. long. It begins in the anterior wall of the tympanic cavity, and, gradually narrowing, ends at the angle of junction of the squamous and petrous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous part; the carotid canal lies on its medial side. It is oblong in transverse section with its greater diameter from side to side.

The *cartilaginous part* of the tube, about 24 mm. long, is formed of a triangular plate of cartilage, the greater part of which is situated in the posteromedial wall of the tube. The apex of the fibrocartilage is attached by fibrous tissue to the circumference of the medial end of the bony part of the tube, while its base lies directly under the mucous membrane of the lateral wall of the nasal part of the pharynx, where it forms an elevation, known as the *tubal elevation*, behind the pharyngeal orifice of the tube. The upper part of the cartilage is bent laterally and downwards, and the cartilage therefore consists of a broad medial *lamina*, and a narrow lateral *lamina*. On transverse section the cartilage has the appearance of a hook; the groove or furrow produced by the bending of the cartilage is open below and laterally, and this part of the wall of the canal is completed by fibrous membrane. The cartilage is fixed to the base of the skull in a groove between the petrous part of the temporal bone and the greater wing of the sphenoid bone; this groove ends near the root of the medial pterygoid plate. The cartilaginous and bony parts of the tube are not in the same plane, the former inclining downwards a little more than the latter. The diameter of the tube is greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous portions, and again increased towards the tympanic cavity; the narrowest part of the tube is termed the *isthmus*.

Anterolaterally the Tensor palati muscle separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani nerve and the middle meningeal artery. This muscle receives some fibres from the lateral lamina of the cartilage and from the membranous part of the tube; these fibres constitute the *Dilatator tubæ* muscle. Postero-medially the tube is related to the petrous part of the temporal bone and to the Levator palati muscle, which arises partly from its medial lamina. The position and relations of the pharyngeal orifice are described with the nasal part of the pharynx (p. 1290).

The mucous membrane of the tube is continuous in front with that of the pharynx, and behind with that of the tympanic cavity; it is covered with ciliated columnar epithelium and is thin in the bony part, while in the cartilaginous part it contains many mucous glands, and near the pharyngeal orifice a considerable amount of adenoid tissue, named by Gerlach the *tube-tonsil*.

The tube is opened during deglutition by the Salpingopharyngeus and Dilatator tubæ muscles. H. Blakeway * is of opinion that contraction of the Tensor palati is more likely to produce closure than opening of the tube.

In the new-born child the pharyngotympanic tube is about half as long as that of the adult. Its direction is more horizontal, and its bony part is relatively shorter, but much wider than in the adult. Its pharyngeal orifice is a narrow slit, which is on a level with the palate and is devoid of a tubal elevation.

Vessels and Nerves.—The *arteries* of the pharyngotympanic tube are derived from the ascending pharyngeal branch of the external carotid artery and from two branches of the (internal) maxillary artery, viz. :—the middle meningeal artery and the artery of the

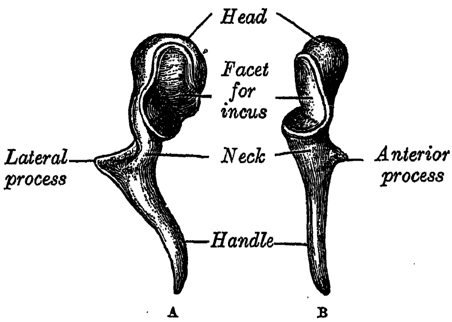
* *Journal of Anatomy and Physiology*, vol. xlviii.

pterygoid canal. The *veins* open into the pterygoid venous plexus. The *nerves* of the tube spring from the pharyngeal plexus and from the pharyngeal branch of the sphenopalatine ganglion.

The Auditory Ossicles

The tympanic cavity contains a chain of three movable ossicles, the *malleus*, *incus*, and *stapes*, the development of which is described on p. 99. The malleus is attached to the tympanic membrane, the base of the stapes to the circumference of the fenestra vestibuli, while the incus is placed between, and articulates with, the malleus and stapes.

Fig. 1052.—The left malleus. A. From behind. B. From the medial side.



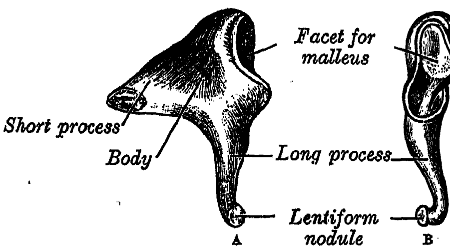
The **malleus** (fig. 1052), so named from its fancied resemblance to a hammer, is from 8 to 9 mm. long, and is the largest of the auditory ossicles. It consists of a head, neck and three processes, viz. the manubrium or handle, and the anterior and lateral processes.

The *head*, which is the large upper end of the bone, is situated within the epitympanic recess; it is ovoid in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is constricted near the middle, and consists of an upper larger and lower smaller part, situated nearly at right angles to each other. Opposite the constriction the lower margin of the facet projects in the form of a process, which is named the *cog-tooth* or *spur* of the malleus.

The *neck* is the contracted part just beneath the head; below the neck there is an enlargement to which the various processes are attached.

The *handle of the malleus* is connected by its lateral margin with the tympanic membrane. It is directed downwards, medially and backwards; it decreases in size towards its free end, which is curved slightly forwards and flattened transversely. Near the upper end of its medial surface there is a slight projection, into which the tendon of the Tensor tympani is inserted.

Fig. 1053.—The left incus. A. From the medial side. B. From the front.



The *anterior process* is a delicate spicule, directed forwards from the enlargement below the neck; it is connected to the petrotympanic fissure by ligamentous fibres. In the fœtus this is the longest process of the malleus, and it is continuous in front with the cartilage of Meckel (p. 99).

The *lateral process* is a conical projection which springs from the root of the handle of the malleus; it is directed laterally, and is attached to the upper part of the tympanic membrane and, by means of the anterior and posterior malleolar folds, to the extremities of the notch at the upper part of the tympanic sulcus.

Ossification.—The malleus, with the exception of its anterior process, is ossified from a single centre, which appears near the neck of the bone. The anterior process is ossified separately, in membrane, and joins the main part of the bone about the sixth month of fœtal life.

The **incus** (fig. 1053) has received its name from its supposed resemblance to an anvil, but its shape is more like that of a premolar tooth, with two widely diverging roots. It consists of a body and two processes.

The *body* is somewhat cubical, but compressed laterally. On its anterior

surface there is a saddle-shaped facet, for articulation with the head of the malleus.

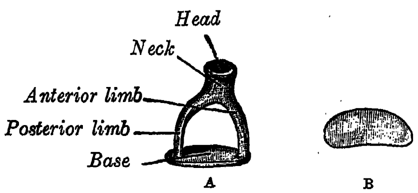
The *long process*, rather more than half the length of the handle of the malleus, descends nearly vertically, behind and parallel to that process ; its lower end bends medially, and terminates in a rounded projection, named the *lentiform nodule*, the inner surface of which is covered with cartilage, and articulates with the head of the stapes.

The *short process*, somewhat conical in shape, projects backwards, and is attached by ligamentous fibres to the fossa incudis, in the lower and posterior part of the epitympanic recess.

Ossification.—The incus is ossified from one centre, which appears in the upper part of its long process ; the lentiform nodule may have a separate centre.

The **stapes** (fig. 1054), so called from its resemblance to a stirrup, consists of a head, neck, two limbs and a base.

FIG. 1054.—A. The left stapes. B. Medial surface of the base of the stapes.



The *head* is directed laterally, and on it there is a depression for articulation with the lentiform nodule of the incus.

The *neck* is the constricted part supporting the head ; the tendon of the Stapedius muscle is inserted into its posterior surface.

The *limbs* diverge from the neck and are connected at their ends by a flattened oval plate, termed the *base*, which forms the footplate of the stirrup and is fixed to the margin of the fenestra vestibuli by a ring of ligamentous fibres. The anterior limb is shorter and less curved than the posterior.

Ossification.—The stapes is ossified from a single centre, which appears in the base of the bone.

The articulations of the auditory ossicles.—The incudomalleolar joint is a saddle articulation. The incudostapedial joint is a ' ball-and-socket ' articulation. Each is enveloped by an articular capsule.

The ligaments of the ossicles.—The ossicles are connected to the walls of the tympanic cavity by ligaments : three for the malleus, and one each for the incus and stapes.

The *anterior ligament of the malleus* is attached by one end to the neck of the malleus, just above the anterior process, and by the other to the anterior wall of the tympanic cavity, close to the petrotympanic fissure, some of its fibres being prolonged through the fissure to reach the spine of the sphenoid bone.

The *lateral ligament of the malleus* is a triangular band passing from the posterior part of the border of the tympanic notch to the head of the malleus. Helmholtz described the anterior ligament and the posterior part of the lateral ligament as forming together the ' axis ligament ' around which the malleus rotates.

The *superior ligament of the malleus* connects the head of the malleus to the roof of the epitympanic recess.

The *posterior ligament of the incus* connects the end of the short process of the incus to the fossa incudis.

A *superior ligament of the incus* has been described, but it is little more than a fold of mucous membrane.

The vestibular surface and the circumference of the base of the stapes are covered with hyaline cartilage ; that encircling the base is attached to the margin of the fenestra vestibuli by a ring of elastic fibres, termed the *annular ligament of the base of the stapes*. The posterior part of this ligament is much narrower than the anterior part, and acts as a kind of hinge on which the base of the stapes moves when the Stapedius muscle contracts.

The **muscles of the tympanic cavity** are the Tensor tympani and Stapedius.

The **Tensor tympani** (fig. 1046) is contained in the bony canal above the bony part of the pharyngotympanic (auditory) tube, from which it is separated by a thin bony septum. It arises from the cartilaginous portion of the pharyngotympanic tube and the adjoining part of the greater wing of the sphenoid, as well as from the bony canal in which it is contained. Passing backwards through the canal, it ends in a slender tendon which bends laterally round the pulley-like processus cochleariformis, and is inserted into the handle of the malleus, near its root.

Nerve-supply.—The Tensor tympani is supplied by a branch of the mandibular nerve through the otic ganglion.

The **Stapedius** arises from the wall of a conical cavity in the pyramid; its tendon emerges from the orifice at the apex of the eminence, and, passing forwards, is inserted into the posterior surface of the neck of the stapes.

Nerve-supply.—The Stapedius is supplied by a branch of the facial nerve.

Actions.—Under normal conditions, the Tensor tympani and the Stapedius contract simultaneously and reflexly in response to sounds of fairly high intensity, exerting "a protective damping effect upon sound vibrations reaching the internal ear." *

Movements of the auditory ossicles.—The handle of the malleus follows all the movements of the tympanic membrane, while the malleus and incus rotate together around an axis which runs through the short process of the incus and the anterior ligament of the malleus. When the tympanic membrane and the handle of the malleus move inwards, the long process of the incus also moves in the same direction and pushes the base of the stapes towards the labyrinth. This motion is communicated to the fluid (perilymph) contained within the labyrinth and the movement of the perilymph causes an outward bulging of the secondary tympanic membrane, which closes the fenestra cochleæ. The conditions are reversed when the tympanic membrane moves in an outward direction, but if this movement of the membrane be exaggerated the incus does not follow the full outward excursion of the malleus, but merely glides on this bone at the incudomalleolar joint, and thus the danger of pulling the foot of the stapes out of the fenestra vestibuli is avoided. When the handle of the malleus is carried inwards, the cog-tooth or spur on the lower margin of the head of the malleus locks the incudomalleolar joint, and this necessitates an inward movement of the long process of the incus; the joint is unlocked when the handle of the malleus is carried outwards.

The **mucous membrane** of the tympanic cavity is continuous with that of the pharynx, through the pharyngotympanic (auditory) tube. It invests the auditory ossicles and the muscles and nerves contained in the tympanic cavity, forms the inner layer of the tympanic membrane, and the outer layer of the secondary tympanic membrane, and lines the tympanic antrum and mastoid air-cells. It forms several vascular folds which extend from the walls of the tympanic cavity to the ossicles; of these, one descends from the roof of the cavity to the head of the malleus and upper margin of the body of the incus, and a second invests the Stapedius muscle; other folds invest the chorda tympani nerve and the Tensor tympani muscle. These folds separate off pouch-like recesses, and give the interior of the tympanum a somewhat honeycombed appearance. One of these pouches, termed the *superior recess of the tympanic membrane*, lies between the neck of the malleus and the membrana flaccida. Two other recesses, termed the *anterior* and *posterior recesses of the tympanic membrane*, may be mentioned: they are formed by the mucous membrane which envelops the chorda tympani nerve, and are situated, one in front of, and the other behind, the handle of the malleus. In the tympanic cavity the mucous membrane is pale, thin, slightly vascular, and covered with cubical epithelial cells, except around the orifice of the pharyngotympanic tube, where the cells are ciliated. There are no mucous glands in the tympanic cavity. The tympanic antrum and the mastoid air-cells are lined by a non-ciliated epithelium, which is squamous in character.

Vessels and Nerves.—The *arteries* are six in number. Two of them are larger than the others, viz. the anterior tympanic branch of the (internal) maxillary artery, which supplies the tympanic membrane, and the stylomastoid branch of the posterior auricular artery, which supplies the posterior part of the tympanic cavity and mastoid air-cells. The smaller arteries are—the superficial petrosal branch of the middle meningeal artery, which enters through the hiatus for the greater superficial petrosal nerve; the superior tympanic branch of the middle meningeal artery, which traverses the canal for the Tensor tympani; a branch from the ascending pharyngeal artery, and another from the artery of the pterygoid canal, which accompany the pharyngotympanic tube; and the tympanic branch from the internal carotid artery, given off in the carotid canal and perforating the thin anterior wall of the tympanic cavity. The *veins* terminate in the pterygoid venous plexus and in the superior petrosal sinus. From the mucous membrane of the tympanic antrum a small group of veins runs medially through the arch formed by the superior semicircular canal. They emerge on the posterior surface of the petrous part of the temporal bone through the subarcuate fossa, and open into the superior petrosal sinus. These small veins are the remains of the large subarcuate veins of the child, and constitute a pathway of infection

* C. S. Hallpike, "On the Function of the Tympanic Muscles," *Proc. Roy. Soc. Med.*, 1935, vol. xxviii.

from the tympanic antrum to the meninges of the brain. The *nerves* constitute the tympanic plexus, which ramifies upon the surface of the promontory. The plexus is formed by (1) the tympanic branch of the glossopharyngeal nerve, and (2) the caroticotympanic nerves.

The *tympanic branch of the glossopharyngeal* enters the tympanic cavity by the *canaliculus for the tympanic nerve,* and divides into branches which ramify on the promontory and enter into the formation of the tympanic plexus. The *superior and inferior caroticotympanic nerves,* from the carotid plexus of the sympathetic, pass through the wall of the carotid canal, and join the plexus. The tympanic plexus supplies, (*a*) branches to the mucous lining of the tympanic cavity, pharyngotympanic tube, and mastoid air-cells; (*b*) a branch which goes through an opening in front of the fenestra vestibuli and joins the greater superficial petrosal nerve; and (*c*) the *lesser superficial petrosal nerve,* which may be looked upon as the continuation of the tympanic branch of the glossopharyngeal nerve through the tympanic plexus. The lesser superficial petrosal nerve traverses a small canal below the canal for the Tensor tympani, runs past, and receives a connecting branch from, the ganglion of the facial nerve, and reaches the anterior surface of the temporal bone through a small opening on the lateral side of the hiatus for the greater superficial petrosal nerve. It then passes through the foramen ovale or the canaliculus innominatus (p. 291 *) and joins the otic ganglion (p. 1054).

The *chorda tympani nerve* crosses the tympanic cavity. It is given off from the facial nerve, about 6 mm. before that nerve emerges from the stylomastoid foramen. It runs upwards and forwards in a canal, and enters the tympanic cavity through the *posterior canaliculus,* and becomes invested with mucous membrane. It traverses the tympanic cavity, crossing medial to the tympanic membrane and the upper part of the handle of the malleus to the anterior wall, where it emerges through the *anterior canaliculus.*

Applied Anatomy.—Fractures of the middle fossa of the base of the skull almost invariably involve the tympanic roof, and are accompanied by a rupture of the tympanic membrane or fracture through the roof of the bony meatus. They are associated with profuse continued bleeding from the ear, and, if the dura mater has also been torn, with discharge of copious amounts of cerebrospinal fluid.

The tympanic cavity is very frequently the seat of disease, both suppurative and non-suppurative, and in practically every case the inflammation spreads upwards from the nose or throat along the pharyngotympanic tube. Acute inflammatory troubles spreading up to the tympanic cavity are usually associated with so much inflammatory swelling of the mucous membrane of the tube as to occlude it, and thus the products of inflammation are pent up in the tympanic cavity and directly involve the tympanic antrum. In such circumstances the only means of escape for the products is by rupture of the tympanic membrane, which usually occurs spontaneously and is followed by a free discharge of pus, with relief from the acute pain which exists in this condition. Should the swelling of the walls of the pharyngotympanic tube then subside, the normal drainage of the cavity will be established and the perforation in the drum will heal, but if not—as is often the case because the opening of the tube may be occluded by adenoid growths in the nasal part of the pharynx or other cause—the pus will continue to accumulate in the middle ear and will overflow through the perforation as a chronic otorrhœa. Several intracranial complications are often produced owing to purulent material being retained; thus an abscess may form between the bone and dura mater, (*a*) above the roof of the tympanic cavity, and immediately beneath the dura covering the temporal lobe of the brain, or (*b*) between the deep aspect of the mastoid process and the sigmoid sinus, possibly extending widely and surrounding the sinus. In this latter type of case thrombosis of the sinus readily occurs, and the clot being also infected tends to disintegrate and be carried into the general circulation, particles becoming lodged in the capillaries of the lungs and setting up abscesses therein. Pyæmia from sigmoid sinus thrombosis is more common than from any other focus of origin. In addition, bone disease of the tympanic cavity or antrum may be associated with severe and fatal septic meningitis, or with the formation of abscess in the brain, the most common sites being the temporal lobe and the hemisphere of the cerebellum.

In many cases of chronic bone disease in the tympanic cavity, the facial nerve becomes exposed as it lies in its canal and an inflammatory process is set up in the nerve, leading to facial paralysis of the infranuclear type (p. 1064).

In dealing with suppuration in the tympanum by operation, the tympanic antrum is first reached through the suprameatal triangle (p. 252), the posterior wall of the external auditory meatus being the direction which is taken. In enlarging the opening from the antrum to the tympanum, the facial nerve may be protected by passing a special probe through the passage, and only removing the bone from the lateral side. In the child the tympanic antrum is close to the surface, and the facial nerve is not covered by the mastoid process.

The Internal Ear

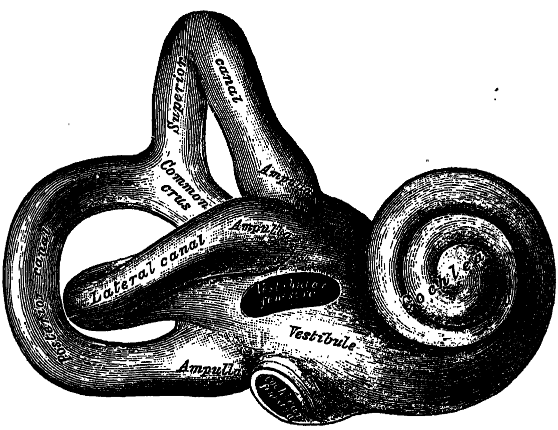
The **internal ear** is the essential part of the organ of hearing. It consists of two parts: (*a*) the *bony labyrinth*, a series of cavities within the petrous part of the temporal bone, and (*b*) the *membranous labyrinth*, a series of communicating membranous sacs and ducts, contained within the bony cavities.

The Bony Labyrinth (figs. 1055, 1056)

The **bony labyrinth** consists of three parts: the *vestibule*, the *semicircular canals* and the *cochlea*. These are cavities hollowed out of the substance of the bone, and lined by periosteum; they contain a clear fluid, known as the perilymph, in which the membranous labyrinth is placed.

The **vestibule** is the central part of the bony labyrinth, and is situated medial to the tympanic cavity, behind the cochlea and in front of the semicircular canals. It is somewhat ovoid in shape, but flattened transversely; it measures about 5 mm. from before backwards, the same from above downwards, and about 3 mm. across. In its *lateral wall* there is the opening of the fenestra vestibuli, closed in the recent state by the base of the stapes and its annular ligament. On the front part of the *medial wall* there is a small *spherical recess*, which lodges the saccule, and is perforated by several minute holes (*macula cribrosa media*). The recess corresponds to the inferior vestibular area in the bottom of the internal auditory meatus, and the foramina transmit filaments of the auditory nerve to the saccule. Behind this recess there is an oblique ridge, termed the *vestibular crest*, the anterior end of which is named the *pyramid of the vestibule*; this ridge divides below to enclose a small depression [the *cochlear recess*], which is perforated by a number of holes for the passage of filaments of the auditory nerve to the vestibular end of the duct of the cochlea. Above and behind the vestibular crest, and situated in the *roof* and medial wall of the vestibule there is an *elliptical recess* which lodges the utricle. The pyramid and adjoining part of the recessus ellipticus are perforated by a number of holes [*macula cribrosa superior*]; the holes in the pyramid transmit the nerves to the utricle, and those in the recessus ellipticus the nerves to the ampullæ of the superior and lateral semicircular ducts. The pyramid and the adjoining part of the elliptical recess correspond to the superior vestibular area at the bottom of the internal auditory meatus. The orifice of the *aqueduct of the vestibule* lies below the recessus ellipticus. This aqueduct extends to the posterior surface of the petrous portion of the temporal bone; it transmits a small vein, and contains a tubular prolongation of the membranous labyrinth which is termed the *ductus endolymphaticus*. At the *posterior part* of the vestibule there are the five orifices of the semicircular canals: at the *anterior part*, an elliptical opening leading into the scala vestibuli of the cochlea.

Fig. 1055.—The right osseous labyrinth. Lateral aspect.



The **semicircular canals** are three in number, superior, posterior and lateral, and are situated above and behind the vestibule. They are compressed from side to side, and each describes about two-thirds of a circle. They are unequal in length, but are about 0·8 mm. in diameter and each presents a dilatation at one end, called the *ampulla*, the diameter of which is nearly twice that of the

canal. They open into the vestibule by five orifices, one of which is common to two of the canals.

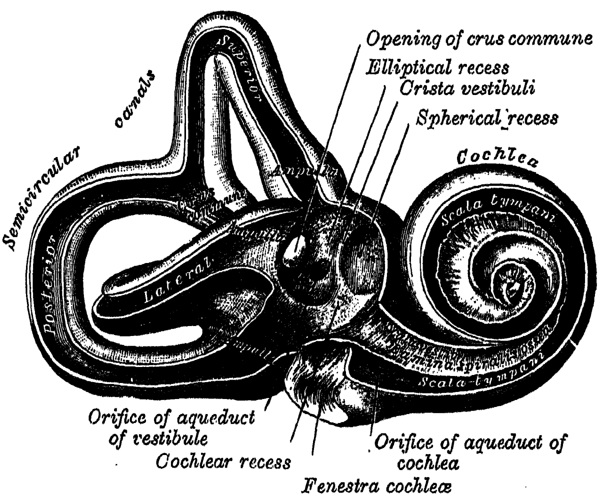
The *superior semicircular canal*, 15 to 20 mm. in length, is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms the arcuate eminence. Its anterolateral end is ampullated, and opens into the upper and lateral part of the vestibule ; the opposite end unites with the upper end of the posterior canal to form the *crus commune*, which is about 4 mm. long, and opens into the medial part of the vestibule.

The *posterior semicircular canal*, also vertical, is directed backwards, nearly parallel with the posterior surface of the petrous bone ; it is from 18 mm. to 22 mm. long ; its ampullated end opens into the lower part of the vestibule, where there are several small holes [*macula cribrosa inferior*] for the transmission of the nerves to this ampulla, their position corresponding to the foramen singulare in the bottom of the internal auditory meatus. Its upper end opens into the crus commune.

The *lateral* or *horizontal canal* is from 12 mm. to 15 mm. long, and its arch is directed horizontally backwards and laterally. Its anterior or ampullated end opens into the upper and lateral angle of the vestibule, just above the fenestra vestibuli and immediately below the ampullated end of the superior canal; its posterior end opens below the orifice of the crus commune.

The lateral semicircular canal of one ear is in the same plane as that of the other ear ; while the superior canal of one ear is in a plane parallel with that of the posterior * canal of the other ear.

FIG. 1056.—The interior of the right osseous labyrinth.



The cochlea (figs. 1056, 1057) bears a resemblance to the shell of the common snail ; it forms the anterior part of the labyrinth, is conical in form, and placed in front of the vestibule ; it measures about 5 mm. from base to apex, and its breadth across the base is about 9 mm. Its apex [or *cupola*] is directed forwards and laterally, with a slight inclination downwards, towards the upper and front part of the medial wall of the tympanic cavity; its base is directed towards the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear nerve. The cochlea † consists of a conical-shaped central axis, termed the *modiolus* ; of a canal, wound spirally around the central axis for two turns and three-quarters ; and of a delicate lamina, termed the *osseous spiral lamina*, which projects from the modiolus into the canal, and partially divides it. In the recent state the division of the canal is completed by the *basilar membrane*, which stretches from the free border of the osseous spiral lamina to the outer wall of the bony cochlea ; the two passages into which the cochlear canal is thus divided communicate with each other at the apex of the modiolus by a small opening, named the *helicotrema*.

The *modiolus* is the conical, central axis or pillar of the cochlea. Its base is broad, and appears at the bottom of the internal auditory meatus, where it corresponds with the tractus spiralis foraminosus, which is perforated by

* E. W. Peet (*Proc. Phys. Society*, 1937) has recently shown that those planes are not actually parallel.

† In the description which follows, the cochlea is supposed to be resting on its base.

numerous orifices for the transmission of the branches of the cochlear nerve; the nerves for the first turn and a half of the cochlea pass through the foramina of the tractus spiralis foraminosus; those for the apical turn, through the foramen centrale. The canals of the tractus spiralis foraminosus pass through the modiolus and successively bend outwards to reach the attached margin of the osseous spiral lamina. Here they become enlarged, and by their apposition form the *spiral canal of the modiolus*, which follows the course of the attached margin of the osseous spiral lamina and lodges the spiral ganglion. The foramen centrale is continued into a canal which runs through the middle of the modiolus to its apex.

The bony canal of the cochlea takes two turns and three-quarters round the modiolus; the first turn bulges into the tympanic cavity and there gives rise to the promontory (p. 1197). It is about 30 mm. long, and diminishes gradually in diameter from the base to the summit, where it ends in the *cupola*, which forms the apex of the cochlea. The beginning of this canal is about 3 mm. in

diameter, and in it there are three openings. One—the *fenestra cochleæ*—communicates with the tympanic cavity and in the recent state is closed by the *secondary tympanic membrane*; another, of an elliptical form, opens into the vestibule. The third is the aperture of the aqueduct of the cochlea, leading to a minute funnel-shaped canal which opens on the inferior surface of the petrous part of the temporal bone. It transmits a small vein to join the inferior petrosal sinus, and establishes a communication between the subarachnoid space and the scala tympani.

The *osseous spiral lamina* is a bony shelf or ledge which winds round and projects from the modiolus into the interior of the canal, like the thread of a screw. It reaches about halfway across the canal, and incompletely divides it into two passages or scalæ: an upper, named the *scala vestibuli*, and a lower, the *scala tympani*. The width of the osseous spiral lamina gradually decreases from the basal to the apical coil of the cochlea, and near the summit of the cochlea the lamina ends in a hook-shaped process, termed the *hamulus of the spiral lamina*; this assists in forming the boundary of the *helicotrema*, through which the two scalæ communicate with each other. From the spiral canal of the modiolus numerous canals pass outwards through the osseous spiral lamina as

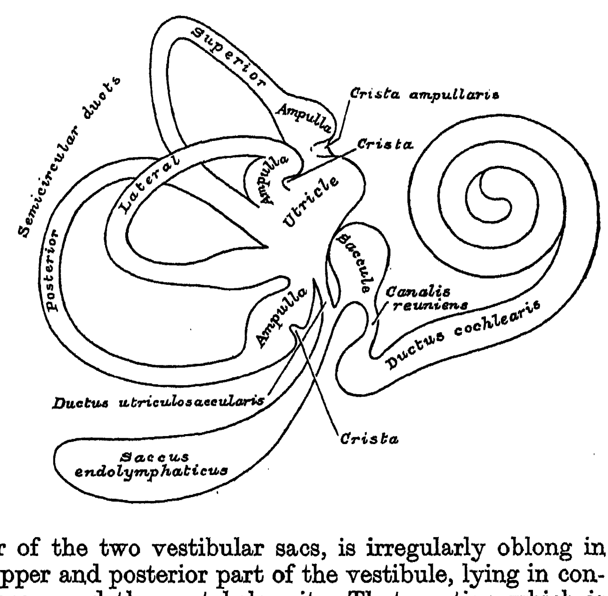
far as its free edge and transmit branches of the cochlear nerve. In the lower part of the first turn of the cochlea a *secondary spiral lamina* projects inwards from the outer wall of the bony tube; it does not, however, reach the osseous spiral lamina, so that if the laminæ be viewed from the vestibule a narrow fissure, termed the *vestibular fissure,* is seen between them.

The *bony labyrinth* is lined by a thin fibroserous membrane which is closely adherent to the bone; the free surface of the membrane is smooth, and covered with a layer of epithelium. The bony labyrinth is filled with *perilymph,* a fluid identical in composition, and confluent with, the cerebrospinal fluid. The part of the petrous bone which immediately surrounds the labyrinth is developed from the cartilaginous ear-capsule; it is denser than the rest of the petrous bone, and exhibits interglobular spaces, which contain cartilage cells (fig. 1061). The modiolus of the cochlea, on the other hand, is formed of spongy membrane-bone (Fraser and Dickie *). A tubular process of the lining membrane is prolonged through the aqueduct of the cochlea to the inner surface of the dura mater. The perilymphatic space of the vestibule communicates behind with that of the semicircular canals, and opens anteriorly into the scala vestibuli of the cochlea, which in turn opens into the scala tympani through the helicotrema, at the apex of the cochlea. The scala tympani is separated from the tympanic cavity by the secondary tympanic membrane, but is continuous with the subarachnoid space through the aqueduct of the cochlea.

The Membranous Labyrinth (figs. 1058 to 1060)

The membranous labyrinth is lodged within, but is smaller than the bony labyrinth; it is filled with fluid named *endolymph,* and in its walls the branches of the auditory nerve are distributed. It consists of: (*a*) the *utricle* and *saccule,* two small sacs, lodged in the vestibule; (*b*) three *semicircular ducts,* enclosed within the semicircular canals; and (*c*) the *duct of the cochlea,* contained within the bony cochlea. The various parts of the membranous labyrinth form a closed system of channels which, however, communicate freely with one another; the semicircular ducts open into the utricle, the utricle into the saccule through the ductus utriculosaccularis, and the saccule into the duct of the cochlea through the canalis reuniens.

Fig. 1058.—A schematic representation of the membranous labyrinth. (J. K. Milne Dickie.)



The membranous labyrinth is fixed at certain points to the wall of the bony labyrinth, but is separated from the greater part of the bony labyrinth by a space which contains the perilymph.

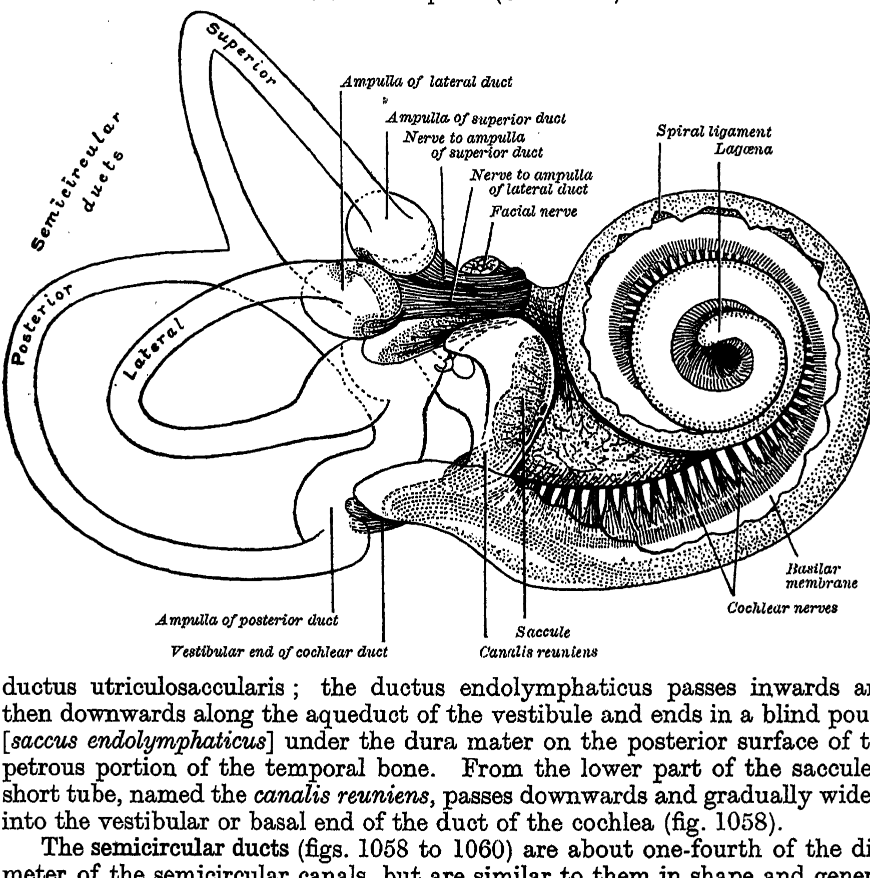
The **utricle**, the larger of the two vestibular sacs, is irregularly oblong in shape, and occupies the upper and posterior part of the vestibule, lying in contact with the elliptical recess and the part below it. That portion which is lodged in the elliptical recess forms a sort of pouch or cul-de-sac; the lateral half of the floor of this is thickened, and forms the *macula of the utricle,* which receives the utricular filaments of the auditory nerve. The ampullæ of the superior and lateral semicircular ducts open into the lateral part of the utricle, while the ampulla of the posterior duct, the crus commune and the posterior end of the lateral duct open into the medial part of the utricle. The posterior

* J. S. Fraser and J. K. Milne Dickie, *Journal of Anatomy and Physiology,* vol. xlix.

end of the lateral duct widens into a flattened cone which joins the medial end of the utricle at a right angle (Milne Dickie *). From its anteromedial part a fine canal, named the *ductus utriculosaccularis*, is given off, and opens into the ductus endolymphaticus.

The saccule lies in the spherical recess near the opening of the scala vestibuli of the cochlea. When seen from the front it presents a nearly globular form, but it is prolonged backwards in the form of a cone, the upper surface of which is in contact with the under surface of the utricle, and the utricle and saccule have here a common wall (Milne Dickie †). On its anterior wall there is an oval thickening, termed the *macula of the saccule* (fig. 1062), to which the saccular filaments of the auditory nerve are distributed. Its cavity communicates indirectly through a Y-shaped tube with that of the utricle. From its posterior part the *ductus endolymphaticus* is given off, and it is joined by the

FIG. 1059.—The right membranous labyrinth of a fifth-month human embryo. × 10. Anterolateral aspect. (G. Retzius.)



ductus utriculosaccularis ; the ductus endolymphaticus passes inwards and then downwards along the aqueduct of the vestibule and ends in a blind pouch [*saccus endolymphaticus*] under the dura mater on the posterior surface of the petrous portion of the temporal bone. From the lower part of the saccule a short tube, named the *canalis reuniens*, passes downwards and gradually widens into the vestibular or basal end of the duct of the cochlea (fig. 1058).

The semicircular ducts (figs. 1058 to 1060) are about one-fourth of the diameter of the semicircular canals, but are similar to them in shape and general form. Each has an ampulla at one end, viz. : the end which lies within the ampulla of the corresponding bony canal. The semicircular ducts open by five orifices into the utricle, one opening being common to the medial end of the superior, and the upper end of the posterior, duct. In each of the ampullæ the wall is thickened, and projects into the cavity as a transverse elevation shaped somewhat like the figure 8, and named the *septum transversum* ; the most prominent part of this septum is termed the *crista ampullaris*.

The utricle, saccule and semicircular ducts are held in position by fibrous bands which stretch across the perilymphatic space to the bony walls.

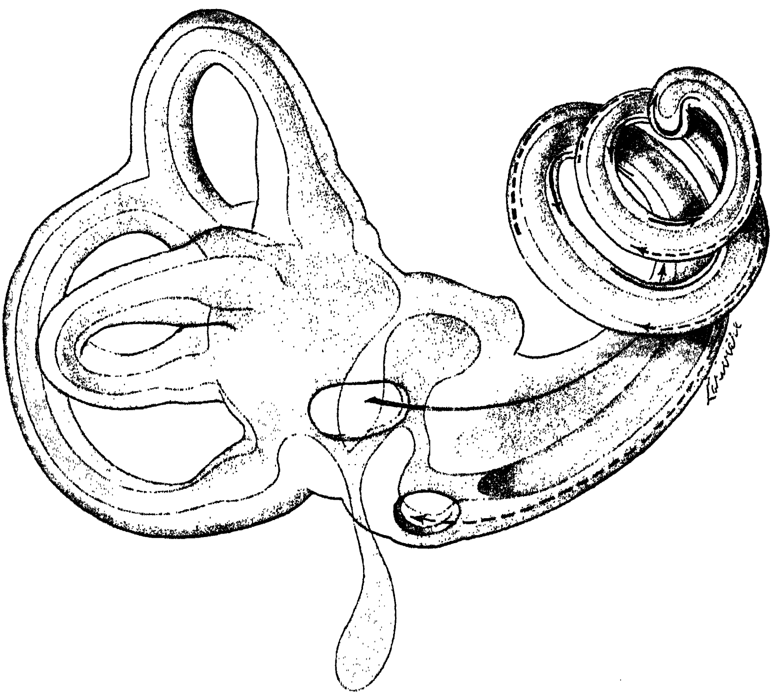
Structure (fig. 1061).—The walls of the utricle, saccule and semicircular ducts consist of three layers. The *outer layer* is composed of ordinary fibrous tissue containing blood-

* J. K. Milne Dickie, *Journal of Laryngology, Rhinology and Otology*, vol. xxxv.

† Loc. cit.

vessels and some pigment-cells. The *middle layer*, thicker and more transparent, is named the *tunica propria*, and presents on its internal surface, especially in the semicircular ducts (fig. 1061), numerous papilliform projections, which, on the addition of acetic acid, exhibit an appearance of longitudinal fibrillation. The *inner layer* is formed of polygonal, nucleated, epithelial cells. In the maculæ of the utricle and saccule (fig. 1062), and in the ampullary crests of the semicircular ducts, the middle coat is thickened and the epithelium is columnar, and consists of *supporting cells* and *hair-cells*. The supporting cells are fusiform, and their deep ends are attached to the tunica propria, while their free extremities are united to form a thin cuticle. The hair-cells are flask-shaped, and their deep, rounded ends do not reach the tunica propria, but lie between the supporting cells. The free end of the cell is surmounted by a long, tapering hair-like filament, which projects into the cavity. The filaments of the vestibular nerve, having pierced the tunica propria, lose their medullary sheaths, and their axis-cylinders split up into fine fibrils which end between the hair-cells.

FIG. 1060.—Scheme of the membranous labyrinth (*blue*) projected on to the osseous labyrinth.



The arrows commence at the fenestra vestibuli and continue up the scala vestibuli to the helicotrema, and then pass down the scala tympani to the fenestra cochleæ.

Two small rounded bodies termed *otoliths*, consisting of crystals of calcium carbonate, are suspended in the endolymph in contact with the free ends of the hairs projecting from the maculæ.

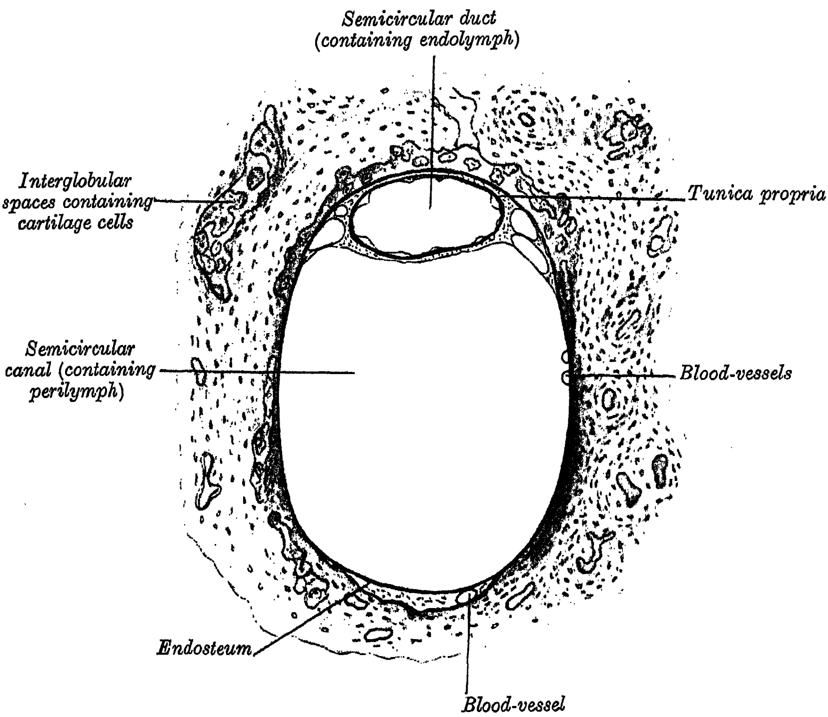
A ridge, named the *crista quarta*, projects into the posterior end of the lateral duct; nerves have been traced to this crest, which is present in most mammals but exists only in a rudimentary condition in the higher vertebrates.

The duct of the cochlea consists of a spirally arranged tube within the bony canal of the cochlea and lying along its outer wall.

As already stated (p. 1206) the osseous spiral lamina extends only part of the distance between the modiolus and the outer wall of the cochlea, while the *basilar membrane* stretches from the free edge of the lamina to the outer wall of the cochlea, and completes the roof of the scala tympani. A second and more delicate membrane, termed the *vestibular membrane*, extends from the thickened periosteum covering the osseous spiral lamina to the outer wall of the cochlea, where it is attached at some distance above the outer edge of the basilar membrane. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the *duct of the cochlea* (figs. 1063, 1064). It is triangular on transverse section, its roof being formed by the vestibular membrane, its outer wall by the periosteum lining the bony canal, and its floor by the basilar

membrane and the outer part of the osseous spiral lamina. The upper extremity of the duct of the cochlea is closed, and is named the *lagæna* ; it is attached to the cupola. The lower end turns medially, and narrows into the *canalis reuniens*, through which it communicates with the saccule (fig. 1058). The spiral organ is situated on the basilar membrane. The vestibular membrane is thin

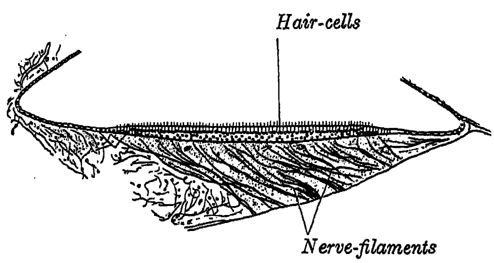
FIG. 1061.—A transverse section through the right posterior semicircular canal and duct of an adult man. ×51. (J. K. Milne Dickie.)



and homogeneous, and is covered on its two surfaces by a layer of flattened epithelium. The periosteum forming the outer wall of the duct of the cochlea is greatly thickened and altered in character. It projects inwards, inferiorly, as a triangular prominence, termed the *crista basilaris*, to which the outer edge of the basilar membrane is fixed ; immediately above this there is a concavity (the *sulcus spiralis externus*), above which the periosteum contains numerous blood-vessels, and is termed the *stria vascularis* (fig. 1064).

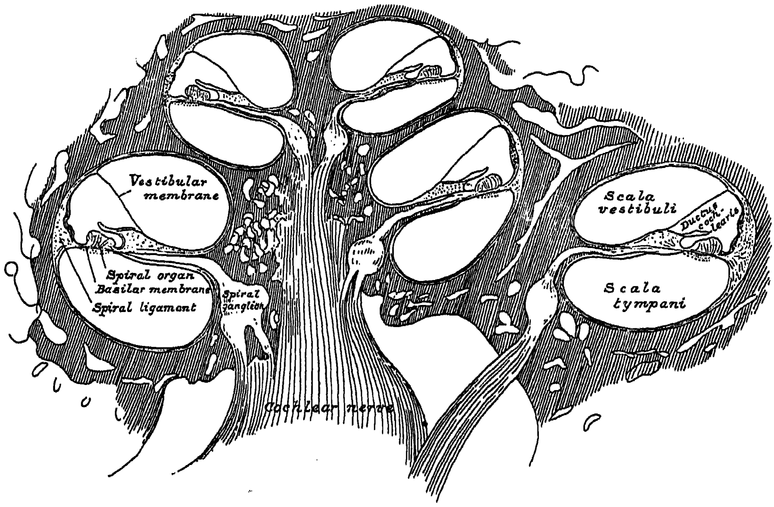
The osseous spiral lamina consists of two plates of bone, and between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the lamina which is contained within the duct of the cochlea the periosteum is thickened to form the *limbus laminæ spiralis* (fig. 1065) ; this ends externally in a concavity (the *sulcus spiralis internus*), which presents, on section, the form of the letter C ; the upper part formed by the overhanging edge of the limbus, is named the *vestibular lip* ; the lower part, prolonged and tapering, is called the *tympanic lip*, and is perforated by numerous foramina for the passage of the branches of the cochlear nerve. The upper surface of the vestibular lip

FIG. 1062.—A transverse section of the macula. (Retzius.)



is intersected at right angles by a number of furrows, separated by numerous elevations; these present the appearance of teeth on the free surface and margin of the lip, and were named by Huschke the *auditory teeth* (fig. 1065). The limbus is covered by a layer of what appears to be squamous epithelium, but only the cells covering the teeth are flattened, those in the furrows being

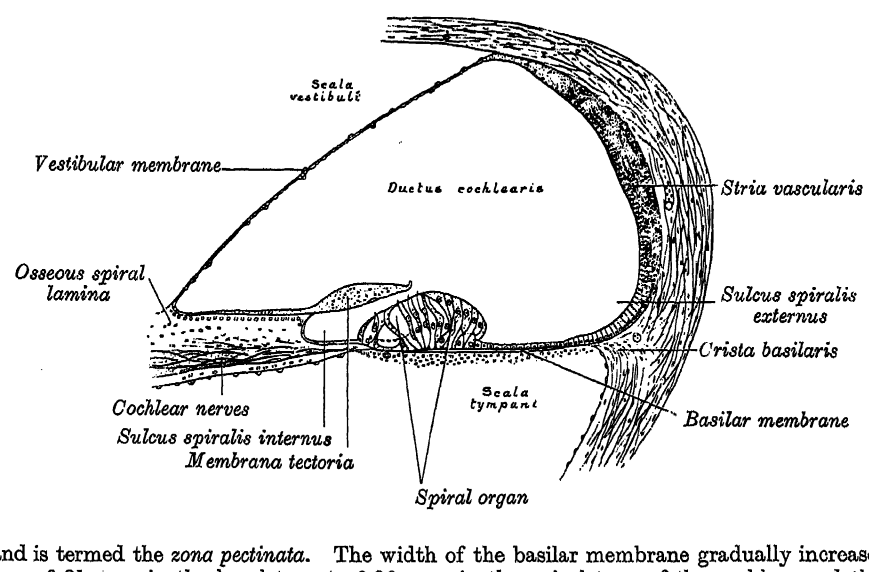
FIG. 1063.—A longitudinal section through the cochlea. Diagrammatic.



columnar, and occupying the intervals between the elevations. This epithelium is continuous on the one hand with that lining the sulcus spiralis internus, and on the other with that covering the under surface of the vestibular membrane.

The basilar membrane.—The basilar membrane (fig. 1066) stretches from the tympanic lip of the osseous spiral lamina to the crista basilaris. Its inner part is thin, and is named the *zona arcuata*; it supports the spiral organ; the outer part is thicker and striated,

FIG. 1064.—A transverse section through the middle coil of the ductus cochlearis. (Retzius.)



and is termed the *zona pectinata*. The width of the basilar membrane gradually increases from 0·21 mm. in the basal turn to 0·36 mm. in the apical turn of the cochlea, and this increase is accompanied by a corresponding narrowing of the osseous spiral lamina, and a

decrease in the thickness of the crista basilaris. The under surface of the membrane is covered by a layer of vascular connective tissue; one of the vessels in this tissue is somewhat larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel.

The spiral organ (figs. 1064, 1066) is composed of a series of epithelial structures placed upon the zona arcuata or inner part of the basilar membrane. The more central of these structures are two rows of rod-like bodies (the *inner and outer rods of Corti*). The bases or *foot-plates* of the rods are expanded, and rest on the basilar membrane, those of the inner row at some distance from those of the outer; the two rows incline towards each other and, coming into contact above, enclose between them and the basilar membrane the *tunnel of Corti* (fig. 1067), which is triangular in cross section. On the medial side of the inner rods there is a single row of hair-cells, and on the lateral side of the outer rods, three or four rows of hair-cells, together with certain supporting cells termed the cells of Deiters and of Hensen. The free ends of the outer hair-cells occupy a series of apertures in a

Part of the vestibular membrane.

net-like membrane, termed the *reticular lamina*, and the entire organ is covered by the *tectorial membrane*.

Rods of Corti (fig. 1067).—Each of these consists of a base or foot-plate, an elongated part or body, and an upper end or head; the body of each rod is finely striated, but in the head there is an oval non-striated portion which stains deeply with carmine. Nucleated cells, which partly envelop the rods and extend on to the floor of Corti's tunnel, occupy the angles between the rods and the basilar membrane; these may be looked upon as the undifferentiated parts of the cells from which the rods have been formed.

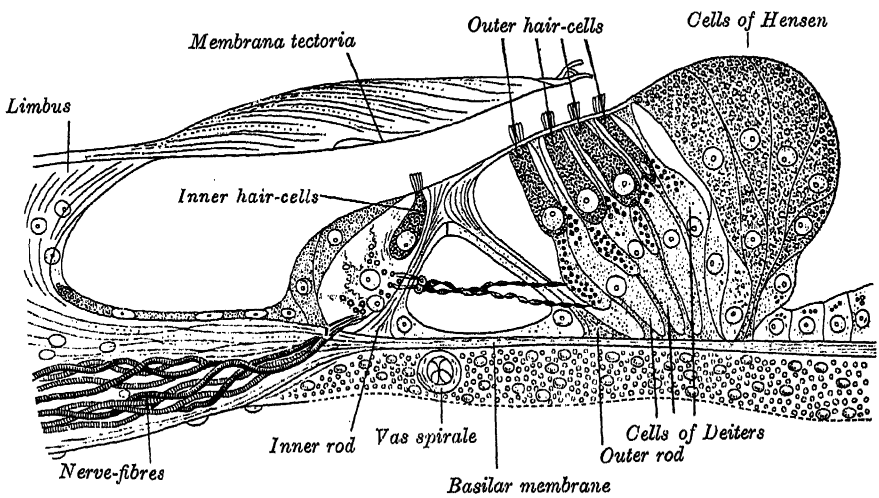
The *inner rods* number nearly 6000, and their bases rest on the basilar membrane close to the tympanic lip of the sulcus spiralis internus. The shaft or body of each is sinuously curved and forms an angle of about 60° with the basilar membrane. The head resembles the proximal end of the ulna, and presents a deep concavity which accommodates a convexity on the head of the outer rod. The head-plate, or portion overhanging the concavity, overlaps the head-plate of the outer rod.

The *outer rods*, nearly 4000 in number, are longer and more obliquely set than the inner, forming with the basilar membrane an angle of about 40°. Their heads are convex internally; they fit into the concavities on the heads of the inner rods, and are continued outwards as thin flattened plates, termed *phalangeal processes*, which unite with the phalangeal processes of Deiters' cells to form the reticular membrane.

The distances between the bases of the inner and outer rods increase from the base to the apex of the cochlea, while the angles between the rods and the basilar membrane diminish.

Hair-cells.—The hair-cells are short columnar cells; their free ends are on a level with the heads of the rods of Corti, and each is surmounted by about twenty hair-like processes arranged in the form of a crescent with its concavity directed inwards. The deep ends of the cells reach about halfway along the rods of Corti, and each contains a large nucleus; the terminal filaments of the cochlear nerve are in contact with the deep ends of the hair-cells. The *inner* hair-cells, about 3500 in number, are arranged in a single row on the inner (axial) side of the inner rods, and, their diameters being greater than those of the rods, each is supported by more than one rod. The free ends of the inner hair-cells are encircled by a cuticular membrane which is fixed to the heads of the inner rods. Adjoining the inner hair-cells there are one or two rows of columnar supporting cells, which, in turn, are continuous with the cubical cells lining the sulcus spiralis internus. The *outer* hair-cells number about 12,000 and are nearly twice as long as the inner. In the basal coil of the cochlea they are arranged in three regular rows; in the apical coil, in four somewhat irregular rows.

FIG. 1066.—A transverse section through the spiral organ. Magnified. (G. Retzius.)



Rows of supporting cells, called the *cells of Deiters* (fig. 1066), are placed between the rows of the outer hair-cells; their expanded bases are planted on the basilar membrane, while the opposite end of each presents a clubbed extremity or *phalangeal process.* Immediately to the outer side of Deiters' cells there are five or six rows of columnar cells, named the *supporting cells of Hensen* (fig. 1066). Near the lagæna these cells contain fat globules which decrease in number and size as the duct of the cochlea is traced towards the basal coil. It has been suggested * that these globules provide a graduated loading mechanism, which tunes the region of the lagæna to low tones.

The *reticular lamina* (fig. 1067) is a delicate framework perforated by circular holes which are occupied by the free ends of the outer hair-cells. It extends from the heads of the outer rods of Corti to the external row of the outer hair-cells, and is formed by several rows of minute fiddle-shaped cuticular structures, called *phalanges,* between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

The *membrana tectoria* (fig. 1066) overlies the sulcus spiralis internus and the spiral organ of Corti. It is wider and thicker in the apical than in the basal part of the cochlea. Its inner part is thin and is attached to the vestibular lip of the limbus laminæ spiralis, the attachment reaching as far as the vestibular membrane. The outer part is thick and padlike, the thickness being greatest over, or slightly to the inner side of, the upper ends of the rods of Corti. Retzius described the outer edge as being attached to the outer row of Deiters' cells, while others maintain that it forms a ragged or frayed margin. Hardesty, † who has examined the membrane in the pig, states that this edge is free and bluntly rounded, but finely and irregularly scalloped. The hairs of the hair-cells project into the under surface of the membrane, and on this surface opposite the interval between the inner and outer rows of hair-cells there is a band, named *Hensen's stripe.*

* C. S. Hallpike, *Journal of Physiology,* vol. lxxiii.

† Irving Hardesty, *American Journal of Anatomy,* vol. viii.

Hardesty has shown that the membrana tectoria "consists of multitudes of delicate fibrils imbedded in a transparent matrix of a soft, collagenous, semi-solid character with marked adhesiveness." The prevailing course of the fibres is obliquely transverse, slanting from the vestibular lip towards the apex of the cochlea. The fibres pass in curves from the vestibular lip and upper surface of the membrane to its under surface, where by their interlacement they produce the appearance known as Hensen's stripe. He also described

a thin, exceedingly delicate *accessory tectorial membrane*, lying along the under surface of the outer zone of the main membrane, and lightly attached to the latter by its outer edge.

The **auditory nerve**, or nerve of hearing, divides near the bottom of the internal auditory meatus into an anterior or cochlear, and a posterior or vestibular portion. The deep connexions of these nerves are described on pp. 1064 to 1067.

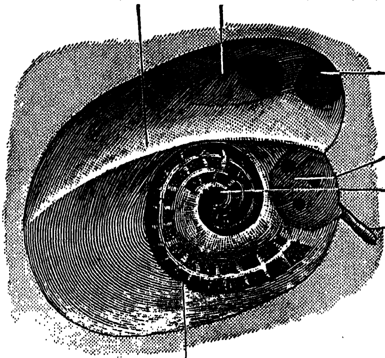
The *vestibular nerve* supplies the utricle, the saccule and the ampullæ of the semicircular ducts. The *vestibular ganglion*, from the bipolar nerve-cells of which the fibres of the nerve take origin, is situated on the trunk of the nerve within the internal auditory meatus. On the distal side of the ganglion the nerve splits into a superior, an inferior and a posterior branch.* The filaments of the *superior branch* are transmitted through the foramina in the superior vestibular area, and end in the macula of the utricle and in the ampullary crests of the superior and lateral semicircular ducts; those of the *inferior branch* traverse the foramina in the inferior vestibular area, and end in the macula of the saccule. The *posterior branch* runs through the foramen singulare at the postero-inferior part of the bottom of the meatus and divides into filaments for the supply of the ampullary crest of the posterior semicircular duct (fig. 1068).

The *cochlear nerve*, the nerve of hearing, divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus spiralis foraminosus, those for the apical coil through the central canal, and the nerves bend outwards and pass between the lamellæ

* The nerve sometimes splits on the proximal side of the ganglion, which is then divided into three parts, one on each branch of the nerve. When this occurs the ganglion of the posterior division is placed in the foramen singulare.

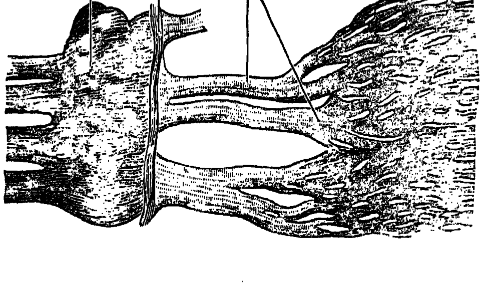
of the osseous spiral lamina. The *spiral ganglion* (fig. 1069), consisting of bipolar nerve-cells from which the fibres of the nerve take origin, occupies the spiral canal of the modiolus. Reaching the outer edge of the osseous spiral lamina, the nerve-fibres pass through the foramina in the tympanic lip; some end by arborising around the deep ends of the inner hair-cells, while

FIG. 1068.—A diagrammatic view of the lateral end of the right internal meatus. (Testut.)



others pass between the rods of Corti and across the tunnel of Corti, and end in a similar manner in relation to the outer hair-cells. The hair-cells in the basal and middle coils are more richly supplied with nerves than those in the apical coil. The cochlear nerve gives off a vestibular branch to supply the vestibular end of the duct of the cochlea; the filaments of this branch traverse the foramina in the cochlear recess (p. 1204).

FIG. 1069.—Part of the cochlear division of the auditory nerve. Highly magnified. (Henle.)



Vessels.—The *arteries of the labyrinth* are (1) the internal auditory artery, which may arise from the basilar artery, but is more often derived from the anterior inferior cerebellar artery, and (2) the stylomastoid branch of the posterior auricular artery. The internal auditory artery divides at the bottom of the internal auditory meatus into two branches: cochlear and vestibular. The cochlear branch subdivides into twelve or fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the lamina spiralis and basilar membrane. The vestibular branches are distributed to the utricle, saccule and semicircular ducts.

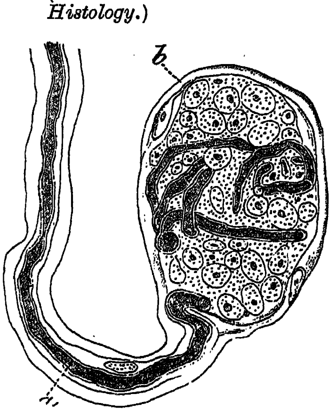
The *veins* of the vestibule and semicircular canals accompany the arteries, and, receiving the veins of the cochlea at the base of the modiolus, unite to form the internal auditory

vein, which ends in the posterior part of the superior petrosal sinus or in the transverse sinus. A small vein, from the basal turn of the cochlea, traverses the aqueduct of the cochlea and joins the internal jugular vein.

THE PERIPHERAL TERMINATIONS OF THE NERVES OF GENERAL SENSATIONS

The peripheral terminations of the nerves associated with general sensations (i.e. the muscular sense and the senses of touch, heat, cold, pain and pressure) are widely distributed throughout the body. These nerves may end (*a*) as *free fibrils* amongst the tissue elements, or (*b*) in *special end-organs* where the terminal nerve-filaments are enclosed in capsules.

FIG. 1070.—A bulbous corpuscle. (From Klein's *Elements of Histology*.)



a. Medullated nerve-fibre. *b*. Capsule.

Free nerve-endings occur chiefly in the epidermis and in the epithelium covering certain mucous membranes; they occur in the stratified squamous epithelium of the cornea, in the root-sheaths and papillæ of the hairs, and around the bodies of the sudoriferous glands.

When the nerve-fibre approaches its termination, the medullary sheath suddenly disappears, leaving the axis-cylinder surrounded by the neurolemma. After a time the fibre loses its neurolemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with gold chloride, to be made up of fine varicose fibrillæ. Finally, the axis-cylinder breaks up into its constituent fibrillæ, which often present regular varicosities, and anastomosing with one another, end in small knobs or discs between the epithelial cells.

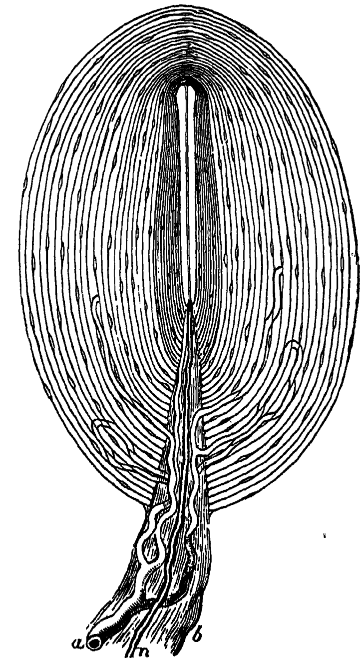
The **special end-organs** exhibit great variety in size and shape, but have one feature in common, viz. the terminal fibrils of the nerve are enveloped by a capsule. The bulbous, lamellated and oval corpuscles are included in this group, together with the neurotendinous and neuromuscular spindles.

The **bulbous corpuscles** (fig. 1070) are minute cylindrical or oval bodies, consisting of a capsule of connective tissue enveloping a soft semi-fluid core in which the axis-cylinder terminates, either in a bulbous extremity or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, (where they are spheroidal in shape in man, but cylindrical in most other animals), in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the penis and clitoris, and have there received the name of *genital corpuscles*; in these situations they have a mulberry-like appearance, being constricted by connective tissue septa into from two to six knob-like masses. In the synovial strata of certain joints (e.g. those of the fingers), rounded or oval end-bulbs occur, and are designated *articular end-bulbs*.

The *lamellated corpuscles* (fig. 1071) are found in the subcutaneous tissue on the nerves of the palm of the hand and sole of the foot, and in the genital organs of both sexes; they also occur on the nerves of the joints, and in some other situations, as in the mesentery and pancreas of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to, and encloses the termination of, a single nerve-fibre. The corpuscle (which is visible to the naked eye and can be most easily demonstrated in the mesentery of a cat) consists of a number of concentric lamellæ or capsules arranged around a central space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective tissue-fibres, and is lined on its inner surface by a single layer of flattened cells. The central space is elongated or cylindrical in shape, and

filled with a transparent core, in the middle of which the naked axis-cylinder traverses the space to near its distal extremity, where it ends in one or more small knobs. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space.

FIG. 1071.—A lamellated corpuscle, with its system of capsules and its central cavity.



a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces; one penetrates to the central capsule. *b.* The fibrous tissue of the stalk. *n.* Nerve-fibre advancing to the central capsule, there losing its medullary sheath, and passing along the core to the opposite end, where it terminates in a tuberculated enlargement.

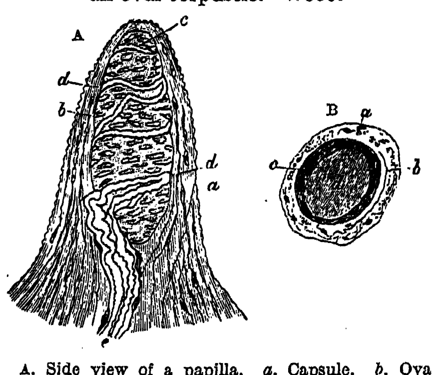
Other corpuscles are found in the subcutaneous tissue of the pulp of the fingers. They differ from lamellated corpuscles in that their capsules are thinner, their contained cores thicker, and in the latter the axis-cylinders ramify more extensively and end in flat expansions.

The *oval corpuscles* (fig. 1072) are oval-shaped bodies which occur in the papillæ of the corium of the hand and foot, the front of the forearm, the skin of the lips, the mucous membrane of the tip of the tongue, the palpebral conjunctiva and the skin of the nipple. The long axis of each corpuscle is placed at right angles to the skin or mucous surface. Each is enveloped by a connective tissue capsule, which sends membranous septa into the interior. The axis-cylinder passes through the capsule and, after making several spiral turns round the body of the corpuscle, ends in small globular or pear-shaped enlargements.

Ruffini described a special variety of nerve-ending in the subcutaneous tissue of the human finger (fig. 1073), and mostly situated at the junction of the corium with the subcutaneous tissue. They are oval in shape, and consist of strong connective tissue sheaths; inside these the nerve-fibres divide into numerous branches, which show varicosities and end in small free knobs.

The *neurotendinous spindles* are chiefly found near the junctions of tendons with muscles. Each is enclosed in a capsule which contains a number of enlarged tendon-fasciculi (*intrafusal fasciculi*). One or more nerve-fibres perforate the side of the capsule and lose their medullary sheaths; the axis-cylinders subdivide and end between the tendon-fibres in irregular discs or varicosities (fig. 1074).

FIG. 1072.—A papilla of the hand, containing an oval corpuscle. × 350.

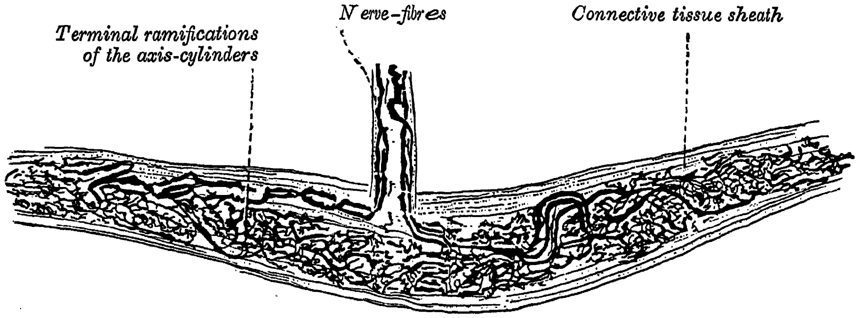


A. Side view of a papilla. *a.* Capsule. *b.* Oval corpuscle. *c.* Small nerve of the papilla, with neurolemma. *d.* Its two nerve-fibres running with spiral coils round the oval corpuscle. *e.* Apparent termination of one of these fibres. B. Transverse section of a tactile papilla. *a.* Capsule. *b.* Nerve-fibre. *c.* Outer layer of the oval corpuscle, with nuclei. *d.* Clear internal substance.

The *neuromuscular spindles* are present in the majority of voluntary muscles, and consist of small bundles of peculiar muscular fibres (*intrafusal fibres*), embryonic in type, invested by capsules, within which nerve-fibres, experimentally shown to be sensory, terminate. These neuromuscular spindles vary in length from 0·8 mm. to 5 mm. and have a fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule, they

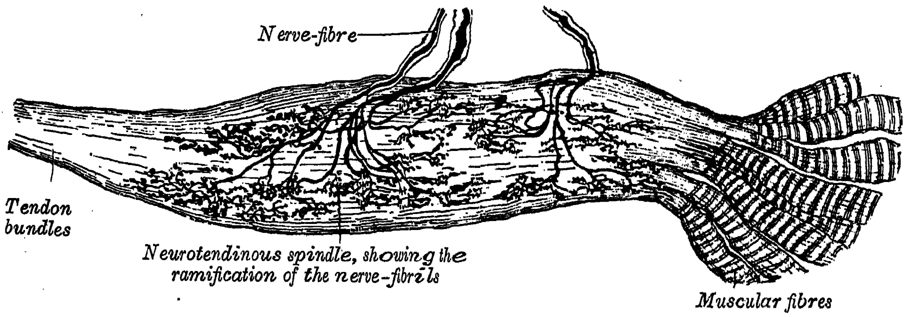
divide several times, and, losing their medullary sheaths, ultimately end in naked axis-cylinders encircling the intrafusal fibres by flattened expansions,

FIG. 1073.—A nerve-ending of Ruffini.



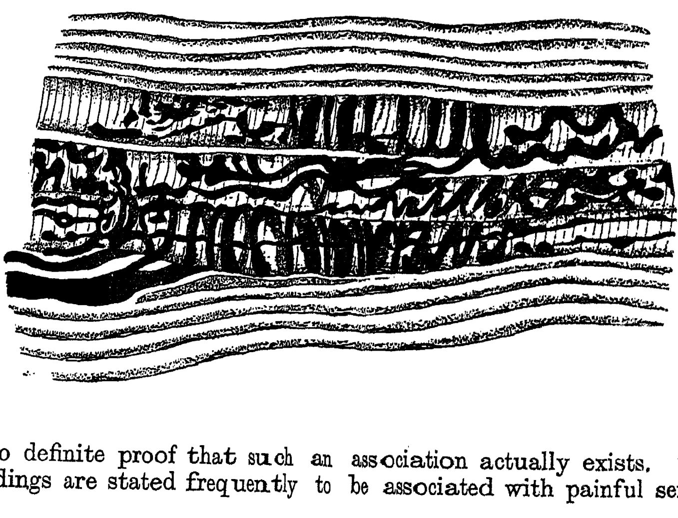
or irregular ovoid or rounded discs (fig. 1075). Neuromuscular spindles have not yet been demonstrated in the muscles of the tongue, and only a few exist in the ocular muscles.

FIG. 1074.—A neurotendinous spindle from the human tendo calcaneus. (After Ciaccio.)



The different ways in which sensory nerve-fibres terminate are strongly suggestive of their association with different types of sensibility, but there is

FIG. 1075.—The middle third of a terminal plaque in the muscle-spindle of an adult cat. (After Ruffini.)



as yet no definite proof that such an association actually exists. The free nerve-endings are stated frequently to be associated with painful sensibility,

but Waterston * has shown that, if they are to be regarded as associated with any one particular type of sensibility, they must be tactile in function. The subject has recently been investigated further by Woollard,† whose observations indicate that a nervous network is formed in association with the fine fibres which form subepidermal endings associated with pain, and that the intra-epidermal endings are concerned with touch.

The end-bulbs, or corpuscles, would appear to be an insulating mechanism and it might be assumed that each responds to only one form of stimulation, but, although Adrian ‡ has shown that the lamellated corpuscles respond to pressure but not to changes of temperature, the available evidence is quite inconclusive.§

THE SKIN

The **skin** (fig. 1076) covers the body and protects the deeper tissues. It contains the peripheral endings of many of the sensory nerves, plays an important part in the regulation of the body temperature, and possesses limited excretory and absorbing powers. It consists principally of a layer of vascular connective tissue, named the *corium*, and an external covering of epithelium, termed the *epidermis*. On the surface of the former layer there are sensitive and vascular *papillæ* ; and within, or beneath it, there are certain organs with special functions : namely, the *sweat* and *sebaceous glands*, and the *hair-follicles*.

The **epidermis** is non-vascular, and consists of stratified epithelium (fig. 1077). It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be in a measure due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layers of cells form the *horny zone* (*zona corneum*), which may be separated by maceration from a deeper stratum, termed the *germinative zone* and consisting of several layers of variously shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, which divide the surface into a number of polygonal or lozenge-shaped areas. These furrows are conspicuous opposite the flexures of the joints, and correspond with the folds in the corium produced by the joint-movements. In other situations, as upon the back of the hand, they are faint, and intersect one another at various angles. Upon the palmar surfaces of the hands and fingers, and upon the soles of the feet, these lines are fine but very distinct, and are disposed in more or less parallel curves ; they depend upon the large size and peculiar arrangement of the papillæ upon which the epidermis is placed. In each individual the lines on the tips of the fingers and thumbs form distinct patterns unlike those of any other person. A method of determining the identity of a criminal is based on this fact, impressions (' finger-prints ') of these lines being made on paper covered with soot, or on white paper after first covering the fingers with ink. The deep surface of the epidermis is accurately moulded upon the papillary layer of the corium, the papillæ being covered by a basement-membrane ; as a result when the epidermis is removed by maceration, its under surface presents a number of pits or depressions corresponding with the papillæ, and ridges corresponding with the intervals between them. The papillary form of the corium prevents the epithelium from being stripped off the surface of the skin by shearing stresses.

Structure.—The epidermis consists of stratified epithelium, which is arranged in two zones, viz. : the germinative zone and the horny zone. The germinative zone, which is the deeper, consists of basal-cell and prickle-cell layers ; the horny zone consists of clear, granular and horny layers.

Germinative zone : (1) The *basal-cell layer* [stratum basale] consists of a layer of columnar cells with oblong nuclei. The cells are placed perpendicularly on a basement-membrane, to which they are attached by denticulated extremities.

* D. Waterston, *Brain*, vol. xlvi. 1923 ; and *Anatomy in the Living Model*, 1931.

† H. H. Woollard, *Journal of Anatomy*, vol. lxxi, Oct. 1936 and July, 1937.

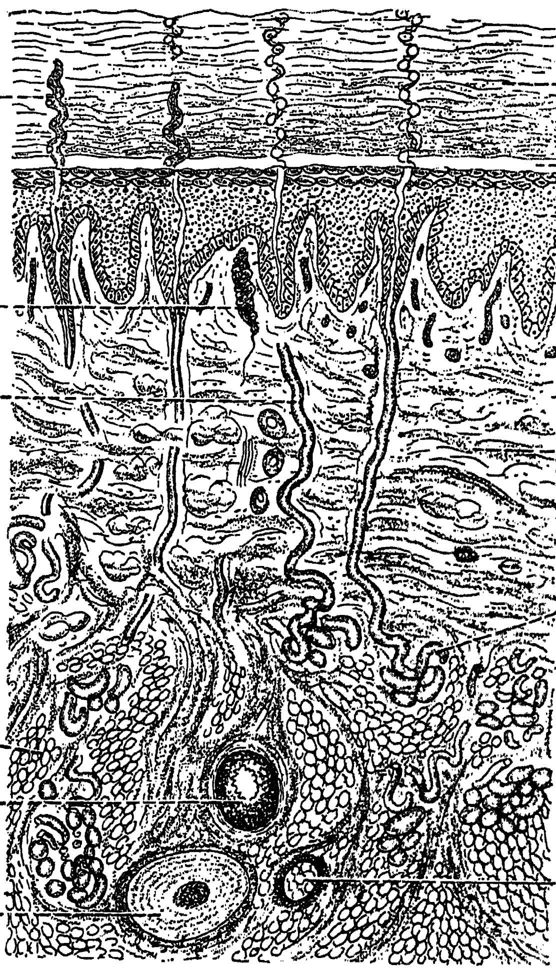
‡ E. D. Adrian, *The Basis of Sensation*, 1928.

§ J. S. B. Stopford, *Sensation and the Sensory Pathway*, 1930.

(2) The *prickle-cell layer* [stratum aculeatum] is composed of several layers of spherical or polyhedral cells, the contents of which are soft, opaque and granular. These cells are joined to one another by fine protoplasmic bridges. When the cells are isolated these bridges are broken and the surfaces of the cells are beset with numerous short thorn-like processes, which give the cells a characteristic appearance and have led to their being named *prickle-cells*. The cells contain numerous fine fibrils which can be stained by carmine or hæmatoxylin, and are continuous with those of neighbouring cells across the protoplasmic bridges. Between the bridges there are minute lymph-channels, in which lymph corpuscles or pigment-granules may be found.

Horny zone : (1) The *granular layer* [stratum granulosum] comprises two or three layers of fusiform cells which contain granules of *eleidin*, a substance readily stained by hæma-

FIG. 1076.—A section through the skin. Magnified. Diagrammatic.



toxylin or carmine, and probably an intermediate stage in the formation of keratin. They are supposed to be cells undergoing transformation from the protoplasmic cells of the stratum aculeatum to the horny cells of the superficial layers.

(2) The *clear layer* [stratum lucidum] appears in section as a homogeneous or dimly striated layer, composed of closely packed cells in which traces of flattened nuclei may be found, and in which the eleidin has been changed into a substance named *keratohyalin*.

(3) The *horny layer* [stratum corneum] consists of several layers of horny, epithelial cells, in which no nuclei are discernible. They are unaffected by acetic acid, and their protoplasm has been converted into a material known as *keratin*. According to Ranvier they contain granules of a substance which has the characteristics of beeswax.

The black colour of the skin in the negro and the tawny colour in some of the white races are due to the presence of pigment in the cells of the epidermis. This pigment is especially distinct in the prickle-cells, and is similar to that found in the cells of the pig-

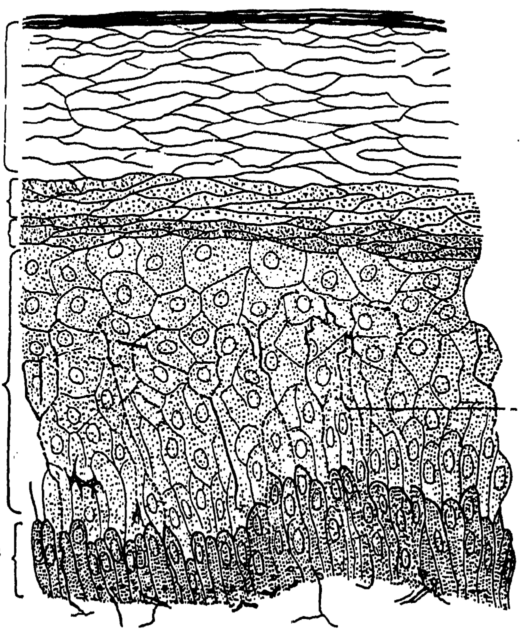
mented layer of the retina. As the cells approach the surface and desiccate, the pigment is partially lost.

The corium is tough, flexible and highly elastic. It is very thick in the palms of the hands and soles of the feet; thicker on the posterior than on the anterior aspect of the body, and on the lateral than on the medial sides of the limbs. It is exceedingly thin and delicate in the eyelids, scrotum, and penis.

Structure.—It consists of felted connective tissue, with a varying number of elastic fibres and numerous blood-vessels, lymphatic vessels and nerves. The connective tissue is arranged in two layers: a deeper or *reticular*, and a superficial or *papillary*. Unstriped muscular fibres are found in the superficial layers of the corium wherever hairs are present; they are also present in the subcutaneous areolar tissue of the scrotum, penis, labia majora and nipples. In the nipples the fibres are disposed in bands, closely reticulated and arranged in superimposed laminæ.

The *reticular layer* consists of strong interlacing bands, composed chiefly of white fibrous tissue, but containing some yellow elastic fibres, which vary in number in different parts;

FIG. 1077.—A section through the epidermis. (Ranvier.)



the connective tissue corpuscles are often to be found flattened against the bundles of white fibrous tissue. Towards the attached surface the fasciculi are coarse, and the large intervals left by their interlacement are occupied by adipose tissue and sweat glands. Below the reticular layer is the subcutaneous areolar tissue, which, except in a few situations, contains fat.

The *papillary layer* consists of numerous highly sensitive and vascular eminences, termed the *papillæ*, which rise perpendicularly from its surface. The papillæ are minute conical projections, having round or blunted extremities, which may be divided into two or more parts, and are received into corresponding pits on the under surface of the cuticle. On the general surface of the body, and especially in parts endowed with slight sensibility, they are few in number and exceedingly minute; but in some situations, as upon the palmar surfaces of the hands and fingers, and upon the plantar surfaces of the feet and toes, they are large, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillæ, and between the rows the ducts of the sudoriferous glands pass outwards to open on the summits of the ridges. Each papilla consists of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue there is a capillary loop, and in some papillæ, especially in the palms of the hands and the fingers, there are oval corpuscles.

The *arteries* supplying the skin form a network in the subcutaneous tissue, and from this

network branches are distributed to the sweat glands, the hair-follicles and the fat. Other branches unite in a plexus immediately beneath the corium, and from this plexus fine capillary vessels pass into the papillæ.

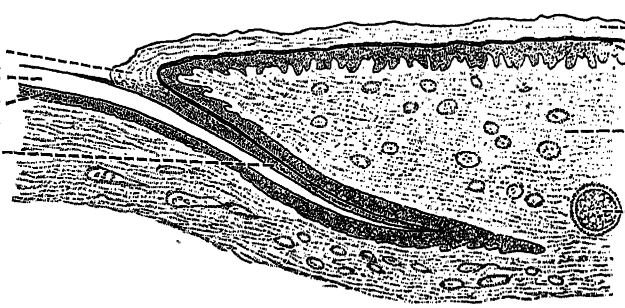
The *lymph vessels* of the skin form a superficial and a deep network, which communicate with each other and with the lymph vessels of the subcutaneous tissue by oblique branches.

The *nerves* of the skin terminate partly in the epidermis and partly in the corium; their different modes of ending are described on pp. 1216 to 1219.

The **appendages of the skin** are the nails, the hairs, and the sweat and sebaceous glands.

The **nails** (fig. 1078) are flattened, elastic structures of a horny texture, placed upon the distal parts of the dorsal surfaces of the fingers and toes. Each is implanted into a groove in the skin by a portion called the *root*; the exposed part is called the *body*, and the distal extremity, the *free border*. The greater part of each collateral border of the nail is overlapped by a fold of skin, named the *nail-wall*. The nail is firmly adherent to the corium, being accurately moulded upon its surface; the part of the corium beneath the nail is called the *nail-bed*. Under the greater part of the body of the nail the matrix is thick, and raised into a series of longitudinal ridges which are very vascular, and the colour is seen through the transparent tissue. Near the root of the

Fig. 1078.—A longitudinal section through the root of a nail.



nail the papillæ are smaller, less vascular, and have no regular arrangement, and here the tissue of the nail is more opaque; hence this portion is of a whiter colour, and is called the *lunula* on account of its shape.

As the epidermis passes forwards on the dorsal surface of the finger or toe it is attached to the surface of the nail a little in advance of its root; at the extremity of the digit it is connected with the under surface of the nail a little behind its free edge. The epidermis and the horny substance of the nail (also an epidermic structure) are thus directly continuous with each other. The superficial, horny part of the nail consists of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (*eponychium*) which overlaps the lunula; the deeper part consists of the stratum aculeatum. The cells in contact with the papillæ of the nail-bed are columnar in form and arranged perpendicularly to the surface; the succeeding cells are round or polygonal, while the more superficial ones are thin and flat, and so closely packed as to make the limits of the cells very indistinct. The nails grow in length by the proliferation of the cells of the stratum aculeatum at the root of the nail, and in thickness from that part of the stratum aculeatum which underlies the lunula.

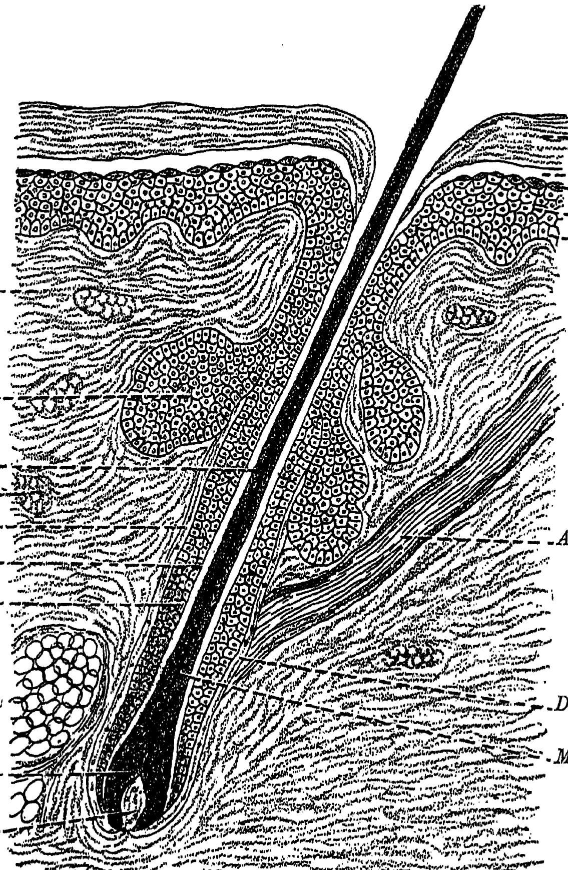
The **hairs** are found on nearly every part of the surface of the body, but are absent from the palms of the hands, the soles of the feet, the dorsal surfaces of the distal phalanges, the glans penis, the inner surface of the prepuce and the inner surfaces of the labia. They vary much in length, thickness, and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; the eyelashes, the hairs of the pubic region, and the whiskers and beard are remarkable for their thickness. Straight hairs are stronger than curly hairs and

present on transverse section a cylindrical or oval outline: curly hairs, on the other hand, are flat.

A hair consists of a *root*, the part implanted in the skin; and a *shaft* [*scapus*], the portion projecting from the surface.

The *root of the hair* ends in an enlargement, named the *hair-bulb*, which is whiter in colour and softer in texture than the shaft, and is lodged in an involution of the epidermis and superficial portion of the corium, called the *hair-follicle* (fig. 1079). When the hair is of considerable length the follicle extends into the subcutaneous tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes

Fig. 1079.—A section through the skin, showing the epidermis and corium, a hair in its follicle, the Arrector pili muscle, and sebaceous glands opening into the hair-follicle.



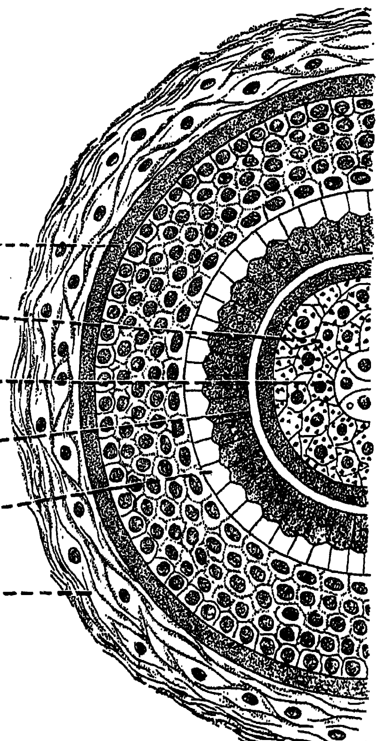
inwards in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the hair-bulb. The ducts of one or more sebaceous glands open into the follicle near its free extremity. At the bottom of each hair-follicle there is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, and is supplied with nerve-fibrils. The hair-follicle consists of two coats—an outer or dermic, and an inner or epidermic (fig. 1080).

The *outer coat* is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and is supplied by numerous, minute, nervous filaments. It consists of three layers (fig. 1080). The most internal is a hyaline basement-membrane, which is well marked in the larger hair-follicles but is not very distinct in the follicles of minute hairs; it is limited to the deeper part of the follicle. Outside this there is a compact layer of fibres and spindle-shaped cells, arranged circularly around the follicle; this layer extends from the bottom of the follicle to the openings of the ducts of the sebaceous glands. Externally there is a thick layer of connective tissue, arranged in longitudinal bundles,

forming a more open texture and corresponding with the reticular part of the corium; this contains the blood-vessels and nerves.

The *inner coat* is closely adherent to the root of the hair, and consists of two strata, named respectively the *outer* and *inner root-sheaths*; the outer root-sheath corresponds with the stratum aculeatum of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The inner root-sheath consists of: (1) a delicate cuticle next the hair, composed of a single layer of imbricated scales with atrophied nuclei; (2) one or two layers of horny, flattened, nucleated cells, known as Huxley's layer; and (3) a single layer of cubical cells with clear, flattened nuclei, called *Henle's layer* (fig. 1080).

Fig. 1080.—A transverse section through one-half of a hair-follicle.



The *hair-bulb* is moulded over the papilla and composed of polyhedral, epithelial cells. As they pass upwards into the root of the hair these cells become elongated and spindle-shaped, except those in the centre, which remain polyhedral.

The *shaft of the hair* consists, from within outwards, of the medulla, the cortex and the cuticle. The *medulla* is usually absent from the fine hairs covering the surface of the body, and commonly from those of the head. When viewed by transmitted light it appears deeper in colour and more opaque than the cortex, but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, with air-spaces between, and sometimes within, the cells. The *cortex* constitutes the chief part of the shaft; its cells are elongated and are united to form flattened, fusiform fibres, which contain pigment-granules in dark hair, and air in white hair. The *cuticle* consists of a single layer of flat scales which overlap one another from below upwards.

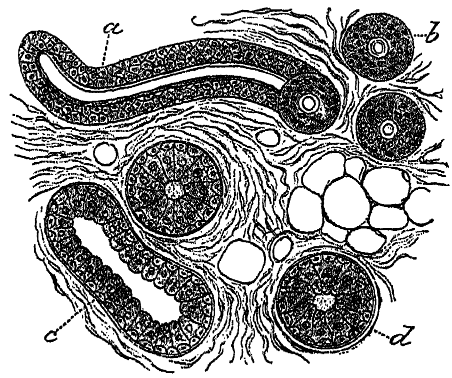
Minute bundles of involuntary muscular fibres, termed the *Arrectores pilorum* (fig. 1079), are connected with the hair-follicles. They arise from the superficial layer of the corium, and are inserted into the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action diminish the obliquity of the follicle and elevate the hair.* The sebaceous gland is situated in the angle which the Arrector muscle forms with the superficial portion of the hair-follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland.

The **sebaceous glands** (fig. 1079) are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which emerges from a cluster of oval or flask-shaped alveoli, usually from two to five, but in some instances as many as twenty in number. Each alveolus is composed of a transparent basement-membrane, enclosing a number of epithelial cells. The outer or marginal cells are small and polyhedral, and are continuous with the cells lining the duct.

* Arthur Thomson suggested that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.

The remainder of the alveolus is filled with larger cells, containing fat, but in its centre the cells are broken up, leaving a cavity filled with their debris and a mass of fatty matter, which constitutes the *sebum cutaneum*. The ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The tarsal glands of the eyelids are elongated, sebaceous glands with numerous, lateral diverticula.

Fig. 1081.—The body of a sudoriferous gland cut in various directions. (From Klein and Noble Smith's *Atlas of Histology*.)



a. Longitudinal section through the proximal part of the coiled tube. *b*. Transverse section through the same. *c*. Longitudinal section through the distal part of the coiled tube. *d*. Transverse section through the same.

The sweat glands (figs. 1076, 1081) are found in almost every part of the skin, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous tissue, surrounded by a quantity of adipose tissue. Each consists of a single tube, the deep part of which is rolled into an oval or spherical ball, named the *body* of the gland, while the superficial part, or *duct*, traverses the corium and cuticle and opens on the surface of the skin by a funnel-shaped aperture. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or twisted; where the epidermis is thick, as in the palms of the hands and soles of the feet, the part of the duct which passes through it is spirally coiled. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mamillated layer of a reddish colour, which corresponds exactly with the situation of the hair in this region; they are large also in the groin. Their number varies. They are very plentiful on the palms of the hands, and on the soles of the feet, where the orifices of the ducts are exceedingly regular, and open on the curved ridges of the epidermis; they are least numerous in the neck and back. The tube, both in the body of the gland and in the duct, consists of two layers—an outer, of fine areolar tissue, and an inner, of epithelium (fig. 1081). The outer layer is thin and is continuous with the superficial stratum of the corium. In the body of the gland the epithelium consists of a single layer of cubical cells, between the deep ends of which and the basement-membrane there is a layer of longitudinally or obliquely arranged non-striped muscular fibres. The ducts are destitute of muscular fibres, and are composed of a basement-membrane lined by two or three layers of polyhedral cells; the lumen of the duct is coated by a thin cuticle. When the epidermis is carefully removed from the surface of the corium, the ducts may be drawn out in the form of short, thread-like processes on its under surface.

The ceruminous glands of the external auditory meatus are modified sweat glands.

SPLANCHNOLOGY

THE organs which constitute the respiratory, digestive and urogenital systems, and the ductless glands, are described under this heading.

THE RESPIRATORY SYSTEM

The respiratory system comprises the two lungs, which are the essential organs of the system, and a series of air-passages which conduct air to them. In addition the two pleural sacs, which are derived from the general cœlom and are inseparably associated with the lungs, are included under this heading.

The air-passages are the nasal cavity, the pharynx, the larynx, the trachea, the bronchi and their smaller subdivisions. Owing to the gaseous nature of their contents the air-passages must be kept constantly patent and their walls are therefore provided with a skeletal framework of bone or cartilage. In the nasal cavity, which is described on pp. 273 to 277, and the pharynx, which is described on pp. 1290 to 1298, the skeletal framework is osseous for the most part, but in the remaining passages it consists entirely of cartilage.

The Larynx

The **larynx**, which is the organ of the voice as well as an air-passage, is situated between the root of the tongue and the trachea, at the upper and anterior part of the neck. In this situation it projects forwards between the great vessels, and is covered anteriorly by the skin, the fasciæ, and the depressor muscles of the hyoid bone (fig. 1082). Above, it opens into the laryngeal part of the pharynx, of which it forms the anterior wall; below, it is continuous with the trachea. In the adult male it is situated opposite the third, fourth, fifth and sixth cervical vertebræ, but it occupies a somewhat higher position in the child and in the adult female. Symington states that in infants of between six and twelve months the tip of the epiglottis, or highest part of the larynx, is a little above the level of the cartilaginous disc between the odontoid process and the body of the axis. Its average measurements in the adult are as follows:

	In males.	In females.
Length	44 mm.	36 mm.
Transverse diameter	43 ,,	41 ,,
Anteroposterior diameter	36 ,,	26 ,,
Circumference	136 ,,	112 ,,

Until puberty the larynx of the male differs little in size from that of the female. In the female its increase at puberty is only small. In the male the increase is considerable; all the cartilages enlarge and the thyroid cartilage projects in the anterior median line of the neck, while the anteroposterior diameter is nearly doubled.

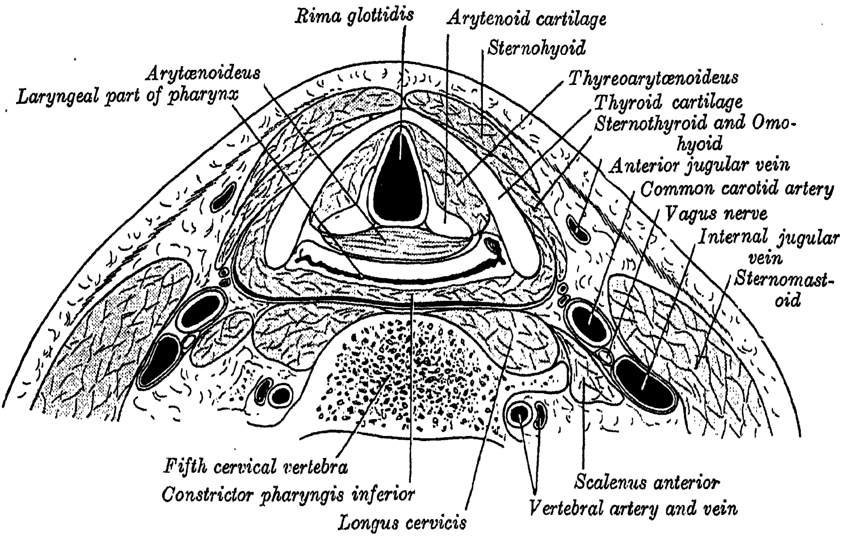
The skeletal framework of the larynx is formed of cartilages, which are connected by ligaments and membranes, and are moved by numerous muscles. It is lined with mucous membrane continuous above and behind with that of the pharynx and below with that of the trachea.

The **cartilages of the larynx** are nine in number, three single and three paired, viz.:

Thyroid.	Two Arytenoid.
Cricoid.	Two Corniculate.
Epiglottis.	Two Cuneiform.

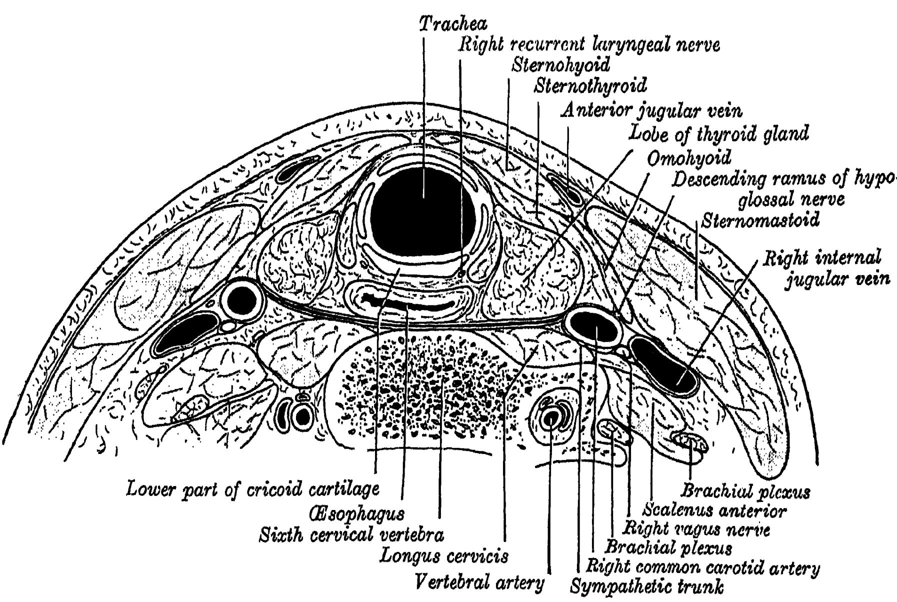
The **thyroid cartilage** (figs. 1082, 1084, 1085) is the largest cartilage of the larynx. It consists of two laminæ, the anterior borders of which are fused at an angle in the median plane, and form a subcutaneous projection named

FIG. 1082.—A section across the anterior part of the neck at the level of the vocal folds.



the *laryngeal prominence* (Adam's apple) (fig. 1082). This prominence is most distinct at its upper part, and is well marked in the male but scarcely visible in the female. Immediately above it the laminæ are separated by a V-shaped notch, termed the *thyroid notch.*

FIG. 1083.—A section across the anterior part of the neck at the level of the lower part of the lamina of the cricoid cartilage.



The *laminæ* are irregularly quadrilateral in shape, and their posterior angles are prolonged into processes termed the *superior* and *inferior horns.*

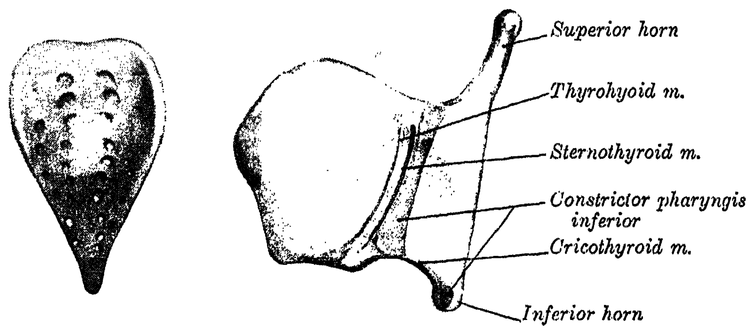
On the *outer surface* of each lamina an *oblique line* runs downwards and forwards from the superior thyroid tubercle, which is situated a little in front

of the root of the superior horn, to the inferior thyroid tubercle on the lower border of the lamina. This line gives insertion to the Sternothyroid, and origin to the Thyrohyoid and Constrictor pharyngis inferior. The *inner surface* is smooth: above and behind, it is slightly concave and covered with mucous membrane. In front, in the angle formed by the junction of the laminæ, the thyro-epiglottic ligament is attached, and on each side the vestibular (ventricular) and vocal ligaments, the Thyreoarytænoideus, Thyreoepiglotticus and Vocalis muscles gain attachment.

The *upper border* of each lamina is concave behind and convex in front; it gives attachment to the corresponding half of the thyrohyoid membrane. The *lower border* is concave behind, and nearly straight in front, the two parts being separated by the inferior thyroid tubercle. A small part of it in and near the median plane is connected to the cricoid cartilage by the cricothyroid ligament.

The *anterior* border is fused with that of the opposite lamina, forming with it an angle of about 90° in men, and about 120° in women. In men the greater projection of the laryngeal prominence, the greater length of the vocal fold and the resultant deeper pitch of the voice are all associated with the smaller size of the thyroid angle. The *posterior border*, thick and rounded, re-

FIG. 1084.—The epiglottis, posterior surface, and the left lamina of the thyroid cartilage, lateral surface.



ceives the insertions of fibres of the Stylopharyngeus and Palatopharyngeus (Pharyngopalatinus) muscles. It ends in the superior and inferior horns. The *superior horn*, long and narrow, is directed upwards, backwards and medially, and ends in a conical extremity, which gives attachment to the lateral thyrohyoid ligament. The *inferior horn*, short and thick, is directed downwards, with a slight inclination forwards and medially; on the medial surface of its lower end there is a small oval facet for articulation with the side of the cricoid cartilage.

During infancy a narrow, lozenge-shaped, flexible strip, named the *intrathyroid cartilage*, occupies the interval between the two laminæ anteriorly and is joined to them by connective tissue.

The **cricoid cartilage** (figs. 1086 to 1089) is smaller, but thicker and stronger than the thyroid cartilage. It is shaped like a signet-ring, and forms the lower parts of the anterior and lateral walls and most of the posterior wall of the larynx. It comprises a quadrate posterior lamina, and a narrow anterior arch.

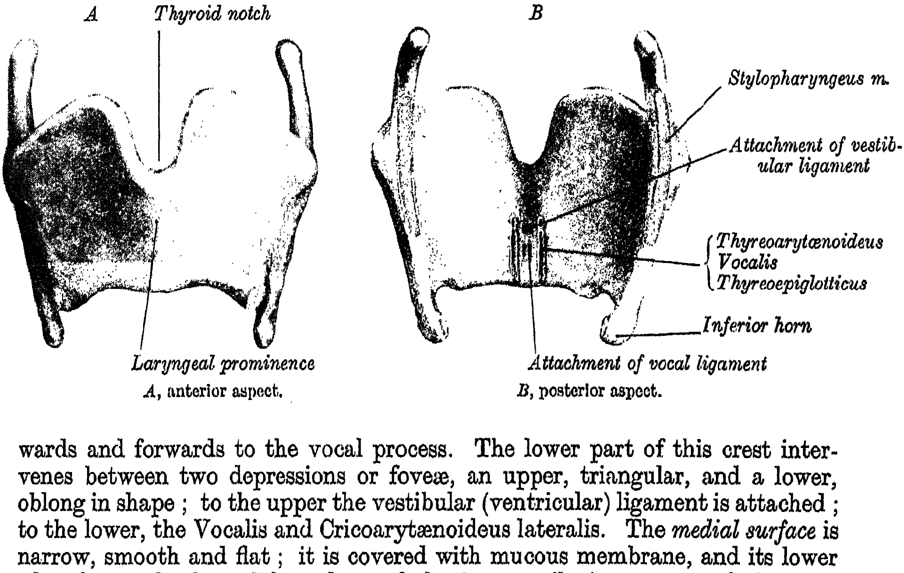
The *lamina* of the cricoid cartilage is deep and broad, and measures vertically from 2 cm. to 3 cm.; the posterior surface is marked by a median, vertical ridge, to the upper part of which the two fasciculi of the longitudinal fibres of the œsophagus are attached by a tendon (p. 1301); and on each side of the ridge there is a shallow depression for the origin of the Cricoarytænoideus posterior. The *arch* is narrow in front, measuring vertically from 5 mm. to 7 mm., but widens posteriorly as it approaches the lamina; on each side it affords attachment in front and at the side to the Cricothyroid muscle, and behind, to part of the Inferior constrictor of the pharynx. It can be felt easily in the living subject below the laryngeal prominence and separated from it by a slight depression which corresponds to the cricothyroid ligament. On each side, at the junction of the lamina with the arch, there is a prominent circular

facet, directed laterally and backwards, for articulation with the inferior horn of the thyroid cartilage. The *lower border* of the cricoid cartilage is horizontal, and connected to the highest ring of the trachea by the cricotracheal ligament. The *upper border* runs obliquely upwards and backwards, owing to the great depth of the lamina. It gives attachment, in front, to the cricothyroid ligament; at the sides, to the cricovocal membrane (conus elasticus) and the Cricoarytænoidei laterales; behind, it presents a median shallow notch, and on each side of this there is a smooth, oval, convex surface, directed upwards and laterally, for articulation with the base of the arytenoid cartilage. The *inner surface* of the cricoid cartilage is lined with mucous membrane.

The paired **arytenoid cartilages** (figs. 1086, 1088) are situated at the upper border of the lamina of the cricoid cartilage, at the back of the larynx. Each is pyramidal in form, and has three surfaces, a base and an apex.

The *posterior surface*, triangular, smooth and concave, is covered with the Arytænoideus transversus. The *anterolateral surface* is somewhat convex and rough. On it, near the apex of the cartilage, there is an elevation (*colliculus*) from which a crest (*crista arcuata*) curves at first backwards and then down-

Fig. 1085.—The thyroid cartilage.



A, anterior aspect. *B*, posterior aspect.

wards and forwards to the vocal process. The lower part of this crest intervenes between two depressions or foveæ, an upper, triangular, and a lower, oblong in shape; to the upper the vestibular (ventricular) ligament is attached; to the lower, the Vocalis and Cricoarytænoideus lateralis. The *medial surface* is narrow, smooth and flat; it is covered with mucous membrane, and its lower edge forms the lateral boundary of the intercartilaginous part of the rima glottidis. The *base* is concave, and presents a smooth surface for articulation with the upper border of the lamina of the cricoid cartilage. Its lateral angle or *muscular process*, rounded and prominent, projects backwards and laterally, and gives insertion to the Cricoarytænoideus posterior behind, and to the Cricoarytænoideus lateralis in front. Its anterior angle or *vocal process* is pointed; it projects horizontally forwards and gives attachment to the vocal ligament. The *apex* curves backwards and medially, and articulates with the *corniculate cartilage*.

The **corniculate cartilages** (figs. 1088, 1095) are two small conical nodules of yellow elastic cartilage which articulate with the summits of the arytenoid cartilages and serve to prolong them backwards and medially. They are situated in the posterior parts of the aryepiglottic folds of mucous membrane, and are sometimes fused with the arytenoid cartilages.

The **cuneiform cartilages** (fig. 1089) are two small, elongated pieces of yellow elastic cartilage, placed one in each aryepiglottic fold, where they give rise to whitish elevations on the surface of the mucous membrane, just in front of the corniculate cartilages.

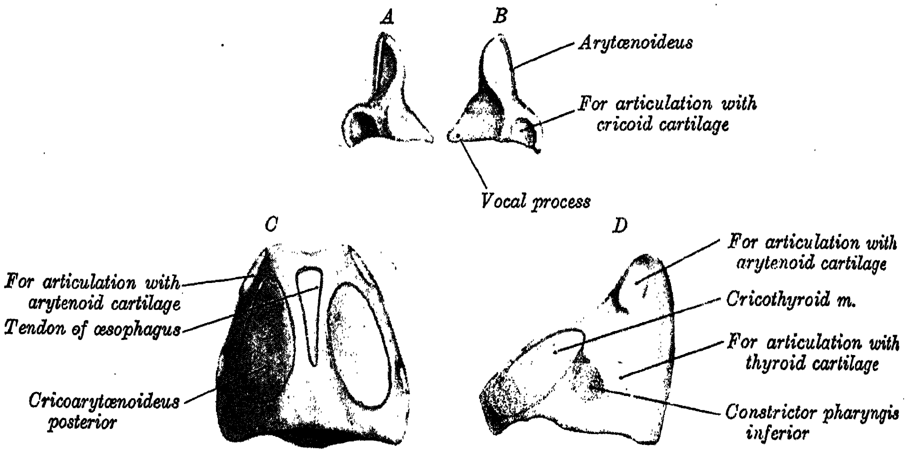
The cartilage of the **epiglottis** * (figs. 1085, 1088, 1089) is a thin, leaf-like lamella of yellow fibrocartilage, which projects obliquely upwards behind the

* The "Function of the Epiglottis" is discussed by V. E. Negus. *Journal of Anatomy*, vol. 62, 1927.

tongue and the body of the hyoid bone, and in front of the entrance to the larynx. The free extremity, broad and rounded, is directed upwards; the attached part or stem is long, narrow, and connected by an elastic ligament, named the *thyro-epiglottic ligament,* to the angle formed by the two laminæ of the thyroid cartilage, a short distance below the thyroid notch. The sides of the epiglottis are attached to the arytenoid cartilages by the aryepiglottic folds of mucous membrane (p. 1233).

The upper part of the *anterior surface* of the epiglottis is free, and covered with mucous membrane, which is reflected on to the pharyngeal part of the tongue and on to the lateral wall of the pharynx, forming a median *glosso-epiglottic fold* and two lateral *pharyngo-epiglottic folds.* The depression on each side of the glosso-epiglottic fold is named the *vallecula.* The lower part of the anterior surface lies behind the hyoid bone and the thyrohyoid membrane, and is connected to the upper border of the hyoid bone by an elastic ligament,

Fig. 1086.—The arytenoid and cricoid cartilages.



A, the left arytenoid cartilage, medial aspect. *B*, the right arytenoid cartilage, medial aspect. *C*, the cricoid cartilage, posterior aspect. *D*, the cricoid cartilage, left lateral aspect.

named the *hyo-epiglottic ligament*; it is separated from the thyrohyoid membrane by some fatty tissue.

The *posterior surface* of the epiglottis is smooth, concave from side to side, concavoconvex from above downwards, and covered with mucous membrane; its lower part projects backwards as an elevation, known as the *tubercle.* When the mucous membrane is removed, the cartilage is seen to be indented by a number of small pits in which mucous glands are lodged.

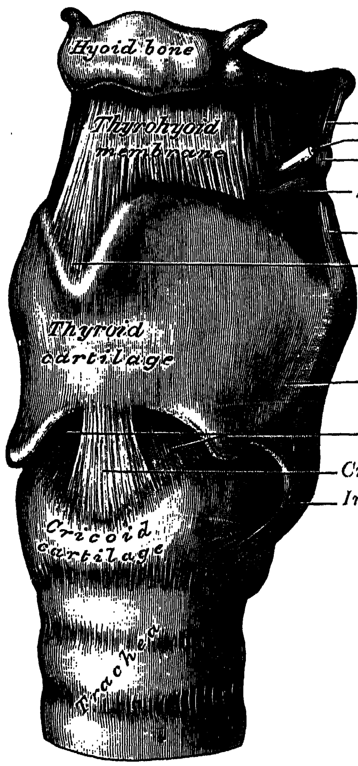
Structure.—The corniculate and cuneiform cartilages, the epiglottis, and the apices of the arytenoids consist of yellow fibrocartilage, which shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, and somewhat later in the cricoid and the arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

Joints.—The joints between the inferior horns of the thyroid cartilage and the sides of the cricoid cartilage are synovial, and each is enveloped by a capsular ligament, which is strengthened posteriorly by a fibrous band. Rotatory and gliding movements occur at these joints. The rotatory movement is one in which the cricoid cartilage rotates upon the inferior horns of the thyroid cartilage around an axis passing transversely through both joints. The gliding movement consists in a limited shifting of the cricoid on the thyroid in different directions.

A pair of synovial joints exist between the facets on the upper border of the lamina of the cricoid cartilage and the bases of the arytenoid cartilages; each joint is enclosed by a capsular ligament, and a strong *posterior crico-*

arytenoid ligament connects the cricoid cartilage with the medial and posterior part of the base of the arytenoid cartilage. These joints permit of two varieties of movement: one is a rotation of the arytenoid on a vertical axis, whereby the vocal process is moved laterally or medially, and the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other; from the direction and slope of the articular surfaces lateral gliding is accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with medial rotation, and the lateral gliding with lateral rotation. The posterior crico-arytenoid ligaments limit the forward movements of the arytenoid cartilages on the cricoid cartilage.

FIG. 1087.—The ligaments of the larynx. Anterolateral aspect.



A cartilaginous, sometimes a synovial, joint exists between the apex of each arytenoid cartilage and the corresponding corniculate cartilage, and a Y-shaped ligament, termed the *cricopharyngeal ligament*, unites the apices of the corniculate cartilages to the upper border of the lamina of the cricoid cartilage.

Ligaments and membranes.—The ligaments of the larynx (figs. 1087, 1088) are (*a*) *extrinsic*, those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and (*b*) *intrinsic*, those uniting the cartilages of the larynx to one another.

Extrinsic ligaments.—The thyroid cartilage is connected to the hyoid bone by the thyrohyoid membrane, and by a median and two lateral thyrohyoid ligaments.

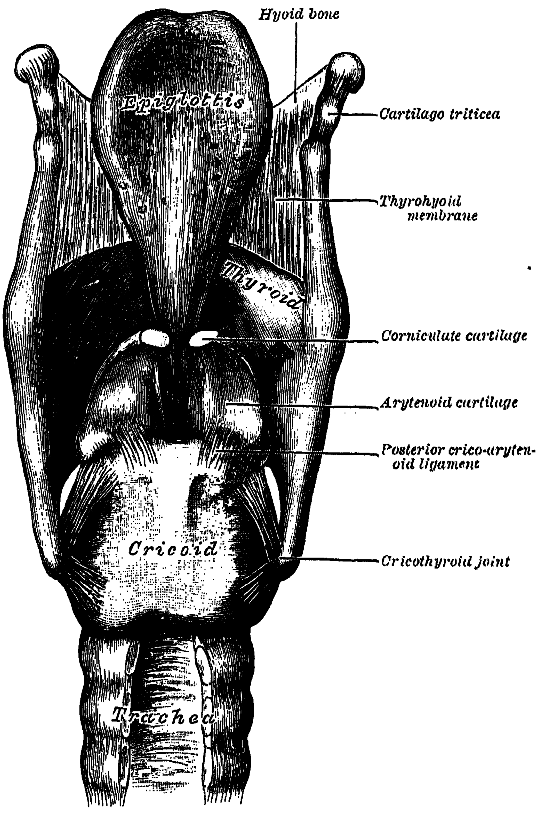
The *thyrohyoid membrane* is a broad, fibro-elastic layer, attached below to the upper border of the thyroid cartilage and to the front of its superior horns, and above to the upper margin of the posterior surface of the body and greater horns of the hyoid bone. As it ascends, it passes behind the posterior surface of the body of the hyoid bone, and is separated from it by a bursa, which facilitates the upward movement of the larynx during deglutition. The middle, thicker, part of the membrane is termed the *median thyrohyoid ligament*; on

each side the lateral thinner portion is pierced by the superior laryngeal vessels and the internal laryngeal nerve. Its outer surface is in relation with the Thyrohyoid, Sternohyoid and Omohyoid muscles, and with the body of the hyoid bone.

The *lateral thyrohyoid ligaments* are round elastic cords which form the posterior borders of the thyrohyoid membrane, and connect the tips of the superior horns of the thyroid cartilage to the posterior ends of the greater horns of the hyoid bone. A small cartilaginous nodule, termed the *cartilago triticea*, is frequently found in each ligament.

The epiglottis is attached to the hyoid bone by the hyo-epiglottic ligament, and to the thyroid cartilage by the thyro-epiglottic ligament (p. 1230).

FIG. 1088.—The ligaments of the larynx. Posterior aspect.



The *cricotracheal ligament* unites the lower border of the cricoid cartilage with the first ring of the trachea. It is continuous below with the fibrous membrane which invests the rings of the trachea.

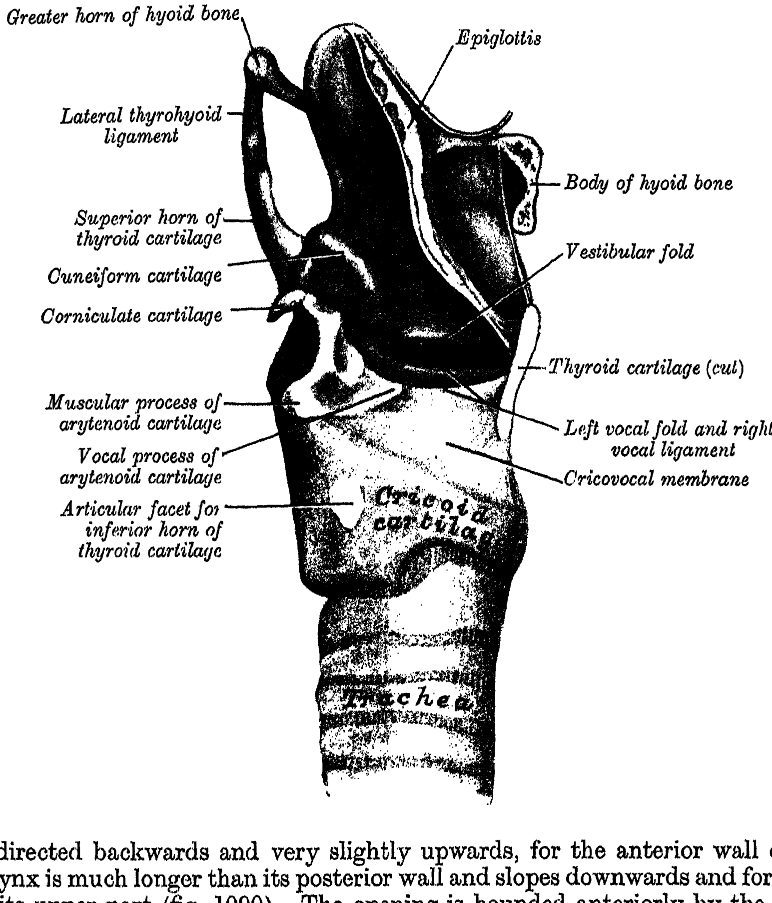
Intrinsic ligaments.—Beneath the mucous membrane of the larynx there is a broad sheet of fibrous tissue which contains many elastic fibres, and is termed the *elastic membrane of the larynx*. It is subdivided on each side by the interval between the vestibular (ventricular) and vocal ligaments; the upper portion extends between the arytenoid cartilage and the cartilage of the epiglottis, and is often poorly defined; the lower part is a well-marked membrane forming, with its fellow of the opposite side, the cricovocal membrane (conus elasticus), which connects the thyroid, cricoid, and arytenoid cartilages one to another. The joints between the individual cartilages are also provided with ligaments, already described.

The *cricovocal membrane* (conus elasticus) (fig. 1089) is composed mainly of yellow elastic tissue. It consists of an anterior and two lateral parts. The *anterior* part, or *cricothyroid ligament*, is thick and strong, narrow above and broad below. It connects the front parts of the contiguous margins of the thyroid and cricoid cartilages. It is overlapped on each side by the Cricothyroid, but between these muscles it is subcutaneous; its upper part is crossed by a small arterial arch, formed by the junction of the two cricothyroid arteries; branches of this arch pierce the ligament. The *lateral* part of the cricovocal membrane is thinner; it is lined with the mucous membrane of the larynx, and is covered with the Cricoarytænoideus lateralis and Thyreoarytænoideus. It extends upwards and medially from the inner edge of the superior border of the cricoid cartilage, and is attached, in front, to the deep surface of the thyroid angle and, behind, to the inferior surface and tip of the vocal process of the arytenoid cartilage. *Between these two attachments, the upper edge of the lateral part of the cricovocal membrane is free and is thickened slightly to form the* vocal ligament (fig. 1089).

Cavum laryngis (figs. 1090, 1091).—The *cavity of the larynx* extends from the laryngeal inlet, by which it communicates with the pharynx, to the level of the lower border of the cricoid cartilage, where it is continuous with the cavity of the trachea. It is divided into three parts by an upper and a lower pair of folds of mucous membrane which project from the sides of the cavity into its interior. The upper folds are named the *vestibular folds* (ventricular folds), and the fissure between them is called the *rima vestibuli*. The lower folds are concerned in the production of the voice, and are therefore named the *vocal folds*, and the fissure between them is called the *rima glottidis*.

The *inlet of the larynx* [aditus laryngis] (fig. 1092) is the aperture through which the laryngeal cavity opens into the pharynx. The plane of the aperture

Fig. 1089.—A dissection to show the right half of the cricovocal membrane. The right lamina of the thyroid cartilage and the subjacent muscles have been removed.



is directed backwards and very slightly upwards, for the anterior wall of the larynx is much longer than its posterior wall and slopes downwards and forwards in its upper part (fig. 1090). The opening is bounded anteriorly by the upper edge of the epiglottis, posteriorly by the mucous membrane stretching between the arytenoid cartilages, and on each side by the free edge of a fold of mucous membrane which stretches between the side of the epiglottis and the apex of the arytenoid cartilage and contains some ligaments and muscular fibres ; this is the *aryepiglottic fold*, and on the posterior part of its free margin there are two oval elevations, an anterior produced by the cuneiform cartilage, and a posterior by the corniculate cartilage. These elevations are separated by a shallow vertical furrow, which is continuous below with the opening into the sinus (ventricle) of the larynx.

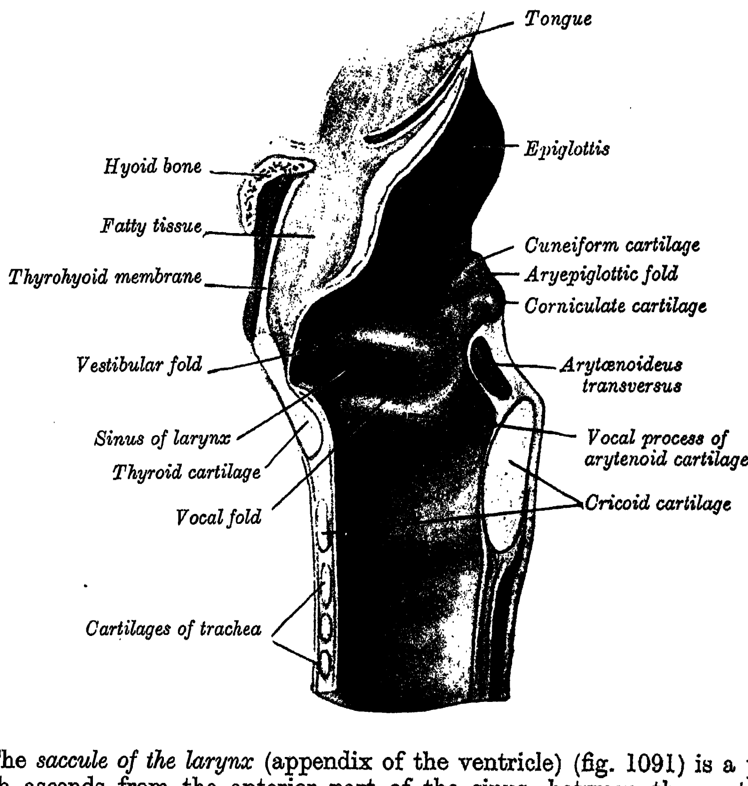
The *vestibule of the larynx* (figs. 1090, 1091) is the part between the laryngeal inlet and the level of the vestibular folds ; it is wide above, and narrow below. Its anterior wall is much deeper than its posterior wall and consists of the posterior surface of the epiglottis, the lower part of which projects backwards,

as the tubercle (p. 1230). Its lateral walls, deep in front and shallow behind, are formed by the medial surfaces of the aryepiglottic folds; its posterior wall consists of the mucous membrane connecting the arytenoid cartilages, above the level of the vestibular folds.

The *middle part* of the laryngeal cavity is the smallest. It reaches from the level of the rima vestibuli to that of the rima glottidis. On each side it opens, through a slit between the vestibular and vocal folds, into a recess which is named the sinus of the larynx.

The *sinus* (ventricle) *of the larynx* (figs. 1090, 1091) is a fusiform recess on each side, between the vestibular and vocal folds, and ascending for a short distance outside the vestibular fold. It is lined with mucous membrane, lateral to which is the corresponding Thyroarytenoid muscle. From the anterior part of the sinus a narrow opening leads upwards into the saccule of the larynx.

FIG. 1090.—A sagittal section through the larynx.



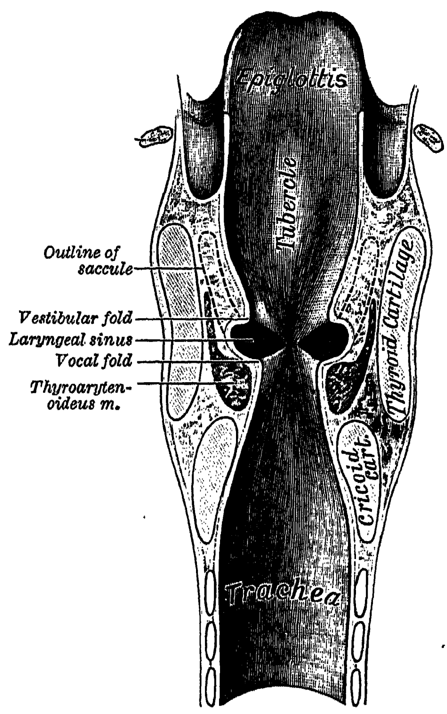
The *saccule of the larynx* (appendix of the ventricle) (fig. 1091) is a pouch which ascends from the anterior part of the sinus, between the vestibular fold and the inner surface of the thyroid cartilage, occasionally extending as high as the upper border of the cartilage; it is conical in form, and curved slightly backwards. On the surface of its mucous membrane there are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. The saccule is enclosed in a fibrous capsule continuous below with the vestibular ligament. Its medial surface is covered by a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilage and, passing forwards between the saccule of the larynx and the mucous membrane of the vestibule, become lost in the aryepiglottic fold; laterally it is separated from the thyroid cartilage by the Thyreoepiglotticus. These muscles compress the sac and express the secretion of its glands upon the vocal fold to lubricate its surfaces.

The *vestibular folds* (ventricular folds) (figs. 1089, 1090, 1091) are two thick folds of mucous membrane, each enclosing a narrow band of fibrous tissue, termed the *vestibular ligament*, which is fixed in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottic cartilage, and

behind to the anterolateral surface of the arytenoid cartilage, a short distance above the vocal process.

The *vocal folds* (figs. 1089, 1090, 1091) are two sharp folds of mucous membrane which stretch from the angle of the thyroid cartilage, at about its middle, to the vocal processes of the arytenoid cartilages. They form the lateral boundaries of the rima glottidis in its anterior part and are intimately concerned in the production of the voice. The epithelium which covers the vocal fold is of the stratified squamous type and is closely bound down to the underlying vocal ligament. As a result of the absence of a submucous layer with its contained blood-vessels, the vocal fold is pearly white in colour in the living subject. The *vocal ligament*, which is continuous below with the lateral part of the cricovocal membrane (conus elasticus) (p. 1232), consists of a band of yellow elastic tissue, related, on its lateral side, to the Vocalis muscles (p. 1238).

FIG. 1091.—A coronal section through the larynx and the upper part of the trachea.



The *rima glottidis* (fig. 1093) is a fissure situated between the vocal folds anteriorly, and between the bases and vocal processes of the arytenoid cartilages posteriorly; it is limited behind by the mucous membrane passing between the arytenoid cartilages, at the level of the vocal folds. The portion between the vocal folds is named the *intermembranous part*, and measures about three-fifths of the length of the entire aperture; that between the arytenoid cartilages is named the *intercartilaginous part*. The average length of the rima glottidis, in the adult male, is 23 mm.; in the adult female, 17 mm. It is the narrowest part of the larynx, but its width and shape vary with the movements of the vocal folds and arytenoid cartilages during respiration and phonation. In the condition of rest, as in quiet respiration, the intermembranous part is triangular, with its apex in front and its base behind—the latter being represented by a line, about 8 mm. long, connecting the anterior ends of the vocal processes—while the medial surfaces of the arytenoid cartilages are parallel to each other and hence the intercartilaginous part is rectangular. During extreme adduction of the vocal folds, as in the production of a high note, the intermembranous part of the rima glottidis is reduced to a linear slit by the approximation of the vocal folds, while the intercartilaginous part becomes triangular, its apex corresponding to the anterior ends of the vocal processes of the arytenoid cartilages, which are brought close together by the medial rotation of the cartilages. Conversely, in extreme abduction of the vocal folds, as in forced inspiration, the arytenoid cartilages are rotated laterally, and their vocal processes are drawn widely apart, with the result that the intercartilaginous part is triangular in shape but with its apex directed backwards. In this condition the rima glottidis is somewhat lozenge-shaped, the sides of the intermembranous part diverging from before backwards, those of the intercartilaginous part diverging from behind forwards—the widest part of the aperture corresponding with the attachments of the vocal folds to the vocal processes.

The *lower part* of the laryngeal cavity extends from the level of the vocal folds to the lower border of the cricoid cartilage. Its upper part is elliptical in form, but its lower part widens, assumes a circular shape, and is continuous with the cavity of the trachea. It is lined with mucous membrane, and its

walls consist of the cricovocal membrane (conus elasticus) above, and the inner surface of the cricoid cartilage below.

Muscles.—The muscles of the larynx are divisible into two groups :—(1) *extrinsic* and (2) *intrinsic.*

(1) The extrinsic muscles pass between the larynx and neighbouring structures, and are described in the section on Myology.

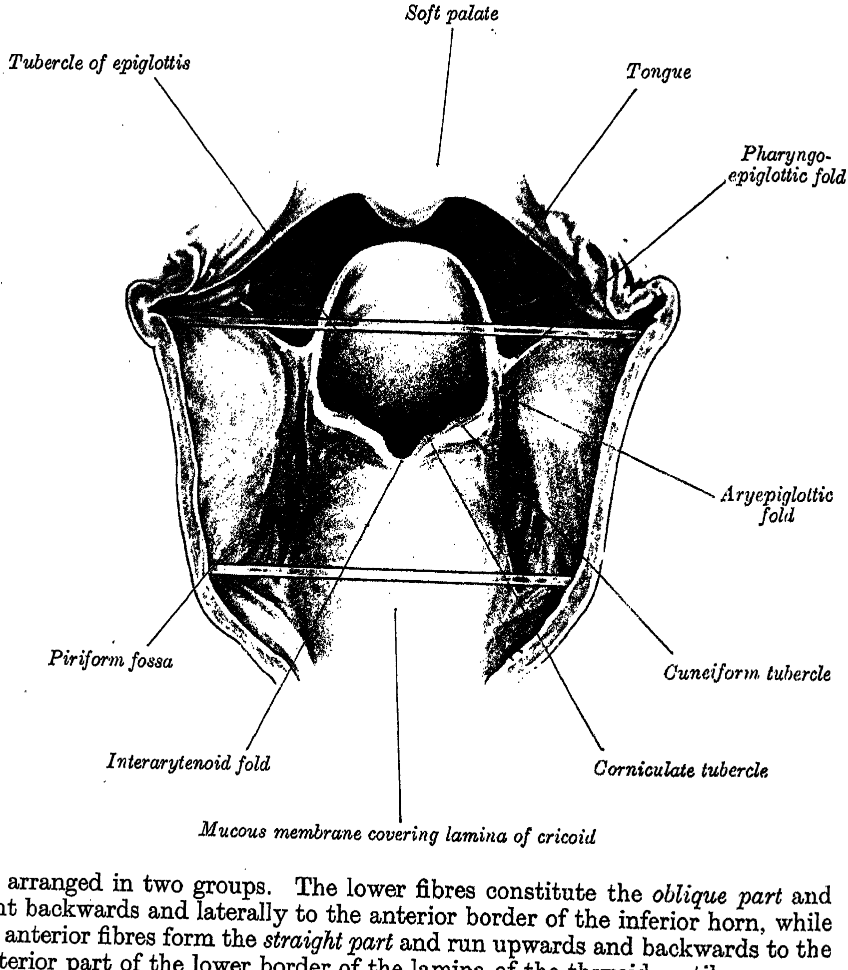
(2) The intrinsic muscles are :

Cricothyreoideus	Arytænoideus transversus.
pars obliqua,	Arytænoideus obliquus.
pars recta.	Aryepiglotticus.
Cricoarytænoideus posterior.	Thyreoarytænoideus.
Cricoarytænoideus lateralis.	Vocalis.
Thyreoepiglotticus.	

With the exception of the Arytænoideus transversus these muscles are paired.

The *Cricothyroid* (fig. 1094), triangular in form, arises from the front and lateral part of the outer surface of the cricoid cartilage ; its fibres diverge, and

FIG. 1092.—The inlet of the larynx, viewed from behind. The posterior wall of the pharynx has been divided in the median plane and two glass rods have been inserted to keep the cut portions apart.



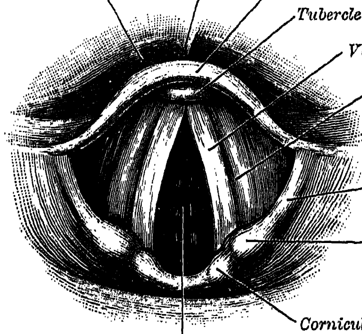
are arranged in two groups. The lower fibres constitute the *oblique part* and slant backwards and laterally to the anterior border of the inferior horn, while the anterior fibres form the *straight part* and run upwards and backwards to the posterior part of the lower border of the lamina of the thyroid cartilage.

The medial borders of the two muscles are separated by a triangular interval occupied by the subcutaneous part of the cricothyroid ligament.

The *Cricoarytænoideus posterior* (fig. 1095) arises from the lower and medial part of the broad depression on the corresponding half of the posterior surface

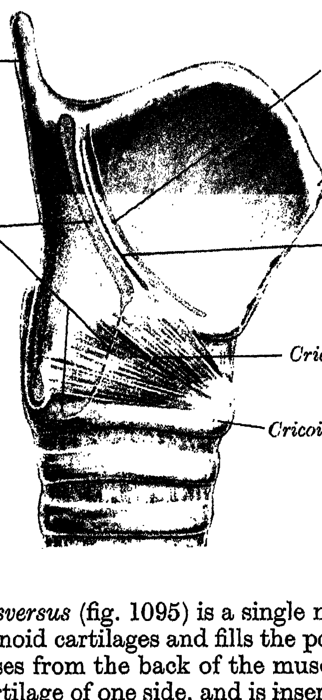
of the lamina of the cricoid cartilage ; its fibres, directed upwards and laterally, converge to be inserted into the back of the muscular process of the arytenoid cartilage. The highest fibres are nearly horizontal, the middle oblique and the lowest almost vertical.

FIG. 1093.—A laryngoscopic view of the interior of the larynx.



The *Cricoarytænoideus lateralis* (fig. 1096) is smaller than the preceding muscle ; it arises from the upper border of the arch of the cricoid cartilage, and, passing obliquely upwards and backwards, is inserted into the front of the muscular process of the arytenoid cartilage.

FIG. 1094.—A side view of the larynx, showing the muscular attachments.



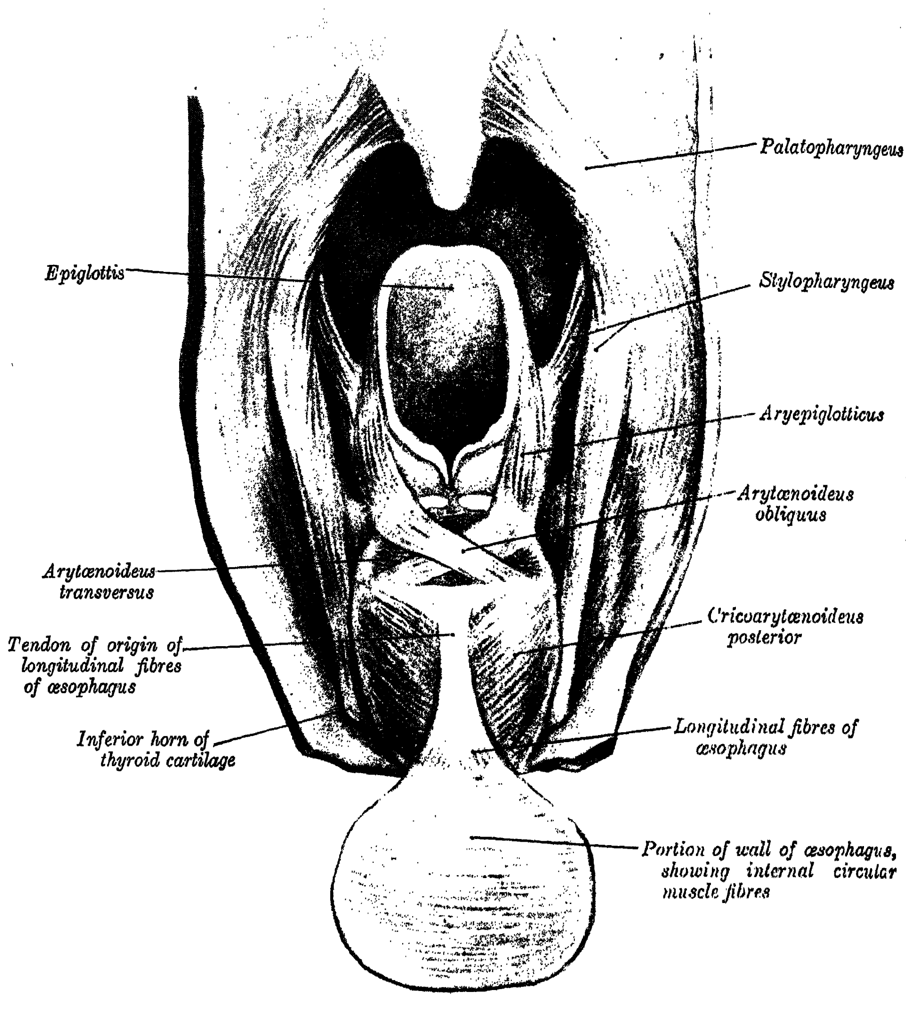
The *Arytænoideus transversus* (fig. 1095) is a single muscle which bridges the interval between the arytenoid cartilages and fills the posterior concave surfaces of these cartilages. It arises from the back of the muscular process and lateral border of the arytenoid cartilage of one side, and is inserted into the corresponding parts of the cartilage on the opposite side.

The *Arytænoideus obliquus* (fig. 1095), superficial to the Arytænoideus transversus, consists of two fasciculi which cross each other like the limbs of the letter X. Each passes from the back of the muscular process of one arytenoid cartilage to the apex of the opposite cartilage. Some of the fibres are continued

round the lateral margin of the apex of the arytenoid cartilage, and are prolonged into the aryepiglottic fold; they constitute the *Aryepiglotticus* muscle.

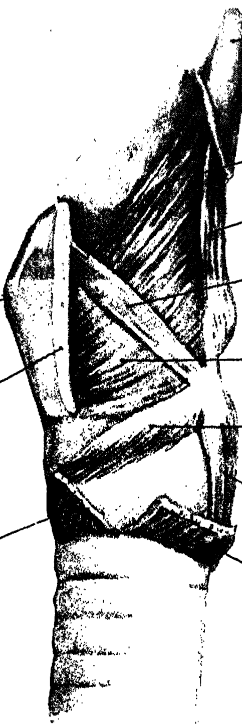
The *Thyreoarytænoideus* (fig. 1096) is a broad, thin muscle, which is situated lateral to the vocal fold, the cricovocal membrane, the sinus and the saccule of the larynx. It arises in front from the lower half of the angle of the thyroid cartilage, and from the cricothyroid ligament. Its fibres pass backwards, laterally and upwards, to be inserted into the anterolateral surface of the arytenoid cartilage. The lower and deeper fibres of the muscle form a band which, in a coronal section, appears as a triangular bundle, and is attached to the lateral surface of the vocal process and to the inferior impression on the anterolateral surface of the arytenoid cartilage. This bundle is named the *Vocalis* muscle, and is parallel with, and just lateral to, the vocal ligament. The Vocalis is thicker behind than in front, because many of its deeper fibres take origin from the vocal ligament, and so do not extend so far forwards as the thyroid cartilage. A considerable number of the fibres of the Thyreoarytænoideus are prolonged into the aryepiglottic fold, where some of them are lost, while others are continued to the margin of the epiglottis, forming the *Thyreoepiglotticus*. A few fibres extend along the wall of the sinus (ventricle) from the lateral margin of the arytenoid cartilage to the side of the epiglottis. The *Thyreoarytænoideus superior* (fig. 1096) is not always present.

FIG. 1095.—The muscles of the larynx. Posterior aspect.



Actions.—The muscles of the larynx may be conveniently divided into three groups, (1) those which open and close the glottis, viz. the Cricoarytænoidei posteriores et laterales and the Arytænoidei ; (2) those which regulate the degree of tension of the vocal ligaments, viz. the Cricothyreoidei, the Thyreoarytænoidei, and the Vocales ; (3) those which modify the inlet of the larynx, viz. the Aryepiglottici and the Thyreoepiglottici.

FIG. 1096.—The muscles of the larynx. Lateral aspect. The left lamina of the thyroid cartilage has been removed.



The *Cricoarytænoidei posteriores* open the glottis, by rotating the arytenoid cartilage laterally around a vertical axis passing through the crico-arytenoid joints, so that the vocal processes and the attached vocal folds are separated.

The *Cricoarytænoidei laterales* close the glottis, by rotating the arytenoid cartilages medially so as to approximate the vocal processes.

The *Arytænoideus transversus* approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its posterior part.

The *Cricothyroids* produce tension and elongation of the vocal ligaments by drawing up the arch of the cricoid cartilage and tilting back the upper border of its lamina ; the distance between the vocal processes and the angle of the thyroid is thus increased, and the vocal ligaments are consequently put on the stretch.

The *Thyreoarytænoidei* draw the arytenoid cartilages forwards towards the thyroid, and thus shorten and relax the vocal ligaments. At the same time they rotate the arytenoid cartilages medially and approximate the vocal folds. The deeper fibres, forming the *Vocales*, produce relaxation of the posterior parts of the vocal ligaments, while the anterior part is tense, the effect being to raise the pitch of the voice.

The *Arytænoidei obliqui* and the *Aryepiglottici* act as a sphincter of the inlet of the larynx, by bringing the aryepiglottic folds together, and by approximating the arytenoid cartilages to the tubercle of the epiglottis.

The *Thyreoepiglottici* tend to widen the inlet of the larynx by their action on the aryepiglottic folds.

The manner in which the inlet of the larynx is closed during deglutition is referred to on p. 1299.

Mucous Membrane.—The mucous membrane of the larynx is continuous above with that of the mouth and pharynx, below with that of the trachea. It is loosely attached to the anterior surface of the epiglottis, and to the underlying tissues in the valleculæ. It covers the aryepiglottic folds, which bound the inlet of the larynx ; in these folds there

is a considerable amount of areolar tissue. It lines the cavity of the larynx, forms, by its reduplication, the chief parts of the vestibular folds, and is continued into the sinus and saccule of the larynx. It is firmly attached to the posterior surface of the epiglottis and to the laryngeal surfaces of the cuneiform and arytenoid cartilages. The parts covering the vocal ligaments are thin and intimately adherent to them. On the anterior surface, and the upper half of the posterior surface, of the epiglottis, the upper part of the aryepiglottic folds, and the vocal folds, the epithelium of the mucous membrane is of the stratified squamous type; patches of stratified squamous epithelium are also found above the glottis. The rest of the laryngeal mucous membrane is covered with ciliated columnar epithelium.

Glands.—The mucous membrane of the larynx is furnished with numerous mucous glands; they are very plentiful upon the epiglottis, where they are lodged in little pits; many are present in the margins of the aryepiglottic folds in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They are large and numerous in the saccules of the larynx. The free edges of the vocal folds are devoid of glands.

Taste-buds, similar to those in the tongue, are scattered over the posterior surface of the epiglottis, in the aryepiglottic folds, and less regularly in some other parts of the larynx.

Vessels and Nerves.—The chief *arteries* of the larynx are the laryngeal branches of the superior and inferior thyroid arteries. The *veins* accompanying the superior laryngeal artery join the superior thyroid vein, which opens into the internal jugular vein; those accompanying the inferior laryngeal artery join the inferior thyroid vein, which opens into the innominate vein. The *lymph vessels* are divisible into two sets, a superior above the vocal folds, and an inferior below; the superior vessels accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and end in the deep cervical lymph glands situated near the bifurcation of the common carotid artery; some of the inferior lymph vessels pierce the cricothyroid ligament and open into a lymph gland lying in front of that ligament or in front of the upper part of the trachea, while others emerge below the cricoid cartilage and pass to the deep cervical lymph glands and to the lymph glands alongside of the inferior thyroid artery. The *nerves* are derived from the internal and external branches of the superior laryngeal nerve, from the recurrent laryngeal nerve and from the sympathetic. The internal laryngeal branch is almost entirely sensory, but some motor filaments are said to be carried by it to the Arytænoideus. It enters the larynx through the postero-inferior part of the thyrohyoid membrane above the superior laryngeal artery, and divides into branches which supply both surfaces of the epiglottis, the aryepiglottic fold, and the interior of the larynx down as far as the level of the vocal folds. The external laryngeal branch supplies the Cricothyroid by entering its lateral surface. The terminal part of the recurrent laryngeal nerve accompanies the laryngeal branch of the inferior thyroid artery, and passes upwards deep to the lower border of the Constrictor pharyngis inferior, immediately behind the cricothyroid joint. It supplies all the intrinsic muscles of the larynx except the Cricothyroid, and distributes sensory branches to the laryngeal mucous membrane below the level of the vocal folds. See also footnote, p. 1073.

Laryngoscopic examination.—The inlet of the larynx, the structures surrounding it, and the cavity of the larynx can be inspected with the laryngoscope. The epiglottis is much foreshortened (fig. 1093), but its tubercle can be seen in the median plane. From the margins of the epiglottis the aryepiglottic folds can be traced backwards and medially and, at their posterior extremities, the elevations produced by the cuneiform and the corniculate cartilages can be recognised. Both the vestibular and the vocal folds are visible within the cavity of the larynx and, when the rima glottidis is opened widely, the rings of the trachea come into view.

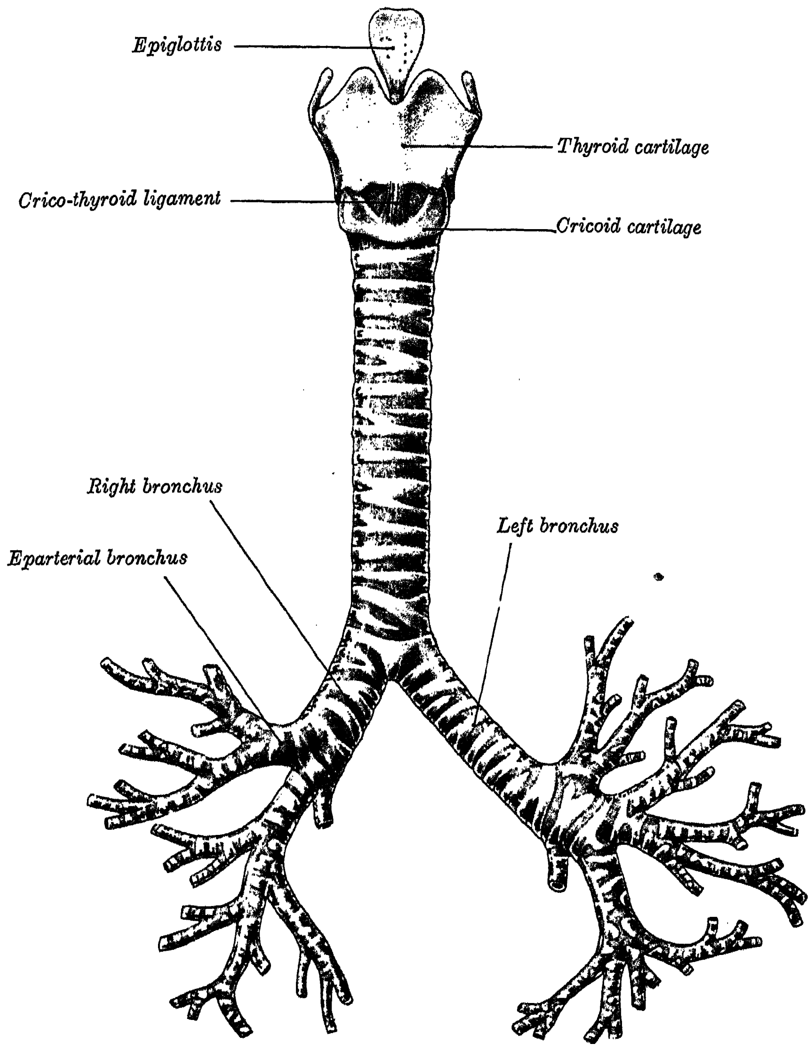
The Trachea and Bronchi (fig. 1097)

The trachea, or windpipe, is a cartilaginous and membranous tube, about 10 or 11 cm. long, continued downwards from the lower part of the larynx, and reaching from the level of the sixth cervical vertebra to that of the upper border of the fifth thoracic vertebra, where it divides into two bronchi, one for each lung. The point of bifurcation usually lies a little to the right of the median plane. The trachea is not quite cylindrical, being flattened posteriorly; its diameter from side to side is about 2 cm. in the adult male, and 1·5 in the adult female. In the child the trachea is smaller, more deeply placed and more movable than in the adult.

Relations of the trachea.—The *cervical part* of the trachea (fig. 1098) presents the following relations. Anteriorly it is covered with the skin, the superficial and deep fasciæ, crossed by the jugular arch connecting the anterior jugular veins and overlapped by the Sternohyoid and Sternothyroid muscles. The second, third and fourth rings of the trachea are crossed by the isthmus of the thyroid gland, and immediately above the isthmus by an anastomosing

vessel which connects the two superior thyroid arteries ; below the isthmus it is related, in front, to the pretracheal fascia, the inferior thyroid veins, the remains of the thymus, and the arteria thyreoidea ima (when that vessel exists). In the child, the innominate artery crosses obliquely in front of the trachea at, or a little above, the level of the upper border of the manubrium sterni. Posteriorly the trachea is related to the œsophagus, which intervenes between it

FIG. 1097.—The cartilages of the larynx, trachea, and bronchi. Anterior aspect.

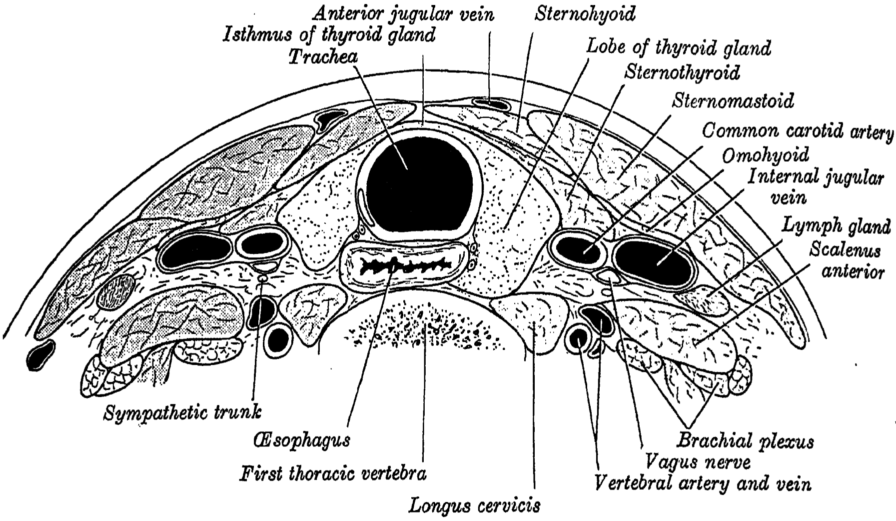


and the vertebral column ; the recurrent laryngeal nerves ascend, one on each side, in the grooves between the sides of the trachea and the œsophagus. *Laterally* the trachea is related to the lobes of the thyroid gland, which descend to the level of the fifth or sixth tracheal ring, and to the common carotid and inferior thyroid arteries.

The *thoracic part* of the trachea (figs. 1099, 1100) descends through the superior mediastinum. *In front*, its *upper* portion is related to the manubrium sterni, the origins of the Sternothyroid muscles, the remains of the thymus, and the inferior thyroid veins ; and its *lower* portion, to the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, the deep part of the cardiac plexus of nerves, and some lymph glands. Owing to the divergence of the innominate and left common carotid arteries as they

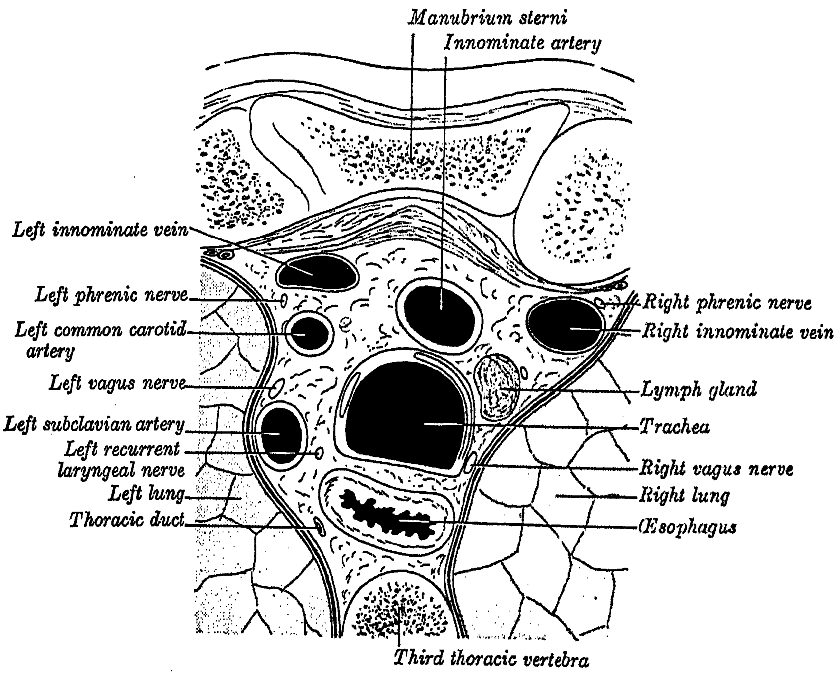
ascend in the neck, the former vessel comes to lie on the right, and the latter on the left of the trachea. *Behind*, it is related to the œsophagus, by which it is

FIG. 1098.—A transverse section through the anterior part of the neck at the level of the body of the first thoracic vertebra.



separated from the vertebral column. On the *right* it is related to the right lung and pleura, the right vagus nerve, and the azygos vein : on the left to the arch of the aorta, the left common carotid and left subclavian arteries. The left

FIG. 1099.—A transverse section through the mediastinum at the level of the body of the third thoracic vertebra.

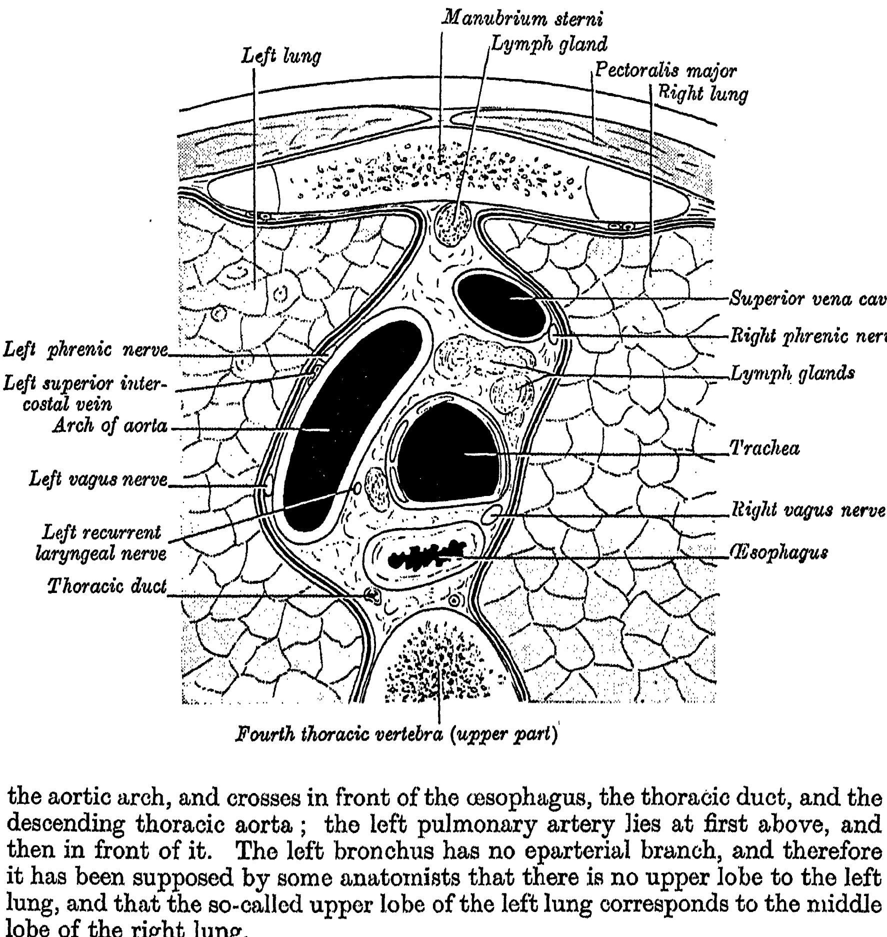


recurrent laryngeal nerve, in its upward course, lies at first between the trachea and the arch of the aorta, and then in the groove between the trachea and the œsophagus.

The **right bronchus**, wider, shorter, and more vertical than the left, is about 2·5 cm. long, and enters the right lung nearly opposite the fifth thoracic vertebra. The azygos vein arches over it from behind ; the right pulmonary artery lies at first below and then in front of it. It gives off a branch to the upper lobe of the right lung ; this is termed the *eparterial bronchus*, because it arises above the right pulmonary artery. The bronchus now passes below the artery, and is known as the *hyparterial bronchus* ; this divides into two branches, one for the middle and the other for the lower lobe of the lung.

The **left bronchus**, narrower than the right, is nearly 5 cm. long, and enters the root of the left lung opposite the sixth thoracic vertebra. It passes below

FIG. 1100.—A transverse section through the mediastinum at the level of the upper part of the body of the fourth thoracic vertebra.



the aortic arch, and crosses in front of the œsophagus, the thoracic duct, and the descending thoracic aorta ; the left pulmonary artery lies at first above, and then in front of it. The left bronchus has no eparterial branch, and therefore it has been supposed by some anatomists that there is no upper lobe to the left lung, and that the so-called upper lobe of the left lung corresponds to the middle lobe of the right lung.

The further subdivision of the bronchi will be considered with the structure of the lung.

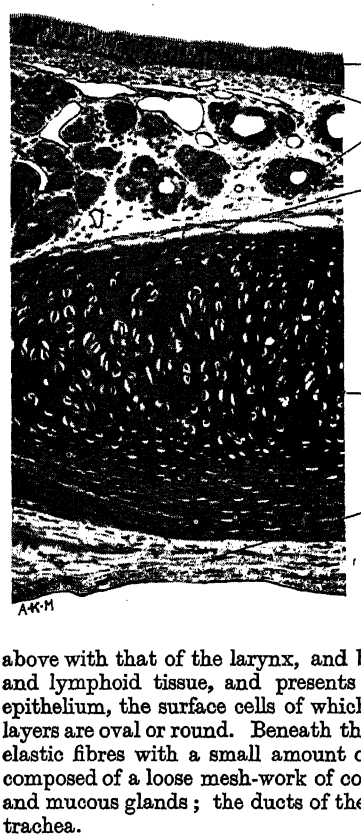
Structure (fig, 1101).—The trachea and extrapulmonary bronchi consist of a framework of imperfect rings of hyaline cartilage, united by fibrous and unstriped muscular tissue. They are lined by mucous membrane.

The *cartilages* of the trachea vary from sixteen to twenty in number. Each is an imperfect ring which occupies the anterior two-thirds or so of the circumference of the trachea ; behind, where the rings are deficient, the tube is flat, and is completed by fibrous tissue and unstriped muscular fibres. The cartilages are placed horizontally one above another, and are separated by narrow intervals. They measure about 4 mm. in depth and 1 mm. in thickness ; their external surfaces are flattened, but their internal surfaces are convex. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified

in advanced life. In the bronchi the cartilages are shorter and narrower than those of the trachea, but have the same shape and arrangement.

The first and the last tracheal cartilages differ from the others (fig. 1097). The *first cartilage* is broader than the rest, and often divided at one end; it is connected by the cricotracheal ligament with the lower border of the cricoid cartilage, with which, or with the succeeding cartilage, it is sometimes blended. The *last cartilage* is thick and broad in the middle, where its lower border is prolonged into a triangular hook-shaped process which curves downwards and backwards between the two bronchi. It forms on each side an imperfect ring which encloses the commencement of the bronchus. The cartilage above the last is somewhat broader at its centre than the others.

FIG. 1101.—A transverse section through a part of the wall of the trachea.



The *fibrous membrane.*—The cartilages are enclosed in an elastic fibrous membrane which consists of two layers, one, the denser, passing over the outer surfaces of the rings, the other over the inner surfaces: at the upper and lower margins of the cartilages the two layers blend and form a stout membrane which connects the rings one with another. Where the cartilages are deficient posteriorly, the membrane forms a single layer.

The *muscular tissue* is placed within the fibrous membrane at the posterior part of the tube, and consists of two layers of non-striped muscle, longitudinal and transverse. The *longitudinal fibres* are external, and consist of a few scattered bundles. The *transverse fibres* (Trachealis muscle) are internal, and form a thin layer which not only extends between the ends of the cartilages but also passes across in the intervals between the cartilages.

Mucous Membrane.—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. It consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting an epithelium, the surface cells of which are columnar and ciliated, while those of the deeper layers are oval or round. Beneath the basement-membrane there is a layer of longitudinal elastic fibres with a small amount of intervening areolar tissue. The *submucous layer* is composed of a loose mesh-work of connective tissue, containing large blood-vessels, nerves and mucous glands; the ducts of the latter pierce the overlying layers and open into the trachea.

Vessels and Nerves.—The trachea is supplied with blood mainly by the inferior thyroid *arteries*. The *veins* end in the thyroid venous plexus. The *lymph vessels* pass to the pretracheal and paratracheal lymph glands. The *nerves* are derived from the vagi and the recurrent laryngeal nerves, and from the sympathetic trunks; they are distributed to the Trachealis muscle and between the epithelial cells.

Applied Anatomy.—Foreign bodies often find their way into the air-passages, and may become lodged in the inlet of the larynx, or in the rima glottidis. Unless they are speedily removed or an opening is made into the air-passages below the obstruction, so as to enable the patient to breathe, they may cause death from suffocation, especially when they consist of large, soft substances, such as pieces of meat. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchi, or may lodge in the sinus of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon reflex spasm of the glottis produced by the irritation of the foreign body.

Beneath the mucous membrane of the upper part of the air-passage there is a considerable amount of submucous tissue, which is liable to become much swollen from effusion in inflammatory affections, constituting the condition known as ‘ œdema of the glottis.’ This effusion does not extend below the level of the vocal folds, on account of the fact that the mucous membrane is closely adherent to these structures without the intervention of

any submucous tissue. In cases of œdema of the glottis in which it is necessary to open the air-passages to prevent suffocation the operation of laryngotomy is sufficient.

The air-passages may be opened in three different situations: by a vertical incision through the centre of the thyroid cartilage (*thyrotomy*); through the cricothyroid ligament (*laryngotomy*); or in some part of the trachea (*tracheotomy*).

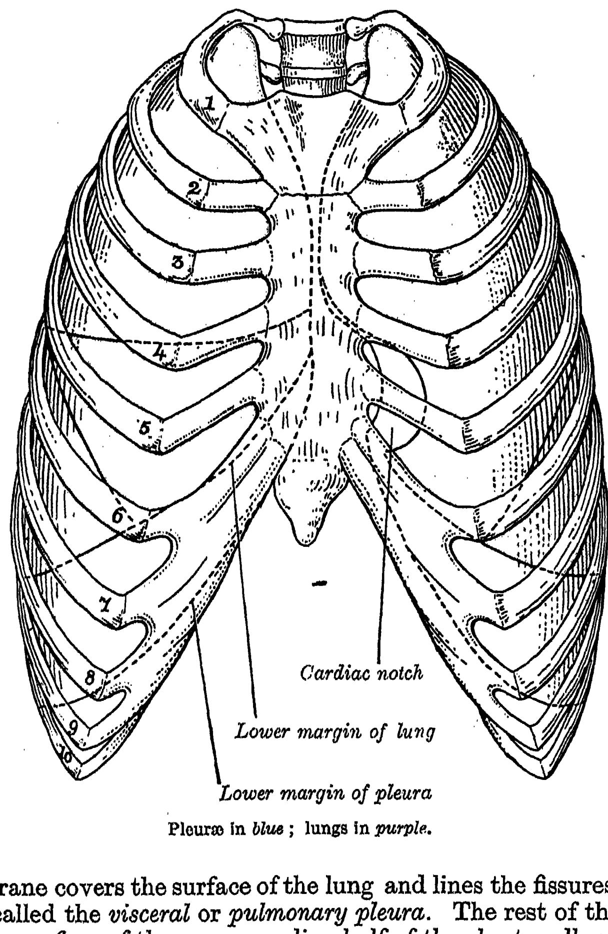
Tracheotomy may be performed either above or below the isthmus of the thyroid gland, or this structure may be divided and the trachea opened behind it. From the relations already described it must be evident that the trachea can be opened more readily above than below the isthmus.

After the trachea has been exposed it is transfixed with a sharp hook and drawn forwards in order to steady it. The knife is then inserted into the trachea and the upper two or three rings are divided in an upward direction.

The Pleuræ

Each lung is invested by a delicate serous membrane which is arranged in the form of a closed invaginated sac and is termed the **pleura.** A portion of this

Fig. 1102.—The relations of the pleuræ and lungs to the chest-wall. Anterior aspect.

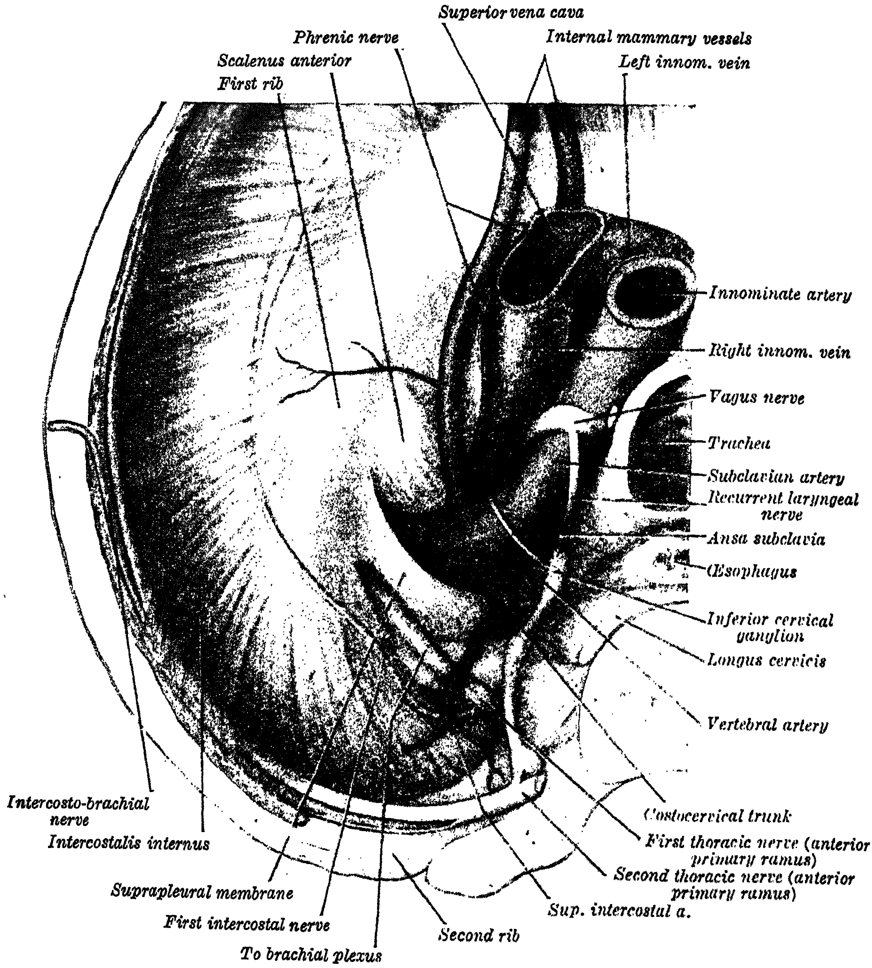


Pleuræ in *blue*; lungs in *purple*.

serous membrane covers the surface of the lung and lines the fissures between its lobes; it is called the *visceral* or *pulmonary pleura.* The rest of the membrane lines the inner surface of the corresponding half of the chest-wall, covers a large part of the Diaphragm, and is reflected over the structures occupying the middle part of the thorax; this portion is termed the *parietal pleura.* The pulmonary and parietal pleuræ are continuous with each other around and below the root of the lung; in health they are in actual contact, but the potential space between them is known as the *pleural cavity.* When the lung collapses or when air or fluid collects between the pulmonary and parietal pleuræ, the pleural cavity becomes apparent. The right and left pleural sacs are distinct from each other,

and come into immediate contact only for a short distance behind the upper half of the body of the sternum, although they are separated only by a narrow interval behind the œsophagus in the midthoracic region. The interval between the two sacs is named the *interpleural space*. The right pleural cavity is wider than the left, because the heart extends further to the left than to the right side. The upper and lower limits of the pleural sacs are approximately the same, but the left sac sometimes descends to a lower level in the midaxillary line.

Fig. 1103.—Structures in relation with the cervical pleura of the right side. Seen from below.

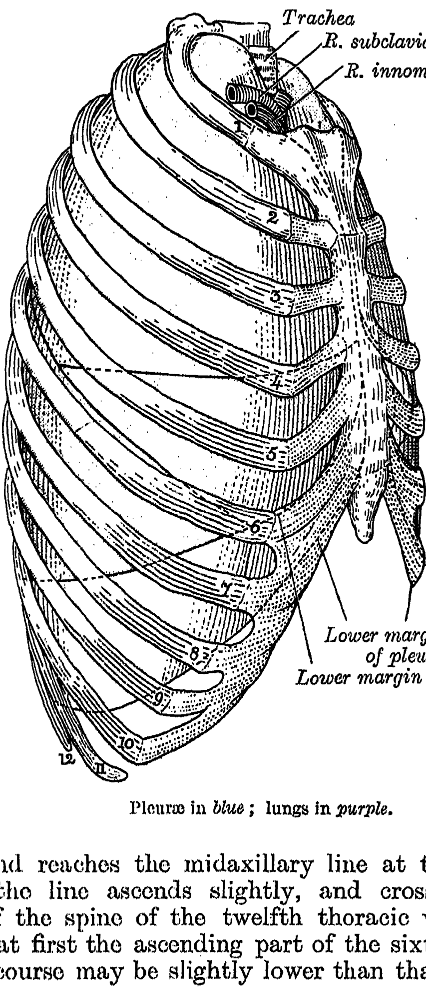


The pulmonary pleura is inseparably connected with the lung. It covers the surfaces of the lung, including those which bound the fissures between the lobes of the lung; it is absent, however, over an area where the lung root enters, and along a line extending downwards from this and marking the attachment of the pulmonary ligament.

The parietal pleura.—Different portions of the parietal pleura have received distinctive names; the part lining the inner surfaces of the ribs and the Subcostales and Intercostales intimi (Intracostales) is the *costal pleura*; that clothing the thoracic surface of the Diaphragm is the *diaphragmatic pleura*; that ascending into the neck over the summit of the lung is the *cervical pleura* (cupula); and that applied to the structures in the middle of the thorax is the *mediastinal pleura*.

The *costal pleura* (figs. 1102, 1104) lines the sternum, ribs, Subcostales and Intercostales intimi, and the sides of the bodies of the vertebræ, and is easily separated from them. In front it begins behind the sternum where it is continuous with the mediastinal pleura. The line of junction of the mediastinal with the costal pleura extends from behind the sternoclavicular joint downwards and medially to a point in the median plane behind the sternal angle. From this point the right and left costal pleuræ descend in contact with each other as far as the level of the fourth costal cartilages, below which the line differs on the two sides. On the right side it is continued down to the posterior surface of the xiphisternal joint. On the left it diverges laterally and descends, close to or a short distance from the margin of the sternum, to the level of the sixth costal cartilage. On each side the costal pleura sweeps laterally, lining the inner surfaces of the costal cartilages, ribs and Intercostales intimi, and at the back of the thorax passes over the sympathetic trunk and its branches, and on to the sides of the bodies of the vertebræ, where it again becomes continuous with the mediastinal pleura. Above, the costal pleura is continuous with the cervical pleura at the inner margin of the first rib. Below, it is continuous with the diaphragmatic pleura along a line which may differ slightly on the two sides. On the right side the line begins behind the xiphoid process, and runs downwards and backwards behind the seventh costal cartilage, and reaches the midaxillary line at the level of the tenth rib; from here the line ascends slightly, and crossing the twelfth rib, reaches the level of the spine of the twelfth thoracic vertebra. On the left side the line follows at first the ascending part of the sixth costal cartilage, and in the rest of its course may be slightly lower than that on the right side.

Fig. 1104.—The relations of the pleuræ and lungs to the chest wall. Lateral aspect.



Pleuræ in *blue*; lungs in *purple*.

The *diaphragmatic pleura* is thin, and covers the upper surface of the corresponding side of the Diaphragm. The outer part of its circumference is the line described above, along which it is continuous with the costal pleura. Medially it is continuous with the mediastinal pleura along the line of attachment of the pericardium to the Diaphragm.

The *cervical pleura* (cupula of the pleura), is the continuation of the costal pleura over the apex of the lung (fig. 1104). It extends from the inner border of the first rib medially and upwards to the apex of the lung, its summit reaching as high as the lower edge of the neck of the first rib; it then descends along the side of the trachea to become continuous with the mediastinal pleura. The cervical pleura is strengthened by a dome-like expansion of fascia, named the *suprapleural membrane* (*Sibson's fascia*). It is attached in front to the inner border of the first rib and behind to the anterior border of the transverse process of the seventh cervical vertebra; it is covered and strengthened by a few spreading muscular fibres derived from the Scaleni. The subclavian artery,

FIG. 1105.—A transverse section through the thorax at the level of the lower part of the fifth thoracic vertebra.

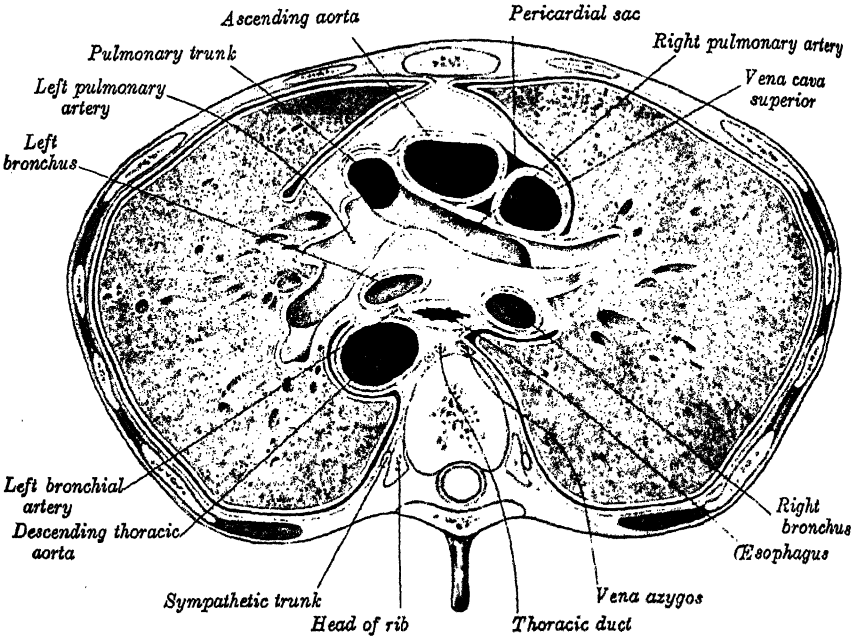


FIG. 1106.—A transverse section through the mediastinum at the level of the upper part of the body of the sixth thoracic vertebra.

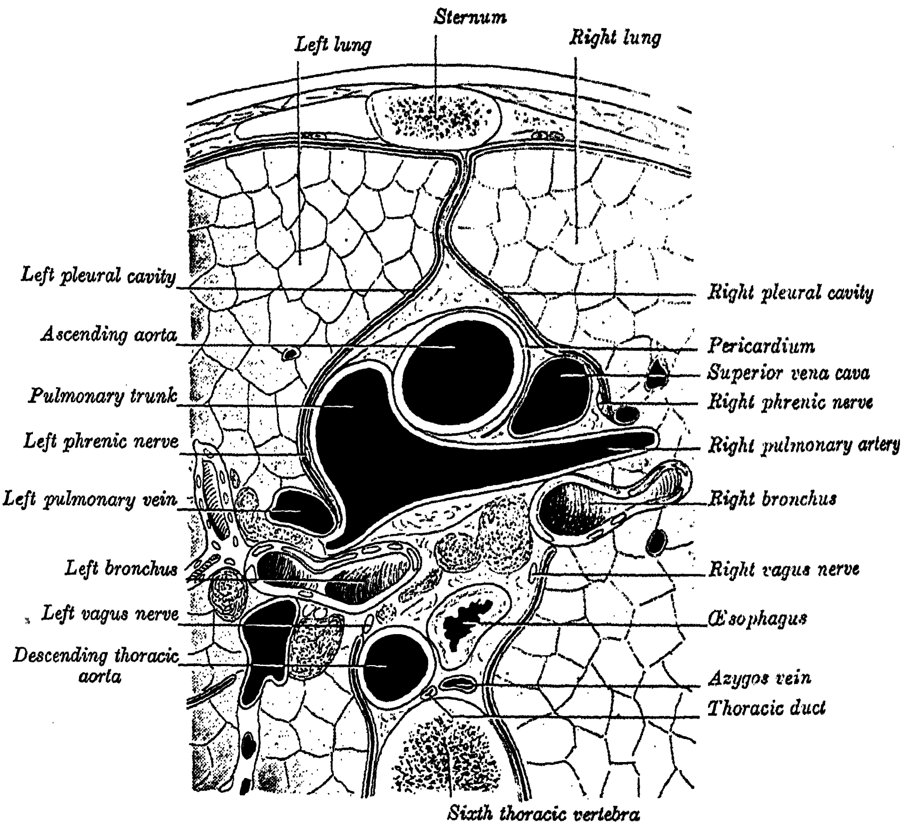
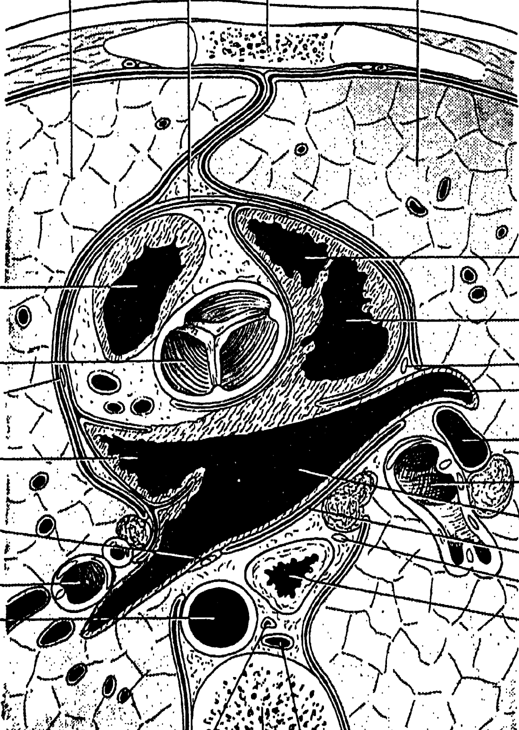


directed upwards and laterally, occupies a furrow a little below the summit of the cervical pleura (fig. 1103).

The *mediastinal pleura* forms the lateral boundary of the interpleural space or mediastinum (see also p. 1251). Above the root of the lung it is a continuous sheet between the sternum and the vertebral column. That of the right side is in contact with the right innominate vein, the upper part of the superior vena cava, the terminal part of the azygos vein, the right phrenic and right vagus nerves, the trachea and the œsophagus. That of the left side is in relation with the arch of the aorta, the left phrenic and left vagus nerves, the left innominate and superior intercostal veins, the left common carotid and sub-

FIG. 1107.—A transverse section through the mediastinum at the level of the lower part of the body of the sixth thoracic vertebra.

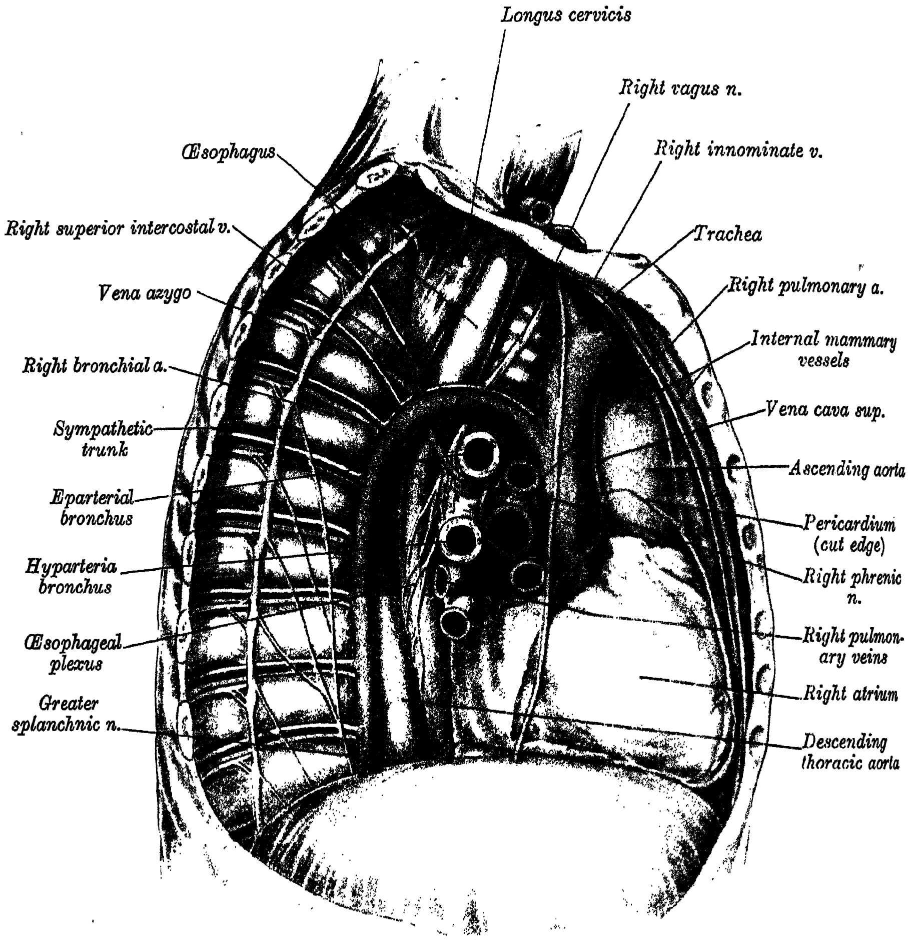


clavian arteries, the thoracic duct and the œsophagus. At the root of the lung the mediastinal pleura is carried laterally as a tube of serous membrane enclosing the structures of the lung-root and passing into continuity with the visceral or pulmonary pleura. Below the lung-root the mediastinal pleura extends as a double layer from the lateral edge of the œsophagus to the mediastinal surface of the lung, where it is continuous with the pulmonary pleura. This double layer is named the *pulmonary ligament* (fig. 1110). It is continuous above with the tube investing the lung-root; below it ends in a free falciform border.

The inferior limit of the pleura is on a considerably lower level than the corresponding border of the lung (figs. 1102, 1104), but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest-wall to the Diaphragm, the latter is in direct contact with the rib cartilages and the muscles in the intercostal spaces. Moreover, in ordinary

inspiration the thin inferior margin of the lung does not extend as low as the line of the pleural reflection, with the result that the costal and diaphragmatic pleuræ are here in contact, the intervening narrow slit being termed the *costodiaphragmatic recess* (phrenicocostal sinus). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity be-

FIG. 1108.—The mediastinum, from the right side.



A portion of the pericardial sac has been removed in order to expose the lateral surface of the right atrium.
In this specimen the fourth right intercostal vein did not join the superior intercostal vein, the œsophagus was somewhat dilated and an unusually large extent of the descending thoracic aorta was visible from the right side.

tween the two layers of pleura forms what is called the *costomediastinal recess* (sinus).

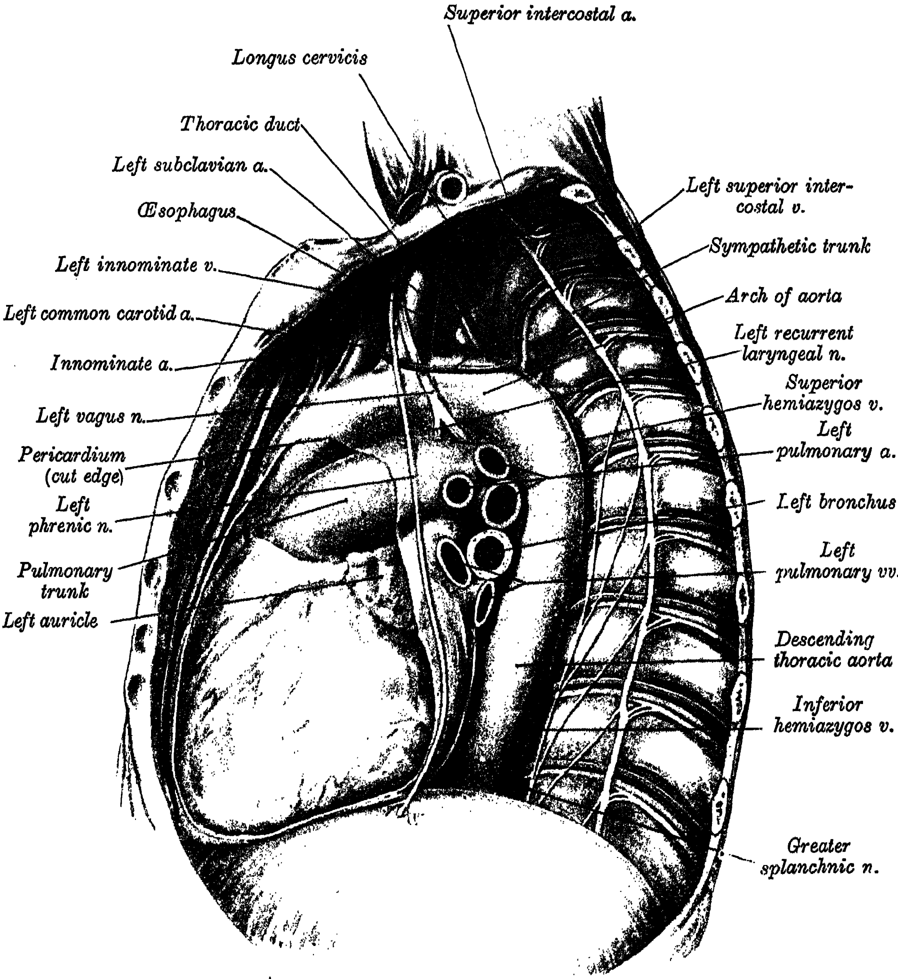
Structure.—The free surface of the pleura is smooth, and moistened by serous fluid. Like other serous membranes, it is covered by a single layer of flattened nucleated cells, united at their edges by cement-substance. These cells form an endothelium, and rest on a basement-membrane. Beneath the basement-membrane there are networks of yellow elastic and white fibres, imbedded in ground-substance which also contains connective tissue cells; in the pulmonary pleura there is a good deal of unstriped muscle. Blood-vessels, lymph vessels and nerves are distributed in the substance of the pleura.

Vessels and Nerves.—The *arteries* of the pleura are derived from the posterior (aortic) intercostal, internal mammary, musculophrenic, thymic, pericardiac and bronchial vessels. The *veins* correspond to the arteries. The *lymph vessels* are described on p. 879. The *nerves* are derived from the phrenic nerve and from the sympathetic trunk. Kölliker

states that nerves accompany the ramifications of the bronchial arteries in the pulmonary pleura.

Applied Anatomy.—Under normal conditions the pulmonary pleura glides smoothly over the surface of the parietal pleura during respiration and causes no sound which can be heard on auscultation, but, when the pleura is inflamed, and prior to, or in the absence of, any effusion of fluid into the pleural cavity, characteristic friction sounds can be

FIG. 1109.—The mediastinum, from the left side.



recognised. When an effusion of fluid occurs into the pleural cavity, the lung gradually collapses and, as the fluid increases in quantity, the heart is displaced towards the opposite side.

When air enters the pleural cavity, either as the result of the rupture of a part of the lung or as the result of its intentional introduction as a therapeutic measure, the elastic tissue of the lung contracts and the organ collapses and may finally shrink away to a dark rounded mass, the size of a closed fist, lying close against the vertebral column. The production of an artificial pneumothorax by the introduction of air into the pleural cavity has been employed in selected cases of pulmonary tuberculosis with the object of giving rest to the diseased lung, and has been attended by a considerable measure of success.

THE MEDIASTINUM

The mediastinum, strictly speaking, is the septum or partition between the two lungs and therefore includes the mediastinal pleura of both sides, but it is much more satisfactory to define it as the interval between the two pleural sacs.

It extends from the sternum in front to the vertebral column behind (figs. 1105, 1106), and from the thoracic inlet above to the Diaphragm below. For purposes of description it is divided into two parts, an *upper*, which is named the superior mediastinum, and a *lower*, which is subdivided into (*a*) the anterior mediastinum, in front of the pericardium, (*b*) the middle mediastinum, occupied by the pericardium and its contents, and (*c*) the posterior mediastinum, behind the pericardium.

The **superior mediastinum** (figs. 1099, 1100) lies between the manubrium sterni in front, and the upper four thoracic vertebræ behind. It is bounded below by a slightly oblique plane passing through the sternal angle in front, and the lower part of the body of the fourth thoracic vertebra behind; above, by the plane of the thoracic inlet, and laterally by the pleuræ. It contains the origins of the Sternohyoid and Sternothyroid and the lower ends of the Longus cervicis (longus colli) muscles; the aortic arch; the innominate, left common carotid and left subclavian arteries; the innominate veins and the upper half of the superior vena cava; the left superior intercostal vein; the vagus, cardiac, phrenic and left recurrent laryngeal nerves; the trachea, œsophagus and thoracic duct; the remains of the thymus, and the paratracheal, innominate and some of the tracheobronchial lymph glands.

The **anterior mediastinum** lies between the body of the sternum in front and the pericardium behind (fig. 1105); above the level of the fourth costal cartilages, it is exceedingly narrow, owing to the close approximation of the two pleural sacs. It contains some loose areolar tissue, the sternopericardiac ligaments, two or three lymph glands and a few small mediastinal branches of the internal mammary artery.

The **middle mediastinum** (figs. 1106, 1107) is the broadest of the subdivisions. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, the terminal part of the azygos vein, the bifurcation of the trachea, the two bronchi, the pulmonary trunk dividing into right and left pulmonary arteries, the right and left pulmonary veins, the phrenic nerves, the deep cardiac plexus and some tracheobronchial lymph glands.

The **posterior mediastinum** (figs. 1105 to 1109) is bounded in front by the bifurcation of the trachea, the pulmonary vessels and the pericardium above, and by the posterior surface of the Diaphragm below; behind, by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebra; and on each side by the mediastinal pleura. It contains the descending thoracic aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, the œsophagus, the thoracic duct, and the posterior mediastinal lymph glands.

The Lungs (Pulmones)

The **lungs** are the essential organs of respiration; they are two in number, placed one on each side within the thorax, and separated from each other by the heart and the other contents of the mediastinum (fig. 1110). The substance of the lung is of a light, porous, spongy texture; it floats in water, and crepitates when handled, owing to the presence of air in its alveoli; it is also highly elastic; hence the retracted state of the lungs when they are removed from the closed cavity of the thorax. The surface is smooth, shining, and marked out into numerous polyhedral areas, indicating the lobules of the lung; each of these areas is crossed by numerous lighter lines.

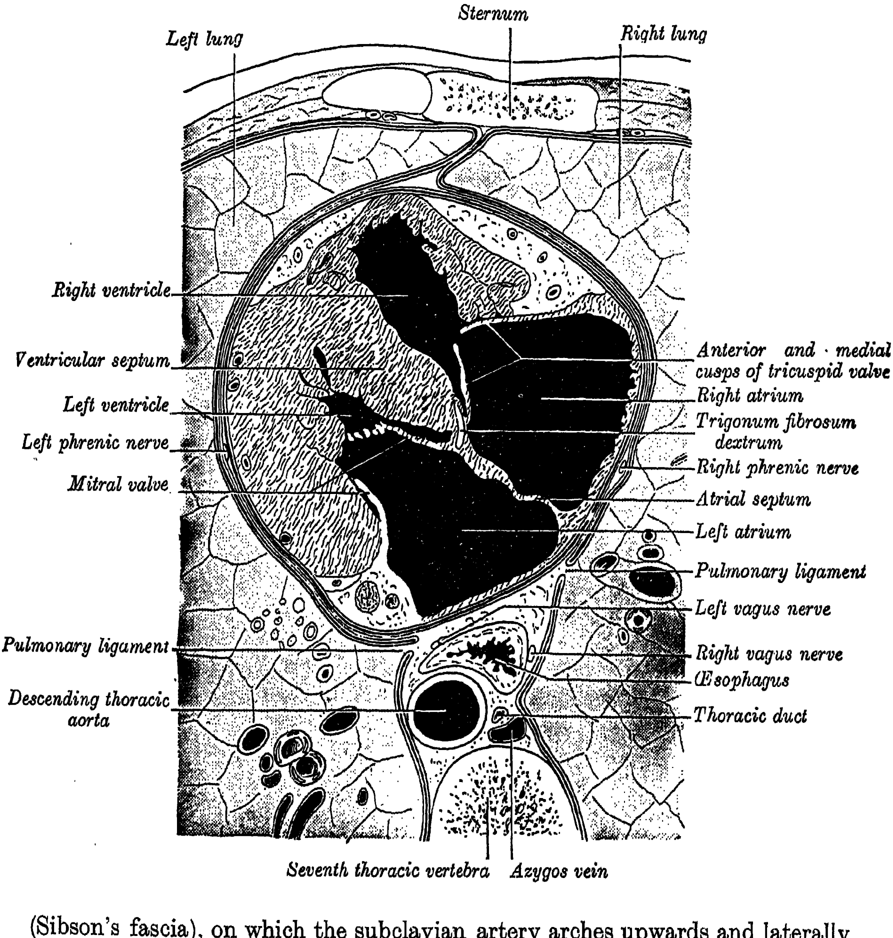
At birth the lungs are pinkish-white in colour; in adult life the colour is a dark slaty-grey, mottled in patches; and as age advances, this mottling assumes a black colour. The colouring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the lung; it increases in quantity as age advances, and is more abundant in men than in women. As a rule, the posterior border of the lung is darker than the anterior.

The right lung usually weighs about 625 gm., the left 567 gm., but much variation occurs, and it is dependent on the amount of blood or serous fluid that they contain. The lungs are heavier in the male than in the female; their proportion to the body is, in the former, as 1 to 37, in the latter as 1 to 43.

Each lung is conical in shape, and has an apex, a base, three borders and two surfaces.

The *apex*, which is rounded, lies in the plane of the thoracic inlet, in close contact with the cervical pleura. Owing to the obliquity of the inlet (p. 238), this part of the lung reaches from 3 cm. to 4 cm. above the level of the first costal cartilage, although it does not rise above the level of the neck of the rib. Its summit lies about 2·5 cm. above the medial third of the clavicle, and the apex is situated therefore in the root of the neck (fig. 1102). The cervical pleura intervenes between the apex of the lung and the suprapleural membrane

Fig. 1110.—A transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra.



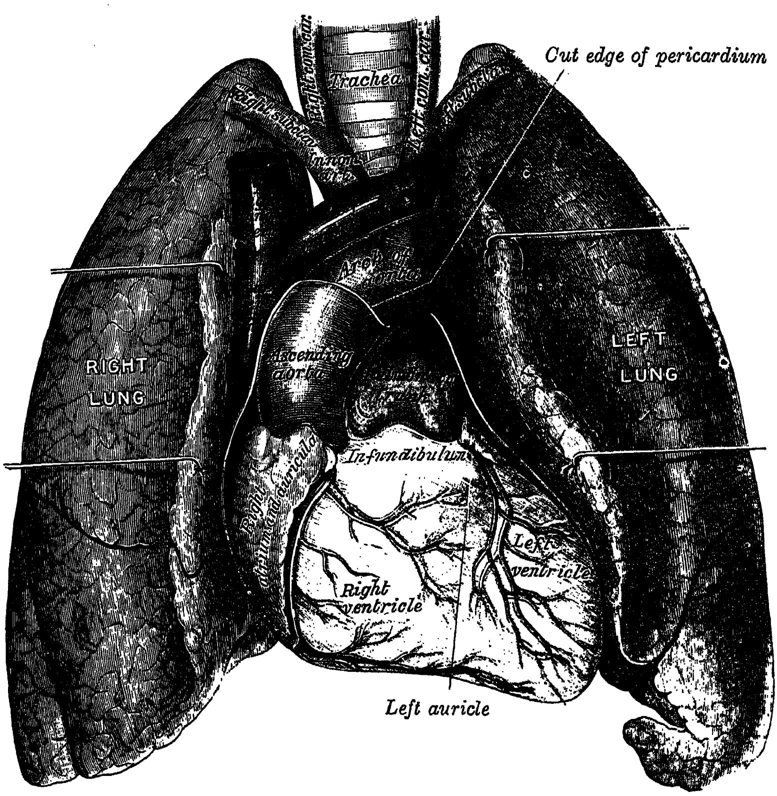
(Sibson's fascia), on which the subclavian artery arches upwards and laterally, producing a groove on the anterior surface of the apex just below its summit and separating it from the Scalenus anterior. Posteriorly the apex is related to the inferior cervical and first thoracic ganglia of the sympathetic trunk, the anterior primary ramus of the first thoracic nerve and the superior intercostal artery (fig. 1103). Laterally, it is related to the Scalenus medius; medially, to the innominate artery, right innominate vein and trachea, on the right side, and to the left subclavian artery and left innominate vein, on the left side.

The *base* is semilunar in shape, and concave; it rests upon the convex surface of the Diaphragm, which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the fundus of the stomach and the spleen. Since the Diaphragm extends higher on the right side than on the left, the concavity on the base of the right lung is deeper than that on the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the costodiaphragmatic recess of the pleura.

The *costal surface* is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, which is deeper behind than in front. It is in contact with the costal pleura, and exhibits, in specimens which have been hardened *in situ*, slight grooves corresponding with the overlying ribs. The pleura separates the costal surface of the lung from the ribs, from the constituent parts of the Transversus thoracis muscle (p. 553), and, in places, from the internal mammary vessels and the intercostal nerves and their accompanying vessels and, near the posterior border of the lung, from the sympathetic trunk and the roots of origin of the splanchnic nerves.

The *medial surface* is divided into a posterior or *vertebral* part, and an anterior

Fig. 1111.—The heart and lungs. Anterior aspect.

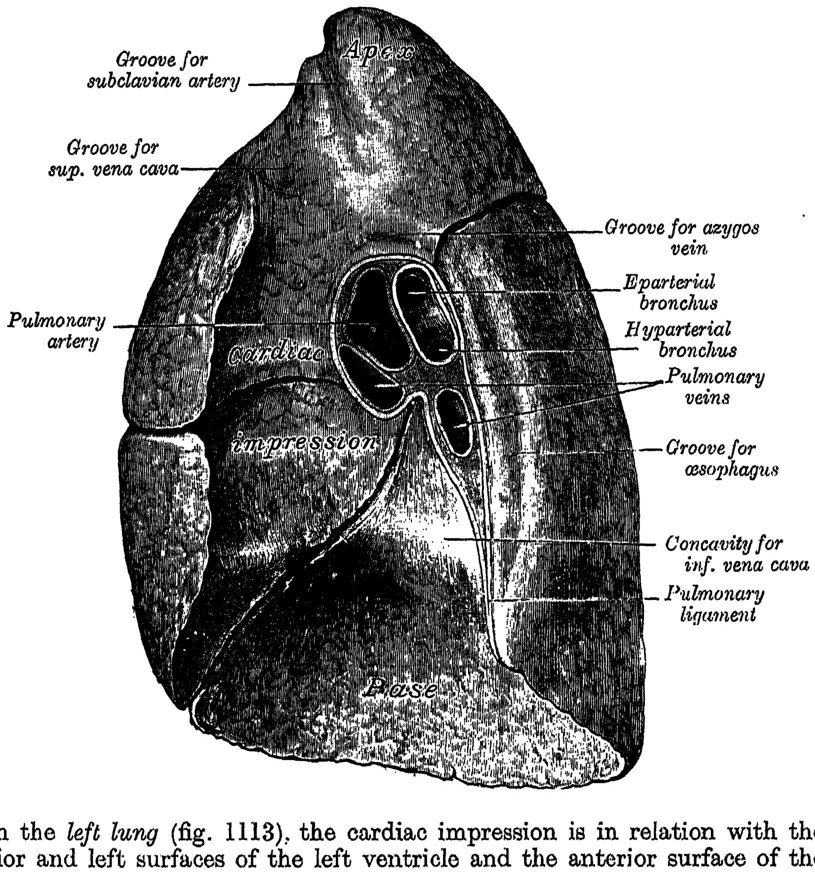


or *mediastinal* part. The vertebral part is in contact with the sides of the thoracic vertebræ and intervertebral discs, the posterior intercostal vessels and the splanchnic nerves. The mediastinal part exhibits a deep concavity, which accommodates the pericardium and is termed the *cardiac impression* ; this concavity is larger and deeper on the left than on the right lung, because the heart projects more to the left than to the right side of the median plane. Above and behind this concavity there is a somewhat triangular depression named the *hilum*, where the structures which form the root of the lung (p. 1257) enter and leave the viscus. These structures are invested by pleura, which extends downwards, below the hilum and behind the cardiac impression, and forms the pulmonary ligament.

Apart from these features, which are shared in common by both lungs, the markings on the mediastinal surface seen in specimens hardened *in situ* are different on the two sides. On the *right lung*, the cardiac impression is in relation with the anterior surface of the right auricle, the anterior and lateral (right) surfaces of the right atrium and a small part of the anterior surface of the right ventricle. It is continued upwards in front of the hilum as a wide groove which lodges the superior vena cava and the lower end of the right innominate

vein (fig. 1112). Posteriorly this groove is joined by a deep, narrow groove which arches forwards above the hilum and is caused by the vena azygos. The right edge of the œsophagus produces a shallow groove which runs vertically downwards behind the hilum and the pulmonary ligament. As it approaches the Diaphragm, the œsophagus inclines towards the left and passes away from the right lung. The œsophageal groove, therefore, does not extend to the lower limit of this surface. The postero-inferior corner of the cardiac impression is confluent with a short but wide notch which accommodates the thoracic part of the inferior vena cava. Between the apex and the groove for the vena azygos, the trachea and the right vagus nerve are in close relation to the lung, although there is no corresponding surface depression.

Fig. 1112.—The medial surface of the right lung.



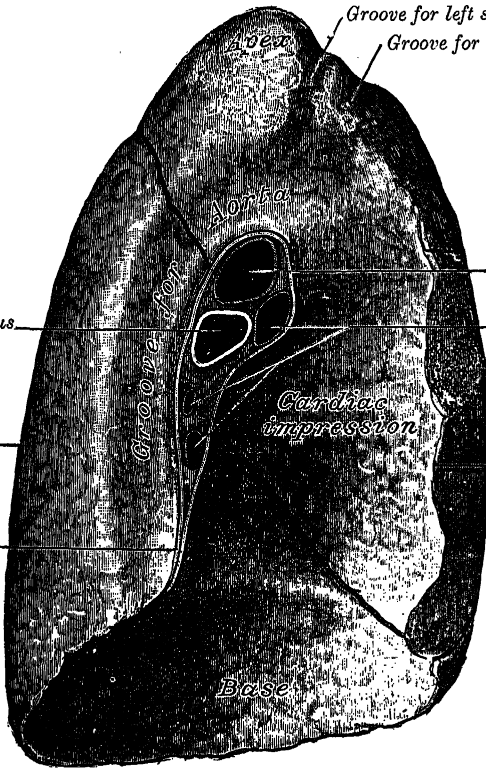
On the *left lung* (fig. 1113), the cardiac impression is in relation with the anterior and left surfaces of the left ventricle and the anterior surface of the infundibulum (conus arteriosus) and adjoining part of the right ventricle. It is continued upwards in front of the hilum to accommodate the pulmonary trunk. A wide, deep groove arches backwards above the hilum and downwards behind it and the pulmonary ligament; it lodges the arch and the descending part of the aorta. Near the summit of its curve it is confluent with a narrower groove which ascends towards the apex and is occupied by the left subclavian artery. Behind this groove and above the aortic groove, the lung is in contact with the thoracic duct and the left edge of the œsophagus. Inferiorly, the left edge of the œsophagus may make a slight impression in front of the lower end of the pulmonary ligament.

The *inferior border* is thin and sharp where it separates the base from the costal surface and extends into the costodiaphragmatic recess; medially, where it divides the base from the mediastinal surface, it is blunt and rounded. The *posterior border* separates the costal surface from the vertebral part of the medial surface, and corresponds to the medial margins of the heads of the ribs. It is not marked by any recognisable ridge or line. The " thick, rounded posterior

border", described in many textbooks, comprises the adjoining parts of the costal and vertebral surfaces.

The *anterior border* is thin and sharp, and overlaps the front of the pericardium ; that of the *right* lung corresponds very closely to the costomediastinal line of pleural reflection and is almost vertical ; that of the *left* corresponds to the costomediastinal line of pleural reflection in its upper part, but below the level of the fourth costal cartilage it presents a notch of variable size, named the *cardiac notch.* The margin of this notch corresponds to, but falls considerably short of, the recessed part of the line of pleural reflection (fig. 1102), leaving the pericardium in this situation covered only with a double layer of pleura.

FIG. 1113.—The medial surface of the left lung.



The fissures and lobes of the lungs.—The *left lung* is divided into a superior and an inferior lobe, by an *oblique fissure* (fig. 1113), which extends from the costal to the medial surface of the lung both above and below the hilum. As seen on the surface, this fissure begins on the medial surface of the lung at the upper and posterior part of the hilum, and runs backwards and upwards to the posterior border, which it crosses at a point about 6 cm. below the apex. It then extends downwards and forwards over the costal surface (fig. 1104), reaching the lower border a little behind its anterior extremity. Its further course can be followed upwards and backwards across the mediastinal surface as far as the lower part of the hilum. The *superior lobe* lies above and in front of this fissure, and includes the apex, the anterior border, a considerable part of the costal surface and the greater part of the medial surface of the lung. A small projection is sometimes present at the lower part of the cardiac notch and is termed the *lingula* of the lung. The *inferior lobe,* the larger of the two, is situated below and behind the fissure, and comprises almost the whole of the base, a large portion of the costal surface, and the greater part of the posterior border.

The *right lung* is divided into three lobes, superior, middle and inferior, by two fissures (fig. 1112). One of these separates the inferior from the middle

and superior lobes, and corresponds closely with the oblique fissure in the left lung. Its direction is, however, more vertical, and it cuts the lower border about 7·5 cm. behind its anterior extremity. A short *transverse fissure* separates the superior from the middle lobe. It begins in the oblique fissure near the mid-axillary line, and, running horizontally forwards, cuts the anterior border on a level with the sternal end of the fourth costal cartilage ; on the mediastinal surface it may be traced backwards to the hilum. The *middle lobe* of the right lung is small and wedge-shaped, and includes a part of the costal surface, the lower part of the anterior border and the anterior part of the base of the lung. Sometimes the right lung is deeply cleft near its apex by a fold of pleura which contains the azygos vein in its free margin.

Since the Diaphragm rises higher on the right side in order to accommodate the liver, the right lung is shorter (by 2·5 cm.) than the left, but, owing to the projection of the heart to the left side, it is broader and its total capacity and weight are greater than those of the left lung.

The roots of the lungs (figs. 1108, 1109).—The root of the lung connects the medial surface to the heart and the trachea and is formed by the structures which enter or emerge at the hilum. It comprises the bronchus, the pulmonary artery, the two pulmonary veins, the bronchial arteries and veins, the pulmonary plexuses of nerves, lymph vessels, bronchopulmonary lymph glands and areolar tissue, all of which are enveloped by pleura. The roots of the lungs lie opposite the bodies of the fifth, sixth and seventh thoracic vertebræ. That of the right lung lies behind the superior vena cava and part of the right atrium of the heart, and below the terminal part of the azygos vein. That of the left lung is below the aortic arch and in front of the descending thoracic aorta. The following relations are common to the two lung-roots, viz. : in front, the phrenic nerve, the pericardiacophrenic artery and vein, and the anterior pulmonary plexus ; behind, the vagus nerve and posterior pulmonary plexus ; below, the pulmonary ligament.

The chief structures composing the root of each lung are arranged in a similar manner from before backwards on both sides, viz. : the upper of the two pulmonary veins in front ; the pulmonary artery in the middle ; and the bronchus behind, with the bronchial vessels on its posterior aspect. Their arrangement differs from above downwards on the two sides ; on the right side their position is—eparterial bronchus, pulmonary artery, hyparterial bronchus, lower pulmonary vein ; but on the left side their position is—pulmonary artery, bronchus, lower pulmonary vein. The lower of the two pulmonary veins is situated below the bronchus, at the lowest part of the hilum.

The divisions of the bronchi.—Just as the lungs differ from each other in the number of their lobes, so the bronchi differ in their mode of subdivision.

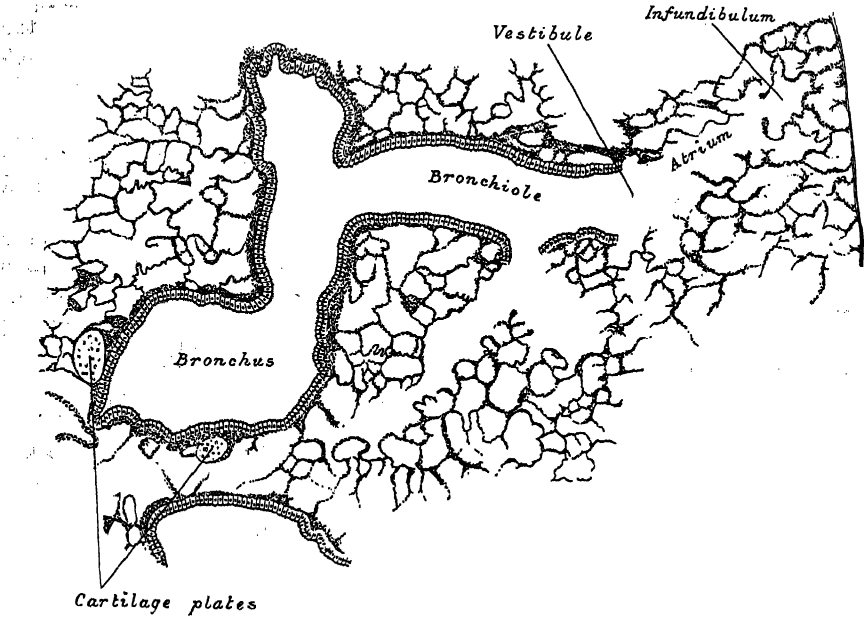
The *right* bronchus gives off, less than 2·5 cm. from the division of the trachea, a branch for the superior lobe ; this branch arises above the level of the pulmonary artery, and is therefore named the *eparterial bronchus*. All the other divisions of the main stem come off below the pulmonary artery, and are consequently termed *hyparterial bronchi*. The first of these is distributed to the middle lobe, and the main tube then passes downwards and backwards into the inferior lobe, giving off in its course a series of large ventral and small dorsal branches. The ventral and dorsal branches arise alternately, and there are usually four of each. The branch to the middle lobe is the first of the ventral series ; the first of the dorsal branches is the largest and is distributed to the upper part of the inferior lobe.

The *left* bronchus passes below the level of the pulmonary artery before it divides, and hence all its branches are hyparterial ; it may therefore be looked upon as equivalent to that portion of the right bronchus which lies on the distal side of its eparterial branch. The first branch of the left bronchus arises about 5 cm. from the bifurcation of the trachea, and is distributed to the superior lobe. The main stem then enters the inferior lobe, where it divides into ventral and dorsal branches similar to those in the right lung. The branch to the superior lobe of the left lung is the first of the ventral series, and the second is distributed to the portion of the upper lobe which corresponds to the middle lobe of the right lung.

Structure.—The lungs are composed of a serous coat, a subserous areolar tissue, and the pulmonary substance.

The *serous* coat is the pulmonary pleura (p. 1246); it is thin, transparent, and invests the entire organ as far as the root.

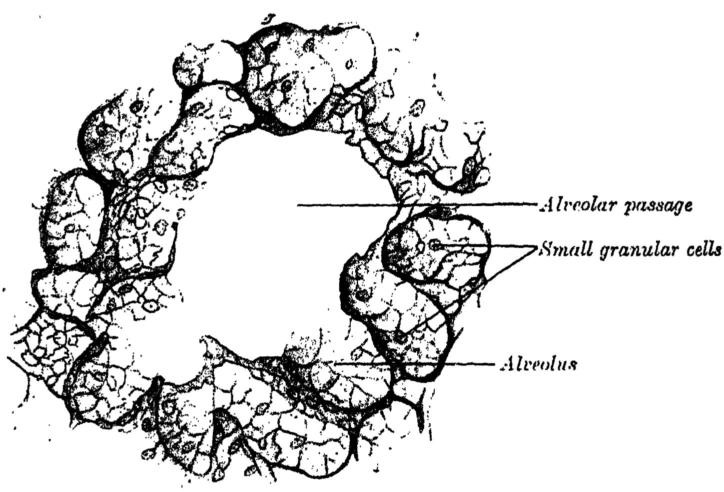
FIG. 1114.—A section through the lung of a cat, showing the termination of a bronchus. × 50.



The *subserous areolar tissue* contains a large proportion of elastic fibres; it invests the entire surface of the lung and extends inwards between the lobules.

The *pulmonary substance* is composed of lobules, which although closely connected by interlobular areolar tissue, are quite distinct from one another, and in the fœtus may be

FIG. 1115.—A section through the lung of a kitten. Silver preparation. × 250.

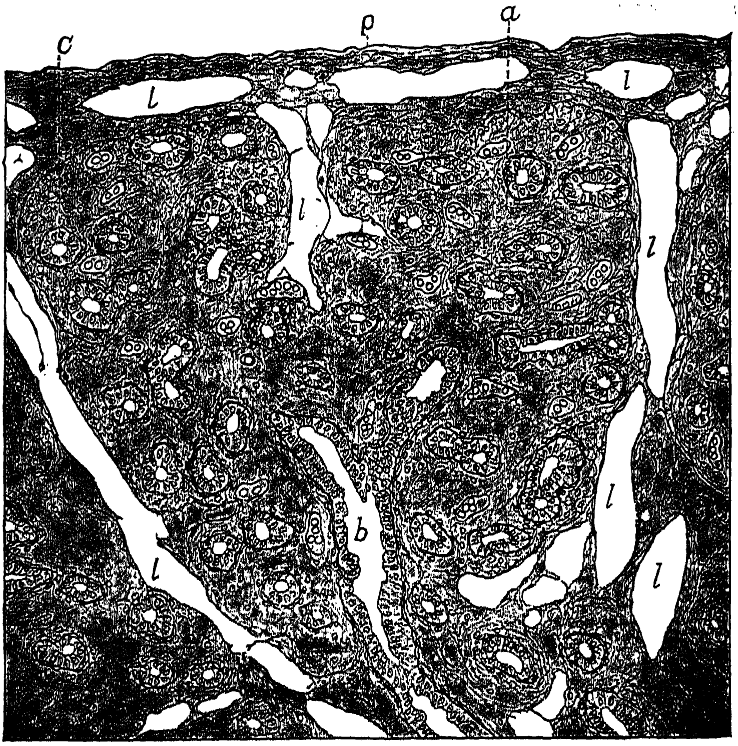


teased apart without much difficulty. The lobules vary in size; those on the surface are large and of pyramidal form with the bases turned towards the surface; those in the interior are smaller, and of various forms. Each lobule is composed of a terminal bronchiole and its air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymph vessels, and nerves; all of these structures being connected together by areolar tissue.

The **intrapulmonary bronchi** divide and subdivide throughout the entire organ, the smallest branches constituting the terminal bronchioles. The *larger branches* consist of: (1) an outer coat of fibrous tissue in which are found at intervals irregular plates of hyaline cartilage, most developed at the points of division; (2) internal to the fibrous coat, a layer of circularly disposed smooth muscular fibres, termed the *bronchial muscle*; and (3) most internally, the mucous membrane, lined by ciliated columnar epithelium resting on a basement-membrane. The mucous membrane contains numerous elastic fibres running longitudinally, and a certain amount of lymphoid tissue; it is traversed by the ducts of mucous glands, the acini of which lie in the fibrous coat. The *terminal bronchioles* are about 0·2 mm. in diameter; they differ from the larger tubes in containing no cartilage and in the fact that the ciliated epithelial cells are cubical in shape.

Each bronchiole ends by opening into a wider space known as the *vestibule*, the point of junction of the two being marked by a circular thickening of the bronchial muscle, and

FIG. 1116.—A section through the lung of a pig-embryo 13 cm. long, showing the glandular character of the developing alveoli. ×70. (J. M. Flint.)



a. Interstitial connective tissue. *b.* A bronchial tube. *c.* An alveolus. *l.* Lymphatic clefts. *p.* Pleura.

by a transition from the ciliated epithelium of the bronchiole to a layer of flattened non-ciliated cells. The vestibule divides into from three to six passages called *atria*. These are lined with flattened non-ciliated epithelium. From each atrium there arise two or more *infundibula*—elongated passages, lined by pavement epithelium and beset on all sides by hemispherical alveoli or air-cells (fig. 1114).

The *alveoli* are lined by a layer of simple flattened epithelium, the cells of which are united at their edges by cement-substance. Between these cells, here and there, smaller polygonal nucleated cells are found. Outside the epithelial lining there is a little delicate connective tissue, containing numerous elastic fibres and a close network of blood-capillaries, and forming a common wall to adjacent alveoli (fig. 1115).

The fœtal lung resembles a gland in that the alveoli have small lumina and are lined with cubical epithelium (fig. 1116). After the first respiration the alveoli become distended, and the epithelium takes on the characters described above.

Vessels and Nerves.—The *pulmonary artery* conveys the deoxygenated blood to the lungs; it divides into branches which accompany the bronchial tubes and lie close to their dorsal aspects. They end in a dense capillary network in the walls of the infundibula and alveoli. The arteries of neighbouring lobules are independent of one another.

The *pulmonary capillaries* form plexuses which lie immediately beneath the lining epithelium, in the walls and septa of the alveoli and of the infundibula. In the septa

between the alveoli the capillary network forms a single layer, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin.

The *pulmonary veins*, two from each lung, arise from the pulmonary capillaries, the radicles coalescing into larger branches which run through the substance of the lung, independently of the pulmonary arteries and bronchi. After communicating freely with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the lung, the artery usually being above, and the vein below, the bronchus. Finally, they open into the left atrium of the heart, conveying oxygenated blood to be distributed to all parts of the body by the left ventricle.

The *bronchial arteries* supply blood for the nutrition of the lung; they are derived from the descending thoracic aorta or from the upper posterior (aortic) intercostal arteries, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form, in the muscular coat, a capillary plexus from which branches are given off to form a second plexus in the mucous coat; this plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary veins. Others are distributed in the interlobular areolar tissue, and end partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The *bronchial veins*, usually two on each side, are formed at the root of the lung, and receive superficial and deep veins corresponding with branches of the bronchial arteries; they do not, however, receive all the blood conveyed by the arteries, as some passes into the pulmonary veins. The right bronchial veins end in the azygos vein, the left bronchial veins in the left superior intercostal vein or the superior (accessory) hemiazygos vein.

The *lymph vessels* of the lungs are described on p. 878.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus. The filaments from these plexuses accompany the bronchial tubes, supplying efferent fibres to the bronchial muscle and afferent fibres to the bronchial mucous membrane and to the alveoli of the lung. Small ganglia are found upon these nerves. It is generally believed that the broncho-constrictors are supplied by the vagus.

Applied Anatomy.—The routine methods of physical examination—inspection, palpation, percussion and auscultation—are nowhere more important than they are in the diagnosis of disease of the lungs, It is essential, too, that in every case the two sides of the chest should be compared with each other, and that the wide variations that may be met with under normal conditions in different persons and at different ages should be kept in mind when the chest is being examined. On *inspection* the thorax will be seen to be enlarged and barrel-shaped in emphysema, in which the volume of the lungs is increased by dilatations of their alveoli, or in an acute attack of asthma, or when a large pleural effusion or mediastinal tumour is present. The chest-wall will be flattened or sunken, on the other hand, over an area of lung that has collapsed or become fibrosed, as often happens in chronic pulmonary tuberculosis. The respiratory movements of the chest-wall will be lessened, or even absent, over a part or the whole of the affected side in such acute disorders as pleurisy, pneumonia, or pleural effusion, or in more chronic disease where the underlying lung is fibrosed, or is crushed to one side by a mediastinal tumour: and by the use of the x-rays a corresponding loss of movement or displacement of the Diaphragm on the affected side can often be observed. Under normal conditions the intercostal spaces are a little depressed: but when a large effusion or new growth fills up one of the pleural cavities they may be obliterated or even bulging on that side.

On *palpation* the hand can be used to verify the eye's impression as to the degree of movement, on respiration, of any part of the chest-wall. The facility with which the vibrations produced by the voice are conducted from the larynx to the hand by the underlying lung (in the form of the *vocal fremitus*) can also be tested. The vocal fremitus is commonly much increased over the consolidated area in pneumonia or in fibrosis of the lung, and much diminished over a pleural effusion when the lung is pushed up by the fluid towards the top of the pleural cavity. It is also diminished, but to a less extent, in emphysema, and in bronchitis when the bronchi are blocked by secretion. It must be remembered that vocal fremitus in front and behind is normally greater at the right apex than the left. This is because the apex of the right lung lies in close contact with the trachea, while the apex of the left lung is separated from it by the œsophagus and other structures.

On *percussion*, the normal resonance of the pulmonary tissue is found to be increased in emphysema, and in pneumothorax (p. 1251) this hyper-resonance may be increased still further. The resonance is lessened in any condition causing collapse or solidification of the lung-tissue, or when its place is taken by fluid (pleural effusion) or some solid growth (mediastinal tumour).

On *auscultation* of the lungs, both in health and disease, the variety of sounds to be heard is very great. It is impossible to give adequate consideration to them here, and for further information reference should be made to the text-books dealing with the subject.

THE DIGESTIVE SYSTEM

The digestive system comprises all the organs which are concerned in the trituration, deglutition and digestion of food and in the elimination from the body of the unabsorbed and unabsorbable constituents. It consists of the digestive tube and certain accessory organs.

The **digestive tube** (alimentary canal), about 9 metres long, extends from the mouth to the anus, and is lined throughout by mucous membrane. It consists of the following parts : it commences at the *mouth*, where provision is made for the mechanical division of the food [*mastication*], and for its admixture with a fluid secreted by the salivary glands [*insalivation*] ; it is conveyed by the organs of deglutition, termed the *pharynx* and the *œsophagus*, into the *stomach*, where the first stages of the digestive process take place ; from the stomach it is passed into the *small intestine*, where the process of digestion is continued and many of the resulting products are absorbed into the blood- and lymph-vessels. Finally the small intestine ends in the *large intestine*, which reaches the surface of the body at the *anus*.

The **accessory organs** are the *teeth*, which break up and triturate the food in the process of mastication ; the three pairs of *salivary glands*—the *parotid*, *submandibular* (submaxillary) and *sublingual*—the secretion from which mixes with the food in the mouth ; the *liver* and the *pancreas*, two large glands in the abdomen, the secretions of which take part in the process of digestion. In addition, it is convenient to describe the *peritoneum*—a serous membrane which lines the abdominal and pelvic cavities and invests the abdominal and pelvic viscera—in the same section with the abdominal part of the alimentary canal.

The Mouth Cavity [Cavum oris]

The **cavity of the mouth** is placed at the commencement of the digestive tube (fig. 1117) ; it consists of an outer, smaller portion, termed the vestibule, and an inner, larger part, termed the mouth cavity proper.

The *vestibule of the mouth* is a slit-like space, bounded externally by the lips and cheeks ; internally, by the gums and teeth. It communicates with the exterior by the *oral fissure*. Above and below, it is limited by the reflection of the mucous membrane from the lips and cheeks to the gums. When the jaws are closed it communicates with the mouth cavity proper by an aperture behind the wisdom tooth on each side, and by narrow clefts between opposing teeth. On the oral surface of the cheek, opposite the second upper molar tooth, a small papilla marks the opening of the duct of the parotid salivary gland.

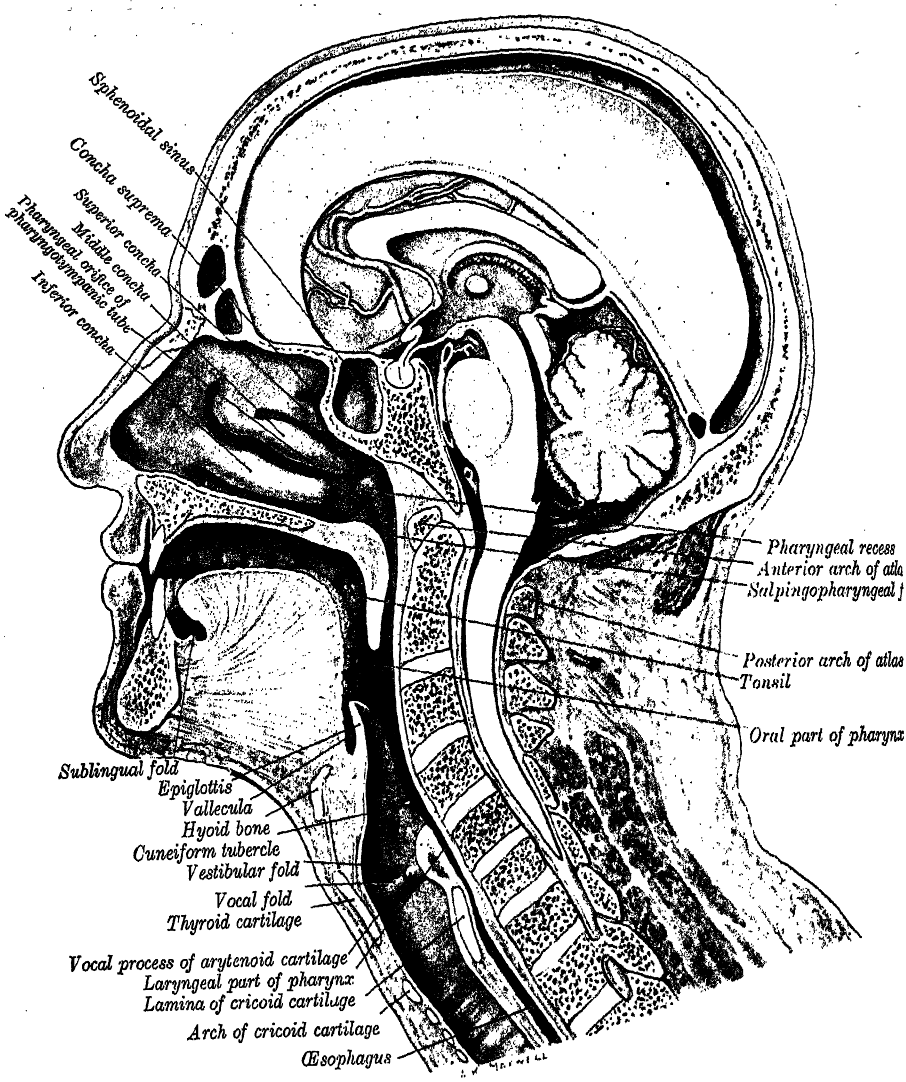
The *mouth cavity proper* (figs. 1141, 1142) is bounded laterally and in front by the alveolar arches, the teeth and the gums ; behind, it communicates with the pharynx by a constricted aperture termed the *oropharyngeal isthmus* (isthmus of the fauces *). Its roof consists of the hard palate and soft palate, while the greater part of the floor is formed by the anterior two-thirds of the tongue, the remainder by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum on the inner surface of the mandible. In the median plane a crescentic fold of mucous membrane, named the *frenulum linguæ*, connects the under surface of the anterior part of the tongue to the floor of the mouth. On each side of the lower end of the frenulum there is a small elevation,

* These two terms are not quite synonymous, as the oropharyngeal isthmus is restricted to the interval between the palatoglossal arches.

termed the *sublingual papilla*, which bears on its surface the orifice of the duct of the submandibular salivary gland. From this papilla a ridge extends laterally and backwards in the mucous membrane of the floor of the mouth; it is produced by the underlying sublingual salivary gland and is termed the *sublingual fold*. The minute openings of the ducts of the gland are situated on the edge of the fold.

The *mucous membrane* lining the mouth is continuous with the skin at the free margins of the lips, and with the mucous lining of the pharynx at the oropharyngeal isthmus; it is

FIG. 1117.—A median sagittal section through the head and neck.



Note.—Where it divides the skull and the brain, the section passes slightly to the left of the median plane, but below that level, it passes slightly to the right of the median plane.

of a rose pink tinge during life, and is very thick where it overlies the hard parts bounding the cavity. It is covered with stratified squamous epithelium.

The *lymph vessels* of the mouth are described on p. 855.

The lips are two fleshy folds which surround the orifice of the mouth. They are formed externally of skin and internally of mucous membrane, and these two layers enclose the Orbicularis oris muscle, the labial vessels, some

nerves, areolar tissue, and numerous small labial glands. The junction of the upper with the lower lip forms, on each side, the *labial commissure*, which bounds the *angle of the mouth*. The middle part of the outer surface of the upper lip is marked by a shallow vertical groove named the *philtrum*; it ends below in a slight prominence and is limited on each side by a ridge. The inner surface of each lip is connected in the median plane to the corresponding gum by a fold of mucous membrane, termed the *frenulum*—that of the upper lip being the larger.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris, round the orifice of the mouth. They are about the size of small peas and in structure they resemble the salivary glands. Their ducts open into the vestibule.

The **cheeks** form a large part of the sides of the face, and are continuous in front with the lips, the junction being indicated on each side by a groove, termed the *nasolabial groove*, which runs downwards and laterally from the side of the nose to the angle of the mouth. The cheeks are composed of a muscular stratum, and a large quantity of fat, together with areolar tissue, vessels, nerves and buccal glands, covered with skin, externally, and with mucous membrane, internally.

The *mucous membrane* lining the cheek is reflected above and below on to the gums, and is continuous behind with the mucous membrane of the soft palate. Opposite the second upper molar tooth there is a small papilla, on the summit of which the parotid duct opens. The principal muscle of the cheek is the Buccinator; but others enter into its formation, viz. the Zygomaticus major, Risorius and Platysma.

The *buccal glands* are placed between the mucous membrane and the Buccinator muscle; their structure is similar to that of the labial glands. Four or five, larger than the rest, and placed between the Masseter and Buccinator muscles around the terminal part of the parotid duct, are called *molar glands*; their ducts open in the mouth opposite the last molar tooth.

The *lymph vessels* of the cheeks and lips are described on p. 853.

The **gums** are composed of dense, fibrous tissue, closely connected to the periosteum of the alveolar processes of the mandible and maxillæ, and covered with smooth and vascular mucous membrane. Around the necks of the teeth this membrane presents numerous fine papillæ, and is reflected into the alveoli, where it is continuous with their lining periosteal membrane.

The **palate** forms the roof of the mouth: it consists of two portions—the hard palate in front, the soft palate behind.

The **hard palate** (fig. 1127) is formed by the palatine processes of the maxillæ and the horizontal plates of the palatine bones; it is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered with a dense tissue, formed by the periosteum and mucous membrane, which are intimately connected. It presents a median, linear raphe, which ends anteriorly in a small papilla underlying the incisive fossa. On each side and in front of the raphe the mucous membrane is thick, pale in colour, and corrugated; behind, it is thin, smooth, and of a redder colour: it is covered with stratified squamous epithelium, and furnished with numerous palatine glands, which lie between the mucous membrane and the periosteum.

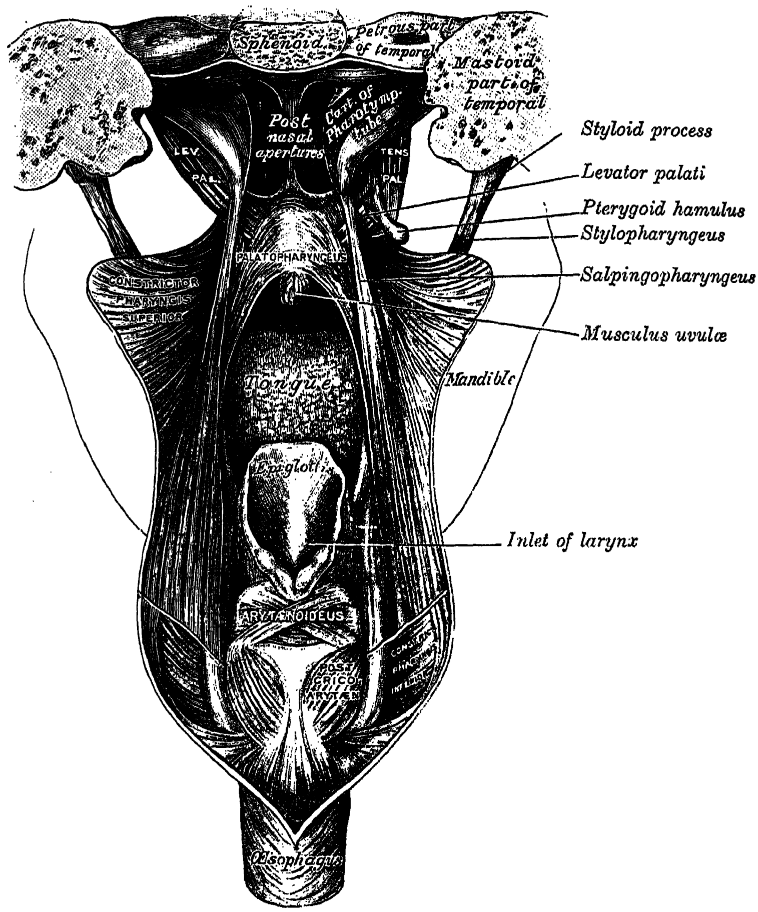
The **soft palate** (fig. 1142) is a movable fold, suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing an aponeurosis, muscular fibres, vessels, nerves, adenoid tissue and mucous glands. When occupying its usual position (i.e. relaxed and pendent) its anterior surface is concave, and marked by a median raphe. Its posterior surface is convex, and continuous with the floor of the nasal cavity. Its superior border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its inferior border is free. The lower portion of the soft palate hangs like a curtain between the mouth and the pharynx.

A small conical process, termed the *uvula*, hangs from the middle of its lower border; and two curved folds of mucous membrane, containing muscular fibres, extend laterally and downwards from each side of the base of the uvula. The anterior of the two contains the Palatoglossus (Glossopalatinus) muscle

and is named the *palatoglossal arch*. Below, it reaches the side of the tongue at the junction of the oral and pharyngeal portions and it forms the lateral boundary of the oropharyngeal isthmus. The posterior fold, which is termed the *palatopharyngeal arch*, descends on the lateral wall of the oral part of the pharynx and is described on p. 1292.

The *mucous membrane of the soft palate* is thin, and covered with stratified squamous epithelium excepting near the pharyngeal orifice of the pharyngotympanic (auditory) tube and on the anterior part of its superior surface, where it is columnar and ciliated. Beneath

FIG. 1118.—The muscles of the palate. Exposed from behind.



the mucous membrane on the oral surface of the soft palate there is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

Vessels and Nerves.—The *arteries* supplying the palate are the ascending palatine branch of the facial (external maxillary) artery, the greater palatine branch of the (internal) maxillary artery, and the palatine branch of the ascending pharyngeal artery. The *veins* end chiefly in the pterygoid and tonsillar plexuses. The *lymph vessels* pass to the deep cervical lymph glands. The *sensory nerves* are derived from the greater and lesser palatine, long sphenopalatine and glossopharyngeal nerves.

The palatine aponeurosis.—A thin, firm fibrous lamella, termed the *palatine aponeurosis*, which supports the muscles and gives strength to the soft palate, is attached to the posterior border of the hard palate. It is thick above, but very thin and difficult to define below. On each side it is continuous with the

tendon of the Tensor palati and, near the median plane, it splits to enclose the Musculus uvulæ.

Blakeway * maintains that the palatine aponeurosis is not a separate structure, but is actually the expanded tendon of the Tensor palati.

The **muscles of the palate** (fig. 1118) are:

Levator palati.	Palatoglossus.
Tensor palati.	Palatopharyngeus.
Musculus uvulæ.	

The **Levator palati** (Levator veli palatini) (figs. 1118, 1146, 1150) is a rounded muscle situated on the lateral side of the posterior nasal aperture. It arises from the under surface of the petrous part of the temporal bone, immediately in front of the lower opening of the carotid canal, and from the medial lamina of the cartilage of the pharyngotympanic (auditory) tube. After passing within the upper concave margin of the Superior constrictor and in front of the Salpingopharyngeus, it spreads out in the soft palate, its fibres running as far as the median plane, where they blend with those of the opposite muscle. It is separated from the mucous membrane on the posterior (upper) aspect of the soft palate by the posterior (upper) part of the Palatopharyngeus.

Action.—The Levator palati elevates the soft palate.

The **Tensor palati** (Tensor veli palatini) (figs. 1118, 1146, 1150) is a thin, triangular muscle, which lies lateral to the medial pterygoid plate, the pharyngotympanic tube and the Levator palati. Its lateral surface is in contact with the upper and anterior part of the Medial Pterygoid muscle, the mandibular nerve, the otic ganglion and the middle meningeal artery. It arises from the scaphoid fossa of the pterygoid process, the lateral lamina of the cartilage of the pharyngotympanic tube and the medial aspect of the spine of the sphenoid bone. As it descends, its fibres converge to form a delicate tendon which turns medially round the pterygoid hamulus, and is inserted into the palatine aponeurosis and into the surface behind the palatine crest on the horizontal plate of the palatine bone. Between the tendon and the pterygoid hamulus there is a small bursa.

Actions.—Acting singly the Tensor palati pulls the soft palate to one side; acting together the two muscles tighten the soft palate and depress it by flattening out its arch.

The **Musculus uvulæ** arises from the posterior nasal spine of the palatine bones and from the palatine aponeurosis; it descends to be inserted into the uvula.

Action.—The Musculus uvulæ pulls up the uvula on its own side.

The **Palatoglossus** (Glossopalatinus) is a small, fleshy fasciculus, narrower in the middle than at the ends, forming, with the mucous membrane covering its surface, the palatoglossal arch. It arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side, and passing downwards, forwards and laterally in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum of the tongue, and others passing deeply into its substance to intermingle with the Transversus linguæ.

Actions.—The Palatoglossus pulls up the root of the tongue and approximates the palatoglossal arch to the median plane.

The **Palatopharyngeus** (Pharyngopalatinus) (figs. 1118, 1150) forms, with the mucous membrane covering its surface, the palatopharyngeal arch. In the palate it consists of two layers, which are separated by the Levator palati. The *posterior* (or *upper*) *layer* is in contact with the mucous membrane covering the posterior surface of the palate; it joins with the posterior layer of the opposite muscle in the median plane. The *anterior* (or *lower*) *layer*, the thicker, lies between the Levator and the Tensor palati muscles. It arises from the posterior border of the hard palate and from the palatine aponeurosis, while some of its fibres join in the median plane with the corresponding layer of the opposite muscle. At the posterolateral border of the palate the two

* *Journal of Anatomy and Physiology*, vol. xlviii.

layers of the muscle unite and are joined by the fibres of the Salpingopharyngeus muscle (p. 1298). Passing laterally and downwards behind the tonsil, the Palatopharyngeus descends posteromedial to, and in close contact with, the Stylopharyngeus, and is inserted with it into the posterior border of the thyroid cartilage, some of its fibres ending on the side of the pharynx, and others passing across the median plane posteriorly, to decussate with those of the opposite muscle. The Palatopharyngeus really forms an internal longitudinal muscular coat for the pharynx.

Actions.—The Palatopharyngeus pulls the walls of the pharynx, on its own side, upwards, forwards and medially, and so shortens the pharynx during the act of swallowing. Acting together the two muscles approximate the palatopharyngeal arches and draw them forwards.

Nerve-supply.—With the exception of the Tensor palati, which is innervated by the mandibular nerve through the otic ganglion, all the muscles of the soft palate are supplied by the accessory nerve through the pharyngeal plexus.

When the soft palate is dissected from its posterior, or pharyngeal, to its anterior, or oral, surface, the muscles are exposed in the following order: (1) the posterior fasciculus of the Palatopharyngeus, covered posteriorly with a continuation of the nasal mucous membrane; (2) the Musculus uvulæ, enclosed in the palatine aponeurosis; (3) the Levator palati; (4) the anterior fasciculus of the Palatopharyngeus; (5) the aponeurosis of the Tensor palati; and (6) the Palatoglossus, covered anteriorly with a continuation of the oral mucous membrane.

The *movements of the soft palate* are described on p. 1298.

Applied Anatomy.—The occurrence of a congenital cleft in the palate has been already referred to as a defect in development (p. 96). Paralysis of the soft palate often occurs after diphtheria. It gives rise to a change in the voice, which becomes nasal, and to the regurgitation of fluids into the nose when swallowing is attempted. On inspection, the palate is seen to hang flaccid and motionless when phonation or deglutition is attempted; it is also anæsthetic.

The Salivary Glands (fig. 1122)

Three pairs of salivary glands pour their secretion into the mouth: they are named the parotid, the submandibular (submaxillary) and the sublingual glands.

The **parotid gland** (figs. 1119, 1120), the largest of the three, has an average weight of about 25 gm. It forms an irregular, lobulated mass, lying below the external auditory meatus, between the mandible and the Sternomastoid; it projects forwards on to the surface of the Masseter, where a small part of it, usually more or less detached, lies between the zygomatic arch above and the parotid duct below; this detached portion is named the *accessory part* of the gland.

The gland is enclosed within a capsule derived from the deep cervical fascia; the part covering the superficial surface of the gland is dense, closely adherent to the gland, and attached to the zygomatic arch; a portion of the fascia, attached to the styloid process and the angle of the mandible, is thickened to form the stylomandibular ligament, which intervenes between the parotid and submandibular glands.

The parotid gland may be described as roughly pyramidal in shape; it presents a small, superior surface, and superficial, anteromedial and postero-medial surfaces. The lower part of the gland tapers to a blunt extremity.

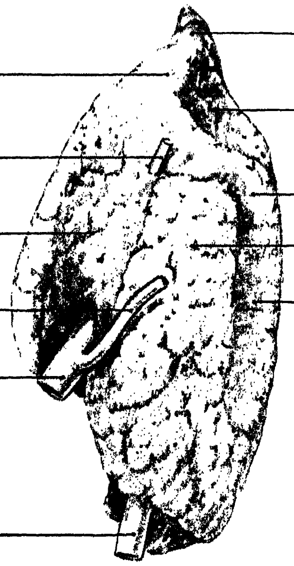
The *superior surface* is concave and is related to the external auditory meatus, and to the posterior surface of the mandibular joint; here the auriculotemporal nerve winds round the neck of the mandible, imbedded in the gland.

The *lower extremity* of the gland overlaps the posterior belly of the Digastric and the carotid triangle to a variable extent.

The *superficial surface* is covered with the skin, and the superficial fascia, which contains the facial branches of the great auricular nerve, some small lymph glands and the posterior border of the Platysma.

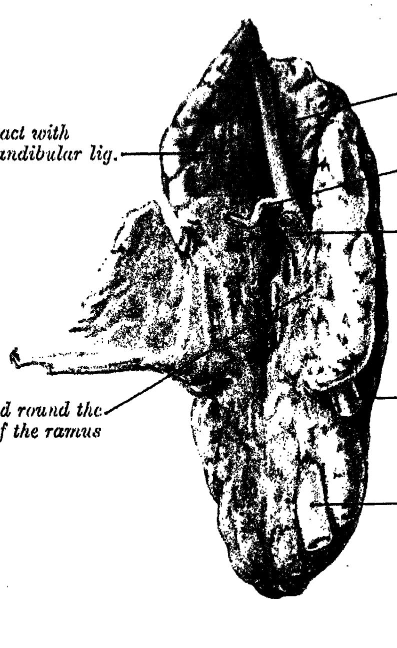
The *anteromedial surface* is grooved by the posterior border of the ramus of the mandible. It covers the postero-inferior part of the Masseter, the lateral

FIG. 1119.—The right parotid gland. Posteromedial aspect.



aspect of the mandibular joint and the adjoining part of the mandibular ramus, and passes forwards on the deep aspect of the ramus to reach the Medial

FIG. 1120.—The right parotid gland. Anteromedial aspect.



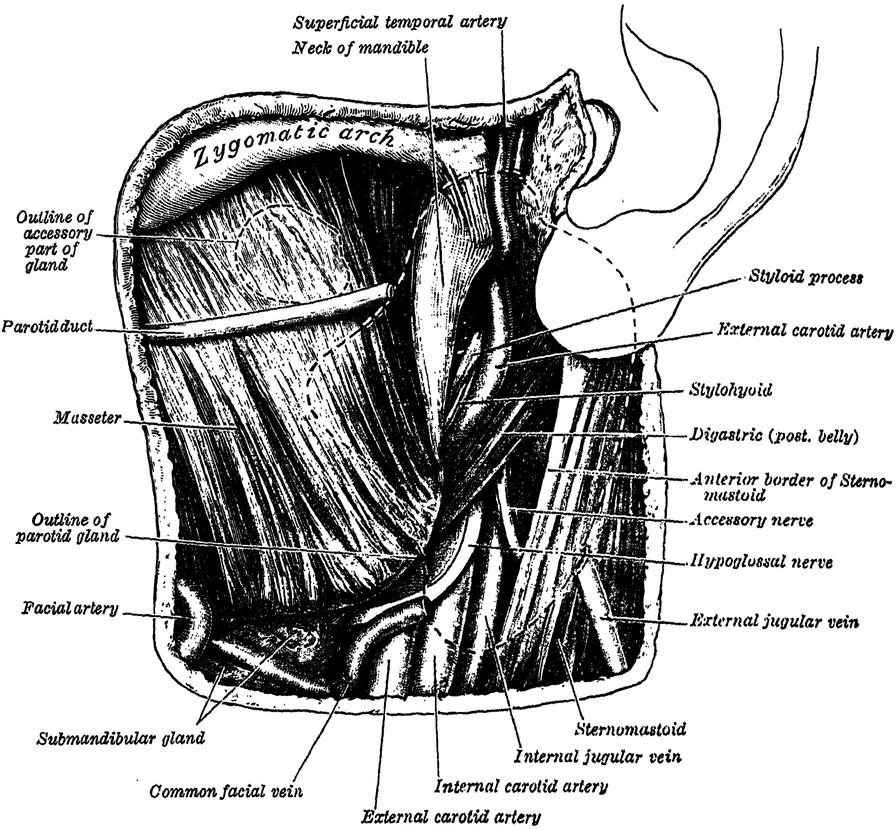
pterygoid muscle. The branches of the facial nerve emerge on the face from under cover of the anterior margin of this surface.

The *posteromedial surface* is moulded on the mastoid process and the Sterno-mastoid, and on the posterior belly of the Digastric, the styloid process and

the styloid group of muscles. The external carotid artery grooves this surface before it enters the substance of the gland. The internal carotid artery and internal jugular vein are separated from the gland by the styloid process and the styloid muscles (fig. 1121).

Structures within the gland.—The external carotid artery pierces the posteromedial surface of the parotid gland, and divides into its terminal branches within its substance. One of these branches—the (internal) maxillary artery—leaves the anteromedial surface of the gland, and runs forwards deep to the neck of the mandible, while the other—the superficial temporal artery—gives off its

Fig. 1121.—A drawing of a dissection to show the principal deep relations of the parotid gland.

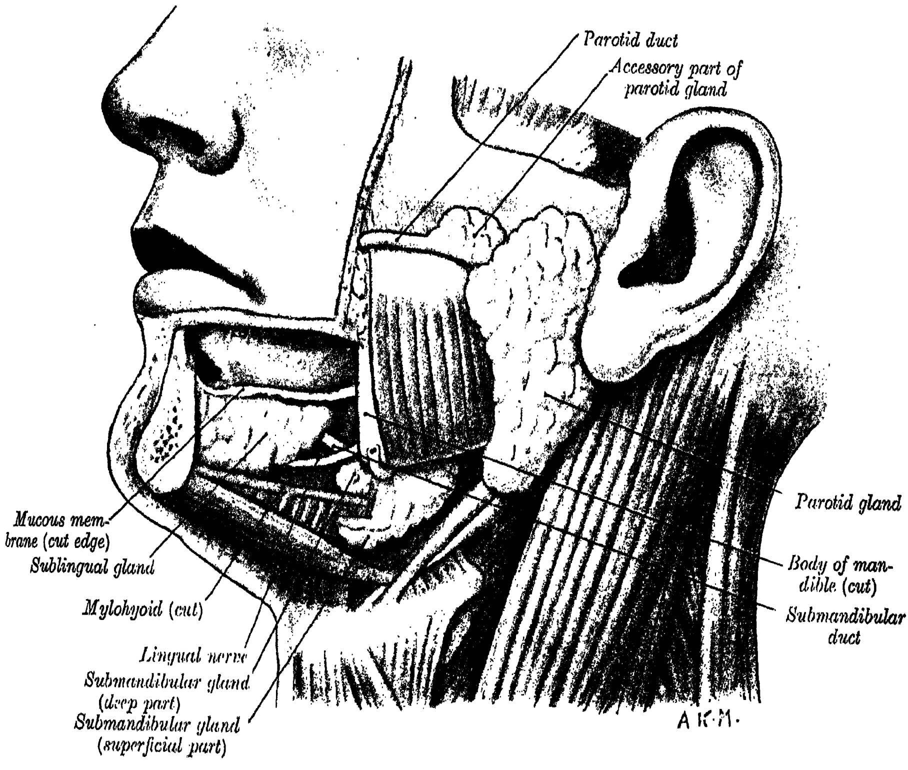


transverse facial branch, and then ascends to appear at the upper limit of the gland (fig. 1120). The posterior auricular artery may rise from the external carotid artery within the gland, and it then leaves the latter on its posteromedial surface. The posterior facial vein (p. 808), formed in the upper part of the gland by the union of the maxillary and superficial temporal veins, which enter the gland at the point of exit of the corresponding arteries, lies superficial to the intraglandular part of the external carotid artery. It passes downwards and divides into two branches which emerge one in front of and the other behind the inferior extremity of the gland. On a still more superficial plane the facial nerve traverses the gland. It enters the upper part of the posteromedial surface (fig. 1119), and passes forwards and downwards in two main divisions from which its terminal branches arise. These leave the anteromedial surface of the gland above, in front, and below, and pass to their destinations from under cover of its anterior margin.

The parotid duct (fig. 1122) is about 5 cm. long. It begins by numerous branches from the anterior part of the gland, crosses the Masseter, and at the anterior border of this muscle turns inwards nearly at a right angle, passes

through the corpus adiposum of the cheek and pierces the Buccinator; it then runs for a short distance obliquely forwards between the Buccinator and mucous membrane of the mouth, and opens upon a small papilla on the oral surface of the cheek opposite the second upper molar tooth. While crossing the Masseter it receives the duct of the accessory portion; in this position it lies between the upper and lower buccal branches of the facial nerve; the accessory part of the gland and the transverse facial artery are above it.

FIG. 1122.—A dissection showing the salivary glands of the left side.



Structure.—The wall of the parotid duct is of considerable thickness, and consists of a thick external fibrous coat which contains unstriped muscular fibres, and an internal mucous coat which is lined with short columnar epithelium. Its canal is about the size of a crow-quill, but at its orifice on the oral surface of the cheek its lumen is greatly reduced in size.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid artery, and from the branches given off by that vessel in or near the gland. The *veins* empty themselves into the external jugular vein, through some of its tributaries. The *lymph vessels* end in the superficial and deep cervical lymph glands, passing in their course through two or three lymph glands on the surface and in the substance of the parotid gland. The *nerves* are derived from the auriculotemporal nerve and from the plexus of the sympathetic on the external carotid artery. It is probable that the branch from the auriculotemporal nerve is the secretomotor nerve of the gland and that it is derived from the glossopharyngeal nerve through the otic ganglion; at all events, this has been proved experimentally to be the case in some of the lower animals.

The submandibular (submaxillary) gland (fig. 1122) is irregular in form and about the size of a walnut. It consists of a larger superficial part and a smaller deep part, which are continuous with each other around the posterior border of the Mylohyoid.

The *superficial part* of the submandibular gland is situated in the digastric triangle, reaching forwards to the anterior belly of the Digastric and backwards

to the stylomandibular ligament, which intervenes between the submandibular and parotid glands. Above, it extends under cover of the body of the mandible; below, it usually overlaps the intermediate tendon of the Digastric and the insertion of the Stylohyoid. It has three surfaces, an inferior, a lateral and a medial.

The *inferior surface* is covered with the skin, Platysma, and deep cervical fascia. It is crossed by the anterior facial vein, and by some filaments of the facial nerve; near the mandible the submandibular lymph glands are in contact with it.

The *lateral surface* is in relation with the submandibular fossa on the inner surface of the body of the mandible, and with the lower part of the medial surface of the Medial pterygoid muscle.

The *medial surface* is in relation with the Mylohyoid, Hyoglossus, Styloglossus, Stylohyoid, and posterior belly of the Digastric; between it and the Mylohyoid the mylohyoid nerve and vessels run forwards.

The facial (external maxillary) artery is imbedded in a groove in the posterior and superior part of the gland.

The *deep part* of the submandibular gland extends forwards as far as the posterior end of the sublingual gland, and lies in the intermuscular interval between the Mylohyoid below and laterally and the Hyoglossus and Styloglossus medially; above, it is related to the lingual nerve and submandibular (submaxillary) ganglion; below, to the hypoglossal nerve and its vena comitans.

The **submandibular duct** (submaxillary duct) is about 5 cm. long, and its wall is much thinner than that of the parotid duct. It begins by numerous branches in the superficial part of the gland, and runs with the deep part of the gland forwards between the Mylohyoid and the Hyoglossus; it then passes between the sublingual gland and the Genioglossus, and opens by a narrow orifice on the summit of the sublingual papilla (fig. 1141). On the Hyoglossus it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed laterally by the lingual nerve; the terminal branches of the lingual nerve ascend on its medial side.

Vessels and Nerves.—The *arteries* supplying the submandibular gland are branches of the facial and lingual arteries. Its *veins* follow the course of the arteries. The *nerves* are derived from the submandibular ganglion, through which it receives filaments from the chorda tympani of the facial nerve, the lingual branch of the mandibular nerve and the sympathetic.

In the dog and cat the submandibular gland receives its nerve-supply through Langley's ganglion (p. 1272).

The **sublingual gland** (fig. 1122) is the smallest of the three salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenulum linguæ, in contact with the sublingual fossa on the inner surface of the mandible, close to the symphysis. It is narrow, flattened, shaped somewhat like an almond, and weighs between 3 and 4 gms. It is in relation, above, with the mucous membrane of the mouth, which it raises in the form of the sublingual fold; *below*, with the Mylohyoid; *in front*, with its fellow of the opposite side; *behind*, with the deep part of the submandibular gland; *laterally*, with the mandible above the anterior part of the mylohyoid line; and *medially*, with the Genioglossus, from which it is separated by the lingual nerve and the submandibular duct. Its excretory ducts are from eight to twenty in number. Of the *smaller sublingual ducts*, some join the submandibular duct: others open separately into the mouth, on the sublingual fold. One or more join to form the *principal sublingual duct*, which opens with or near to the submandibular duct.

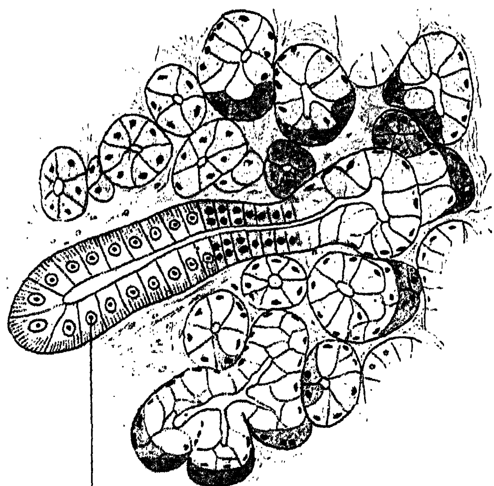
Vessels and Nerves.—The sublingual gland is supplied with blood by the sublingual and submental arteries. Its nerves are derived from the lingual and chorda tympani nerves, and from the sympathetic.

Structure of the salivary glands.—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of lobules, connected together by dense areolar tissue, vessels and ducts. Each lobule consists of the ramification of a single duct, the branches ending in dilated ends or alveoli on which the capillaries are distributed. The

alveoli are enclosed by a basement-membrane, which is continuous with the membrana propria of the duct and consists of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, viz. serous and mucous, which differ in the nature of their secretion and in the appearance of their cells. (1) The mucous alveoli secrete a viscid fluid which contains mucin; (2) the serous secrete a thinner and more watery fluid. The sublingual gland consists of mucous, and the parotid gland of serous, alveoli. The submandibular gland contains both mucous and serous alveoli (fig. 1125).

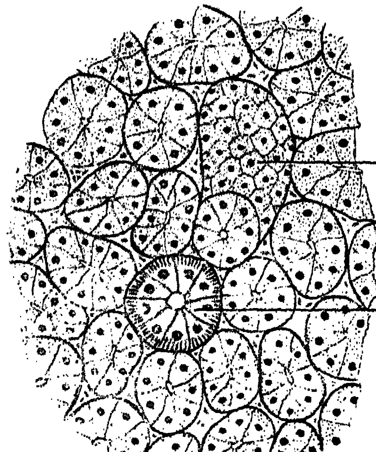
FIG. 1123.—A section through the submandibular gland of a kitten. Duct semi-diagrammatic. ×200.



The cells in the *mucous alveoli* are columnar in shape (fig. 1123), and in the fresh condition contain large granules of mucinogen. In hardened preparations a delicate protoplasmic network is seen, and the cells are clear and transparent. The nucleus is usually situated near the basement-membrane and is flattened.

In some alveoli peculiar crescentic bodies are seen between the cells and the basement-membrane. They are termed the *crescents of Giannuzzi*, or the *demilunes of Heidenhain* (fig. 1123), and are composed of polyhedral granular cells. Fine canaliculi pass between the mucus secreting cells to reach the demilunes and penetrate their cells.

FIG. 1124.—A section through the parotid gland of a cat. ×200.



In the resting condition of the gland the cells in the *serous alveoli* fill the cavity almost completely, so that the lumen is barely perceptible; they contain granules imbedded in a closely reticulated protoplasm (fig. 1124). The cells are more cubical than those of mucous alveoli; the nucleus of each is spherical and placed near the centre of the cell, and the granules are smaller.

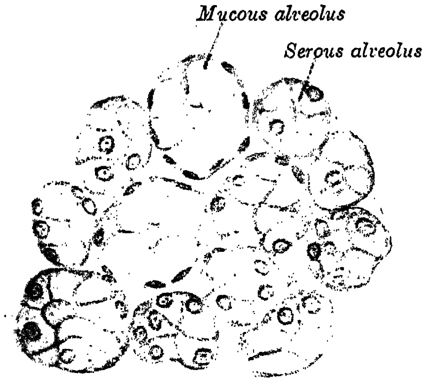
Both mucous and serous cells vary in appearance according to whether the gland is in a resting condition or has been recently active. In the former case the cells are large and contain many granules; in the latter case the cells are shrunken and contain few granules, chiefly collected at the inner ends of the cells. The granules are best seen in fresh preparations.

The ducts are lined at their origins by pavement epithelium, but as they enlarge, the

epithelial cells change to the columnar type, and the part of the cell next the basement-membrane is finely striated.

The lobules of the salivary glands are richly supplied with blood-vessels, which form a dense network in the inter-alveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. In the hilum of the submandibular gland in some animals there is a collection of nerve-cells termed *Langley's ganglion.*

Fig. 1125.—A section through a human submandibular gland. Stained with hæmatoxylin and eosin. ×300.



Accessory glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. Some of these occur in the tongue (p. 1289); others lie around and in the tonsil between its pits, and large numbers are present in the soft palate, the lips and cheeks. These glands are of the same structure as the larger salivary glands and are of the mucous or mixed type.

The Teeth [Dentes] (figs. 1127 to 1129)

Man is provided with two sets of teeth, which make their appearance at different periods of life. Those of the first set are temporary and appear during the first and second years; they are called the *deciduous* or *milk* teeth. Those of the second set begin to replace the deciduous set about the sixth year; they are all established by the twenty-fifth year, and, since they may continue until old age, are named the *permanent* teeth.

The *deciduous teeth* are twenty in number: four incisors, two canines, and four molars in each jaw.

The *permanent teeth* are thirty-two in number: four incisors, two canines, four premolars, and six molars in each jaw.

The dental formulæ may be represented as follows:

Deciduous Teeth.

	mol.	can.	in.	in.	can.	mol.	
Upper jaw . .	2	1	2	2	1	2	Total 20
Lower jaw . .	2	1	2	2	1	2	

Permanent Teeth.

	mol.	premol.	can.	in.	in.	can.	premol.	mol.	
Upper jaw .	3	2	1	2	2	1	2	3	Total 32
Lower jaw .	3	2	1	2	2	1	2	3	

General characteristics.—Each tooth consists of three portions: the *crown,* projecting beyond the gum; the *root,* imbedded in the alveolus; and the *neck,* the constricted portion between the crown and the root.

The roots of the teeth are firmly implanted in the alveoli of the maxillæ and mandible. Each alveolus is lined by periosteum (periodontal membrane), which invests the tooth as far as its neck and is continuous above with the fibrous tissue of the gums.

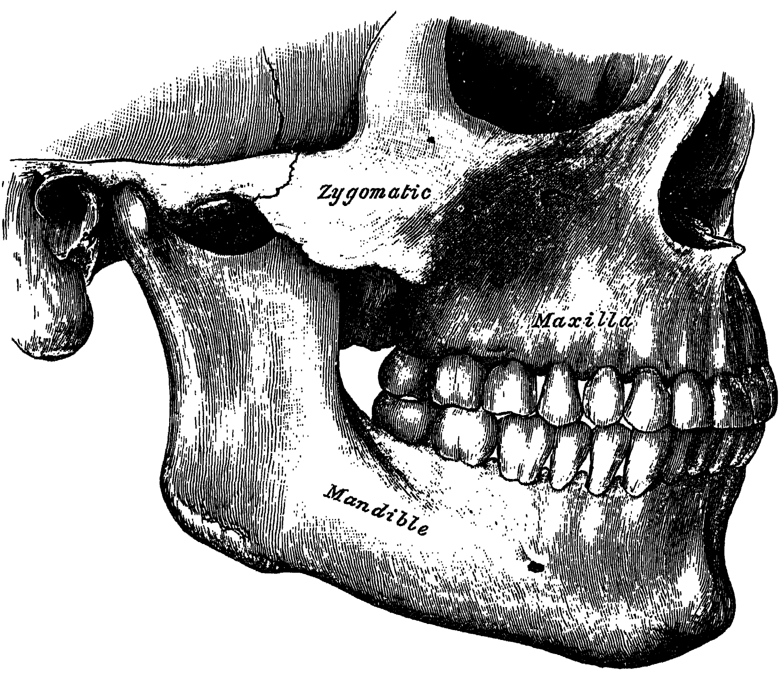
In consequence of the curve of the dental arch, terms such as anterior and posterior, if applied to the teeth, would be misleading and confusing. Special terms are therefore used to indicate the different surfaces of a tooth: the surface directed towards the lips or cheek is known as the *labial* or *buccal* surface; that directed towards the tongue is described as the *lingual* surface; those surfaces which touch neighbouring teeth are termed *contiguous surfaces.* In the case of the incisor and canine teeth the contiguous surfaces are medial and lateral; in the premolar and molar teeth they are anterior and posterior.

The superior dental arch is larger than the inferior, so that in the normal condition the teeth of the maxillæ slightly overlap those of the mandible both in front and at the sides. The upper central incisors are wider than the lower, and the corresponding teeth of the upper and lower sets are not opposed accurately to each other when the mouth is closed. Thus the upper canine tooth rests partly on the lower canine and partly on the first premolar, and the tubercles of the upper molar teeth lie behind the corresponding tubercles of the lower molar teeth. The dental arches, however, end at nearly the same points behind because the upper molars, especially the third, are smaller than the lower.

The Permanent Teeth (figs. 1126 to 1129)

The incisor teeth are so named because they present sharp cutting edges, adapted for biting the food. They are eight in number, and form the four front teeth in each dental arch.

Fig. 1126.—The teeth and jaws. Right lateral aspect.



The *crown* of each is directed vertically, and is chisel-shaped, being bevelled so as to present a sharp, horizontal, cutting edge. Before it is subjected to attrition, this edge presents three small prominent points separated by two notches. The crown is convex on its labial surface; concave on its lingual surface near the cutting edge, but becoming convex near the gum. In this situation in the teeth of the upper arch, it is frequently marked by a V-shaped eminence, known as the *cingulum*. The *neck* is constricted. The *root* is long, single, conical, transversely flattened, thicker in front than behind, and slightly grooved on each side.

The *upper incisors* are larger and stronger than the lower, and are directed obliquely downwards and forwards. They overlap the lower incisors and their free edges are consequently bevelled at the expense of their lingual surfaces. Their roots are conical and nearly cylindrical. The central upper incisors are larger than the lateral.

The *lower incisors* are smaller than the upper. They are placed vertically and are somewhat bevelled in front, where they have been worn down by contact with the overlapping edges of the upper teeth. Their roots are flattened

at the sides. The central lower incisors are slightly smaller than the lateral, and are the least of all the incisors.

The **canine teeth** are four in number, two in the upper, and two in the lower arch, one being placed lateral to each lateral incisor. They are larger and stronger than the incisors, and their long roots, which are relatively superficial, cause well-marked bony prominences.

The *crown* of each is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp, which projects beyond the level of the other teeth. The *root* is single, but longer and thicker than that of the incisors ; it is conical in form, and marked by a slight groove on each side.

The *upper canine teeth* (popularly called *eye-teeth*) are larger and longer than the lower, and usually present a distinct cingulum.

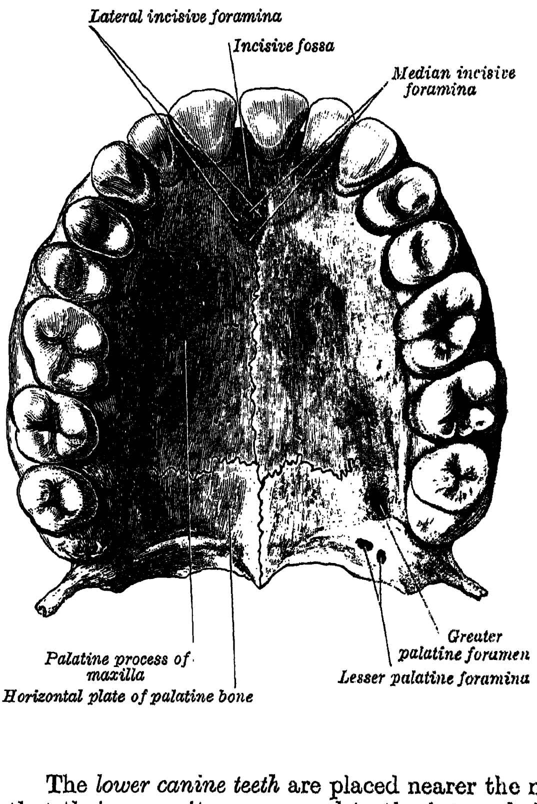


FIG. 1127.—The permanent teeth of the upper dental arch. Inferior aspect.

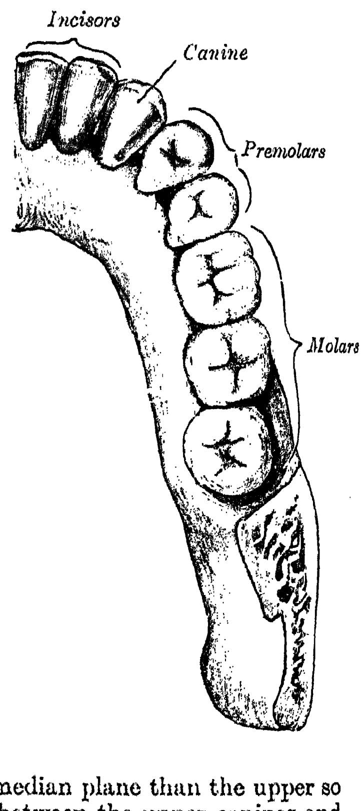

FIG. 1128.—The permanent teeth of the right half of the lower dental arch. Superior aspect.

The *lower canine teeth* are placed nearer the median plane than the upper so that their summits correspond to the intervals between the upper canines and lateral incisors. The roots of the lower canines are occasionally double.

The **premolar teeth** are eight in number, four in each arch. They are smaller and shorter than the canine teeth and are placed behind and lateral to them.

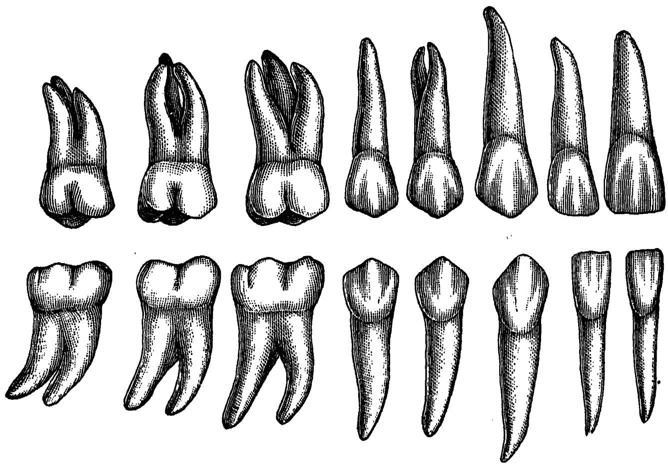
The *crown* of each is compressed from before backwards, and surmounted by two pyramidal tubercles separated by a groove. Of the two tubercles the labial is larger and more prominent than the lingual. The *neck* is oval. The *root* is generally single, but presents in front and behind a deep groove, which indicates a tendency in the root to become double.

The *upper premolars* are larger, and show a greater tendency to the division of their roots than the lower ; this is especially the case in the first upper premolar. The roots of the *lower premolars* are nearly cylindrical.

The **molar teeth** are the largest of the permanent set, and their broad crowns are adapted for grinding the food. They are twelve in number, six in each arch, three being placed behind each second premolar.

The *crown* of each is nearly cubical in form, convex on its buccal and lingual surfaces, and flattened on its surfaces of contact; it is surmounted by four or five tubercles, separated from each other by a cruciform depression. The *neck* is distinct, large and rounded.

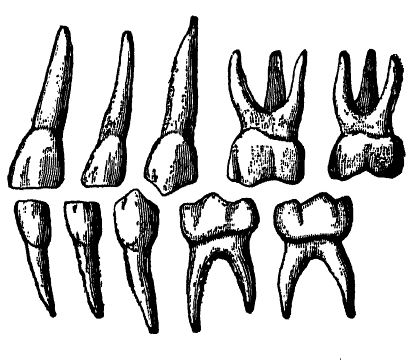
FIG. 1129.—The permanent teeth of the right side. (Burchard.)



The *upper molars*.—As a rule the first of the upper molars is the largest, and the third the smallest. The crown of the first has usually four tubercles, of which the posterior lingual tubercle is the smallest; that of the second, three or four; that of the third, three, the posterior lingual tubercle being absent. Each upper molar has three roots, two of which are buccal, and nearly parallel to each other; the third is lingual and diverges from the others as it ascends. The roots of the third molar (dens serotinus or wisdom-tooth) are more or less fused together.

The *lower molars*.—The lower molars are larger than the upper. On the crown of the first there are usually five tubercles, of which the posterior buccal tubercle is the smallest; on the crowns of the second and third, four or five, the posterior buccal tubercle being inconstant. Each lower molar has two roots, an anterior and a posterior, which are curved backwards; both roots are grooved longitudinally, indicating a tendency to division. The two roots of the third molar are more or less united.

FIG. 1130.—The deciduous teeth of the left side.



THE DECIDUOUS TEETH (fig. 1130)

The deciduous or milk-teeth resemble in form the teeth which bear the same names in the permanent set; they are, however, smaller and their necks are more constricted. The second molar is the largest of the deciduous teeth. The first upper molar has three tubercles, the second has four. The first lower molar has four tubercles; the second has five. The roots of the deciduous molars are smaller than those of the permanent molars; they are also more divergent, owing to the fact that the crowns of the permanent premolars are lodged between them. The deciduous molars are replaced by the permanent premolars.

THE STRUCTURE OF THE TEETH

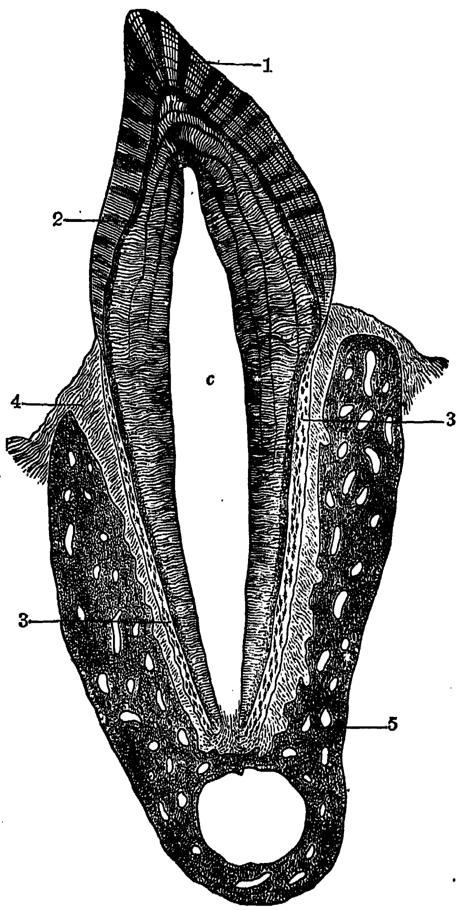
When a vertical section is made through a tooth (figs. 1131 to 1134), a cavity is seen in the crown and in the centre of each root; it opens by a minute orifice at the extremity of the latter. This is called the *pulp cavity*, and contains the *dental pulp*, a loose connective

tissue richly supplied with blood-vessels and nerves, which enter the cavity through the small foramen at the point of each root. Some of the cells of the pulp are arranged as a layer on the wall of the pulp cavity; they are named *odontoblasts*, and during the development of the tooth are columnar in shape, but after the dentine is fully formed they become flattened. Each sends a fine process into a canaliculus in the dentine.

The solid portion of the tooth consists of (1) the *dentine* or *ivory*, which forms the bulk of the tooth; (2) the *enamel*, which covers the exposed part of the crown; and (3) a thin layer of bone, termed the *cement*, which covers the root or roots.

The dentine (fig. 1131) is a modification of osseous tissue, from which, however, it differs in structure. On microscopic examination it is seen to consist of a number of minute wavy

Fig. 1131.—A vertical section through a tooth *in situ*. ×15.



c is placed in the pulp cavity, opposite the neck of the tooth; the part above it is the crown, that below is the root. 1. Enamel with radial and concentric markings. 2. Dentine with tubules and contour lines. 3. Cement with bone-cells. 4. Dental periosteum. 5. Mandible.

Fig. 1132.—A vertical section through a molar tooth.

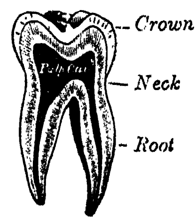


Fig. 1133.—A vertical section through a premolar tooth. (Magnified.)

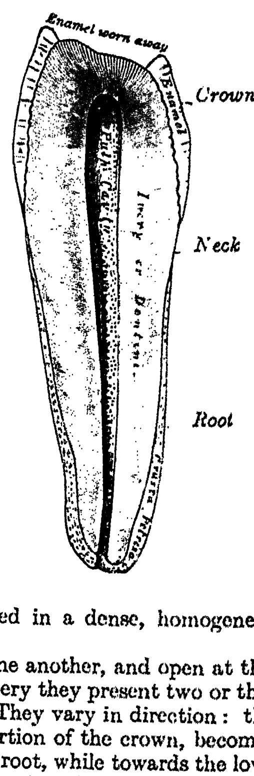


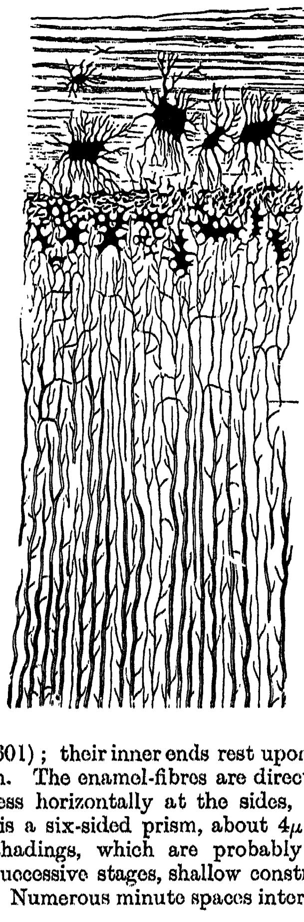
and branching tubes, termed the *dental canaliculi*, imbedded in a dense, homogeneous *matrix*.

The *dental canaliculi* (fig. 1134) are placed parallel with one another, and open at their inner ends into the pulp cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. They vary in direction: thus in a tooth of the mandible they are vertical in the upper portion of the crown, becoming oblique and then horizontal in the neck and upper part of the root, while towards the lower part of the root they are inclined downwards. In their course they divide and subdivide, and, especially in the root, give off minute branches, which join together in loops in the matrix, or end blindly. Near the periphery of the dentine, the finer ramifications of the canaliculi terminate imperceptibly by free ends. The dental canaliculi have definite walls consisting of an elastic homogeneous membrane, named the *dentinal sheath*, which resists

the action of acids; they contain slender cylindrical prolongations of the odontoblasts named *dentinal fibres*.

The *matrix* is translucent, and contains the chief part of the earthy matter of the dentine. It contains a number of fine fibrils, which are continuous with the fibrils of the dental pulp. After the earthy matter has been removed by the action of weak acid, the animal matter may be torn into laminæ which run parallel with the pulp cavity, and across the canaliculi. The planes separating these laminæ are indicated in a section of dry dentine by a series of somewhat parallel lines—the *contour lines of Owen*—composed of imperfectly calcified dentine. In consequence of the imperfection in the calcifying process, little irregular cavities are left, termed *interglobular spaces* (fig. 1134). A series of these spaces is found towards the outer surface of the dentine, where they form a layer which is sometimes known as the *granular layer of Tomes*. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines, named the *lines of Schreger*, may be seen parallel to the surface; they are due to the optical effect of simultaneous curvature of the dentinal fibres.

Fig. 1134.—A transverse section through a portion of the root of a canine tooth. ×300. (From Stricker's *Handbook of Histology*.)



Chemical composition.—According to Berzelius and von Bibra, dentine consists of 29 parts of animal, and 72 parts of earthy, matter. The animal matter is converted when boiled, into gelatin. The earthy matter consists of phosphate, carbonate, and a trace of fluoride of calcium, phosphate of magnesium and other salts; over 80 per cent. of the earthy matter consists of calcium phosphate.

The enamel is the hardest and most compact part of the tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the root. It is thickest on the grinding surface of the crown, until worn away by attrition (fig. 1133), and becomes thinner towards the neck. The cement may overlap, or be overlapped by, the enamel, but they generally meet without overlapping. Sections usually show a series of brown lines which form acute angles with the contour of the underlying dentine. The enamel consists of minute parallel rods termed *enamel-prisms*, each of which is surrounded by a cuticle which can be deeply stained by Heidenhain's hæmatoxylin (H. C. Malleson, *British Dental Journal*, vol. xlv., p. 601); their inner ends rest upon the dentine, their outer form the free surface of the crown. The enamel-fibres are directed vertically on the summit of the crown, and more or less horizontally at the sides, but pursue a somewhat wavy course. Each enamel-fibre is a six-sided prism, about 4μ in diameter, and presents numerous, dark, transverse shadings, which are probably due to the manner in which the fibres are developed in successive stages, shallow constrictions being produced, as will be explained subsequently. Numerous minute spaces intervene between the enamel-fibres near their dentinal ends.

Chemical composition.—Enamel consists of from 98 to 99 per cent. of earthy matter, and from 1 to 2 per cent. of animal matter. The earthy matter consists of phosphate of lime, with traces of fluoride and carbonate of calcium, phosphate of magnesium and other salts. Tomes asserts that there is no animal matter in properly calcified enamel.

The cement (figs. 1131, 1134) is disposed as a thin layer on the roots of the teeth, from the enamel to the apex of each root. In structure and chemical composition it resembles bone. It contains a few lacunæ and canaliculi; the canaliculi of adjacent lacunæ intercommunicate as in ordinary bone; and those more deeply placed join with the adjacent dental canaliculi. Normal cement is non-vascular.

Arteries.—The upper molars and premolars receive their blood-supply from the posterior superior dental branch of the (internal) maxillary artery; the upper canine and incisors from the anterior superior dental branches of the infra-orbital artery. The lower teeth are supplied by the inferior dental branch of the maxillary artery.

Nerves.—The superior dental branches of the maxillary nerve supply the upper, and the inferior dental branch of the mandibular nerve (p. 1053) the lower, teeth. In the case

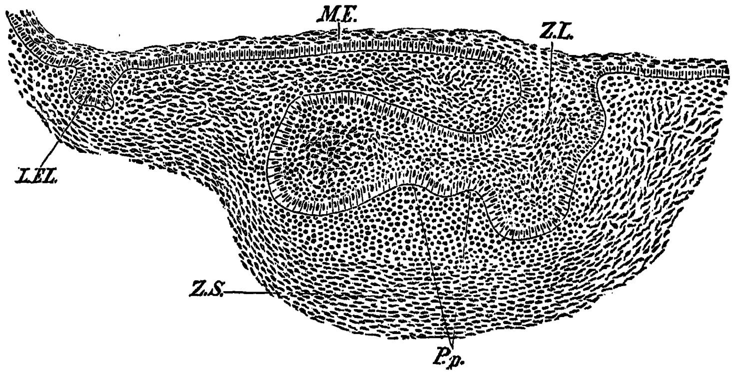
of the mandibular teeth, however, Stewart and Wilson * have shown that the lingual and buccal (buccinator) nerves may take part in the innervation of the pulp.

The *lymph vessels* are described on p. 855.

The Development of the Teeth (figs. 1135 to 1139)

In describing the development of the teeth, the mode of formation of the deciduous teeth must first be considered, and then that of the permanent teeth.

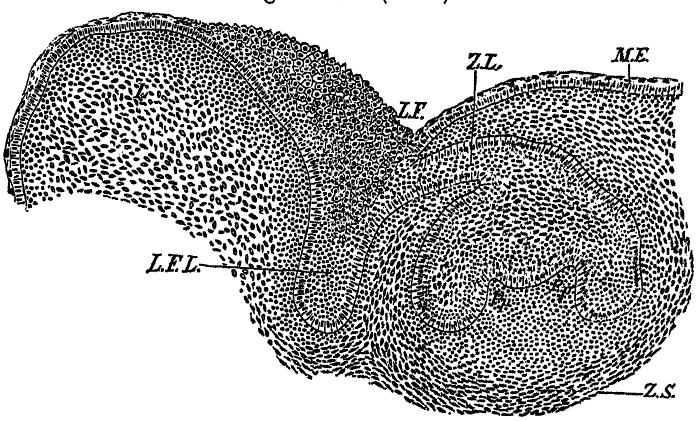
Fig. 1135.—A sagittal section through the first lower deciduous molar of a human embryo 30 mm. long. ×100. (Röse.)



L.E.L. Labiogingival lamina, here separated from the dental lamina. *M.E.* Mouth-epithelium. *P.p.* Bicuspidate papilla, capped by the enamel germ. *Z.L.*, placed over the shallow dental furrow, points to the dental lamina, which is spread out below to form the enamel germ of the future tooth. *Z.S.* Condensed tissue forming dental sac.

The development of the deciduous teeth begins about the sixth week of intrauterine life as a shallow *dental furrow* in the epithelium covering the surface of the mandibular arch (p. 97). Along the line of this furrow the epithelium grows into the subjacent mesoderm as a band of cells which splits into a medial (dentogingival) and a lateral (labiogingival) lamina (Bolk †). The cells of the labiogingival lamina ultimately break down and a groove is formed which

Fig. 1136.—A sagittal section through the canine tooth of an embryo 40 mm. long. ×100. (Röse.)



L.F. Alveololabial furrow. The other lettering as in fig. 1135.

separates the alveolar process from the lips and cheeks. In the dentogingival lamina the enamel-organs of the teeth are developed, and hence it is usually known as the *dental lamina* or *common dental germ*. Bolk has pointed out that the dental lamina also forms the epithelium of the gums, on the inner surface of the alveolar ridge. The common dental germ forms a flat band of cells, which grows into the substance of the embryonic jaw, at first horizontally, and then, as the teeth develop, vertically, i.e. upwards in the upper jaw, and downwards in

* *Proceedings of the Anatomical Society of Great Britain and Ireland*, June 1928.

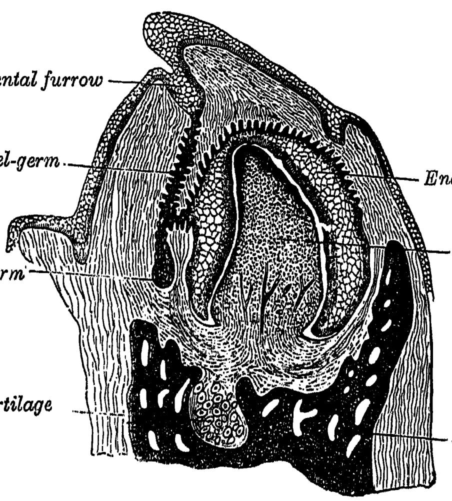
† L. Bolk, " Odontological Essays," *Journal of Anatomy*, vols. lv., lvi., lvii.

the lower jaw. While still maintaining a horizontal direction it has two edges—an *attached edge*, continuous with the epithelium lining the mouth, and a *free edge*, imbedded in the mesodermal tissue of the embryonic jaw.

About the ninth week the dental lamina begins to develop enlargements along its free edge. These are ten in number in each jaw, and each corresponds with a future deciduous tooth. They consist of masses of epithelial cells; and the cells of the deeper parts of each mass increase rapidly and spread in all directions. Each mass thus comes to assume the shape of a club, connected with the epithelial lining of the mouth by a narrow neck, embraced by mesoderm. These masses are now known as *special dental germs*. After a time the lower expanded portion of each mass inclines outwards, so as to form an angle with the superficial constricted portion, which is sometimes known as the *neck* of the special dental germ. About the tenth week the mesodermal tissue beneath the special dental germs becomes differentiated into papillæ; these come in contact with the special dental germs, which become folded over them like a hood or cap. There is, at this stage, a papilla (or papillæ) which has already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentine and pulp of the tooth are developed, surmounted by a dome or cap of epithelial cells from which the enamel is derived.

While these changes are going on, the dental lamina extends backwards behind the special dental germ of the second deciduous molar tooth, and about the seventeenth week

Fig. 1137.—A vertical section through the mandible of an early human fœtus. ×25.



of intrauterine life, it presents an enlargement, the special dental germ for the first permanent molar, soon followed by the formation of a mesodermal papilla for the same tooth. About the fourth month after birth a further extension backwards of the dental lamina occurs, with the formation of another special dental germ and its corresponding papilla for the second molar. The process is repeated for the third molar, the papilla of which appears about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except on the lingual aspect of each of the special germs of the temporary teeth, where it undergoes a local thickening to form the special dental germ of each of the successional permanent teeth—i.e. the ten anterior ones in each jaw. Here the same process goes on as has been described in connexion with those of the deciduous teeth: that is, they recede into the mesoderm, behind the germs of the deciduous teeth. As they recede they become club-shaped, form expansions at their distal ends, and finally meet papillæ which have been formed in the mesoderm. The apex of each papilla indents the dental germ, which forms a cap for it, and becomes converted into the enamel, while the papilla forms the dentine and pulp of the permanent tooth.

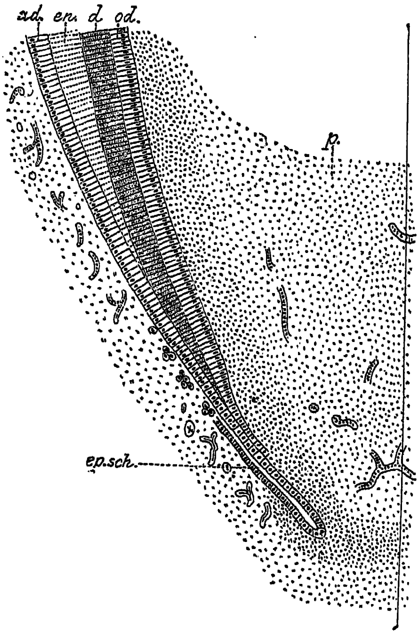
The special dental germs consist at first of round or polyhedral epithelial cells. After the formation of the papillæ, these cells undergo a differentiation into three layers. Those in contact with the papilla become elongated, and form a stratum of well-marked columnar epithelium. These cells form the enamel-fibres, and are therefore termed *enamel-cells* or *ameloblasts*. The cells of the outer layer of the special dental germ are cubical in form, and are named the *external enamel epithelium*. The intermediate cells become stellate in shape and form a network into which fluid is secreted; this has the appearance of a jelly, and to it the names of *stellate reticulum* or *enamel-pulp* are given. Between the stellate

reticulum and the layer of ameloblasts there is a *stratum intermedium* consisting of two or three layers of round or polygonal cells. The special dental germ, thus transformed, is now named the *enamel-organ* (fig. 1137).

Bolk (*loc. cit.*) has pointed out that in mammals, with one or two exceptions, the enamel-organ is, during a certain phase of development, connected with the common dental germ by a *medial* and a *lateral enamel band*, separated by what he names the *enamel-niche*. These two bands unite and convert the niche into a short tunnel which is filled with mesoderm, and is open posteriorly. The lateral enamel-band degenerates and is broken up into epithelial islets.

While these changes are going on, a sac is formed around each enamel-organ from the mesodermal tissue. This is known as the *dental sac*, and it is a vascular membrane of connective tissue. It encloses the whole tooth germ, and causes the neck of the enamel-organ to atrophy and disappear, so that the connexion between the enamel-organ and the superficial epithelium is severed.

Fig. 1138.—A longitudinal section through the lower part of a growing tooth, showing the extension of the layer of ameloblasts beyond the crown to mark off the limit of formation of the dentine of the root. (Röse.) (From Quain's *Elements of Anatomy.*)



ad. Ameloblasts, continuous below with *ep. sch.*, the epithelial sheath. *d.* Dentine. *en.* Enamel. *od.* Odontoblasts. *p.* Pulp.

The formation of the enamel.—The enamel is formed exclusively from the enamel-cells or ameloblasts of the special dental germ (fig. 1138), either by direct calcification of the columnar cells, which become elongated into the enamel-fibres, or, as is more generally believed, as a secretion from the ameloblasts, within which calcareous matter is subsequently deposited.

The process begins at the ends of the enamel-cells in contact with the dental papilla. Here a fine globular deposit takes place, being apparently shed from the ends of the ameloblasts. It is known by the name of the *enamel-droplet*, and resembles keratin in its resistance to the action of mineral acids. This droplet then becomes fibrous and calcifies, and forms the first layer of the enamel; a second droplet now appears and calcifies, and so on; successive droplets of keratin-like material are shed from the ameloblasts and form layers of enamel, the ameloblasts gradually receding as each layer is produced, until at the termination of the process they have almost disappeared. The enamel-pulp or stellate reticulum and the stratum intermedium atrophy and disappear, so that the newly formed calcified material and the external enamel-epithelium come into apposition. The crown of the tooth is covered for a time by a distinct membrane, known as the *cuticula dentis* (*Nasmyth's membrane*), and believed to be developed from the enamel-epithelium. It forms a horny layer, which may be separated from the subjacent calcified mass by the action of strong acids. It is marked by the hexagonal impressions of the enamel-fibres, and when stained by nitrate of silver, shows the characteristic lines of interepithelial cement.

The formation of the dentine.—As before stated, the first germs of the dentine are the papillæ, which grow upwards into the enamel-germs and become covered by them, both being enclosed in the dental sacs, in the manner above described. Each papilla then consists of round cells, and is very vascular, and soon begins to assume the shape of the future tooth. The next step is the appearance of the *odontoblasts*, which have a relation to the development of the teeth somewhat similar to that of the osteoblasts to the formation of bone; they are formed from the superficial cells of the papilla; these cells become elongated, one end of the elongated cells resting against the epithelium of the special dental germs, the other being tapered and often branched. By the direct transformation of the peripheral ends of these cells, or by a secretion from them, a layer of uncalcified matrix (*prodentine*) is formed, which caps the cusp, or cusps if there be more than one, of the papilla. This matrix becomes fibrillated, and in it islets of calcification make their appearance, and, coalescing, give rise to a continuous layer of calcified material, which covers each cusp and constitutes the first layer of dentine. The odontoblasts retire towards the centre of the papilla, and, as they do so, produce successive layers of dentine—that is to say, they form the dentinal matrix in which calcification subsequently takes place. As they recede from

the periphery of the papilla, they leave behind them filamentous processes of cell-protoplasm; these are surrounded by the calcified material, and thus the dental canaliculi are formed; the processes of protoplasm contained within these constitute the dentinal fibres. The central part of the papilla does not undergo calcification, but persists as the pulp of the tooth. In certain places uncalcified portions of the matrix remain between the successive layers of dentine, and give rise to the interglobular spaces alluded to above.

The formation of the cement.—The root of the tooth begins to be formed shortly before the crown emerges through the gum, but is not completed until some time afterwards. Its form is determined by a downgrowth of the epithelium of the dental germ which extends below the region where the enamel is to be formed, almost as far as the situation of the apex of the future root; this fold of epithelium is known as the *epithelial sheath* (fig. 1138). The vascular tissues of the dental sac then break through the epithelial sheath, and spread over the surface of the root as a layer of bone-forming material. In this layer osteoblasts make their appearance, and the process of ossification goes on as in the intramembranous ossification of bone. The remains of the epithelial sheath may sometimes be seen in the adult as isolated groups of cells in the alveolar periosteum (periodontal membrane).

The formation of the alveoli.—About the fourteenth week of embryonic life the dental lamina is enclosed in a trough or groove of mesodermal tissue, which at first is common to all the dental germs, but subsequently is divided by septa into loculi, each loculus containing the special dental germ of a deciduous tooth and its corresponding permanent tooth. After birth each cavity becomes subdivided, so as to form separate loculi for each deciduous tooth and its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, the latter never completely encloses it, since there is always an aperture over the top of the crown filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the *gubernaculum dentis.*

The development of the permanent teeth—Developmentally considered the permanent teeth may be divided into two sets: (1) the *successional permanent teeth* which replace the deciduous teeth, and, like them, are ten in number in each jaw; and (2) the *superadded permanent teeth* which have no deciduous predecessors, but are developed behind the temporary molars. The superadded permanent teeth are the three permanent molars, the molars of the deciduous set being replaced by the permanent premolars. During their development the successional permanent teeth, enclosed in their sacs, are placed on the lingual side of the deciduous teeth, but are separated from them by bony partitions. As the crown of the permanent tooth grows, absorption of the bony partition and of the root of the deciduous tooth takes place, through the agency of *osteoclasts*, which appear at this time, and finally nothing but the crown of the deciduous tooth remains. This is shed or removed, and the permanent tooth takes its place.

The superadded permanent teeth are developed in the manner already described, by extensions backward of the posterior part of the dental lamina in each jaw (p. 1278).

The *eruption of the teeth.*—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be subjected, eruption takes place, the tooth making its way through the gum. The eruption of the deciduous teeth commences about the seventh month after birth, and is completed about the end of the second year, the teeth of the lower jaw preceding those of the upper.

C. S. Tomes gives the following as the most usual times of eruption of the deciduous teeth:

Lower central incisors	6 to 9 months
Upper incisors	8 to 10 months
Lower lateral incisors and first molars . .	15 to 21 months
Canines	16 to 20 months
Second molars	20 to 24 months

There are, however, considerable variations in these times. According to Holt: a child at the age of one year should have six teeth; at the age of a year and half, twelve; at the age of two years, sixteen; and at the age of two and a half years, twenty.

Calcification of the permanent teeth proceeds in the following order in the lower jaw (in the upper jaw it takes place a little later): the first molars, at birth; the incisors, and canines, about six months after birth; the premolars, at the third year, or a little later; the second molars, about the end of the fourth year; the third molars, about the tenth year.

The eruption of the permanent teeth takes place at the following

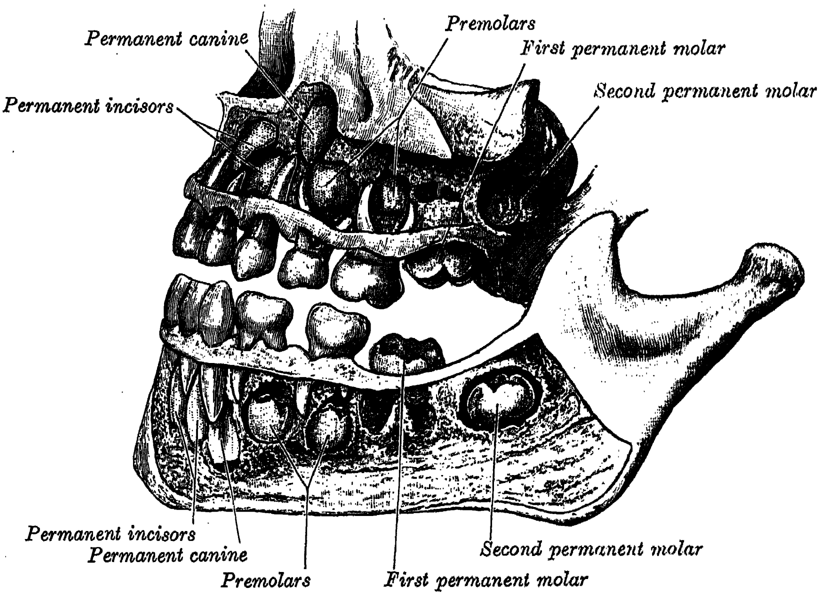
periods, the teeth of the lower jaw preceding those of the upper by short intervals:

First molars	6th year
Two central incisors	7th year
Two lateral incisors	8th year
First premolars	9th year
Second premolars	10th year
Canines	11th to 12th year
Second molars	12th to 13th year
Third molar	17th to 25th year

Towards the sixth year, before any of the deciduous teeth are shed, there are twenty-four teeth in each jaw, viz. the ten deciduous teeth and the crowns of all the permanent teeth except the third molars (fig. 1139).

It should be noted that the first molars are the earliest of the permanent teeth to erupt. This arrangement provides for the satisfactory mastication of food during the period when the premolars are erupting and the milk molars,

Fig. 1139.—The teeth of a child about six years. The permanent teeth are coloured *blue*.



which are in process of being shed, are of little value for this purpose. It is of interest to observe that in the eruption of both the deciduous and the permanent teeth, the canine appears in the interval between two teeth which have already erupted.

Development of the gums.—West,* who has investigated the development of the gums in human embryos and fœtuses from the seventh to the fortieth week, points out that the gum is developed in two parts, a labiobuccal and a lingual. The *labiobuccal part* lies between the lip-groove and the dental-groove. It appears before the lingual part, grows more rapidly, and is the more prominent; it takes the chief share in the formation of the adult gum, and becomes divided into segments which correspond in size and number with the tooth-sacs. The *lingual part* is not segmented, and its surface remains almost entirely smooth. The tissue of the gum in advance of the tooth is highly vascular, and furnishes a source of nutrition for the developing tooth.

Applied Anatomy.—As a consequence of diseases such as the acute infective fevers, which cause a temporary diminution in the calcium content of the blood, both the deciduous and the permanent teeth may show defective development or irregular transverse furrows

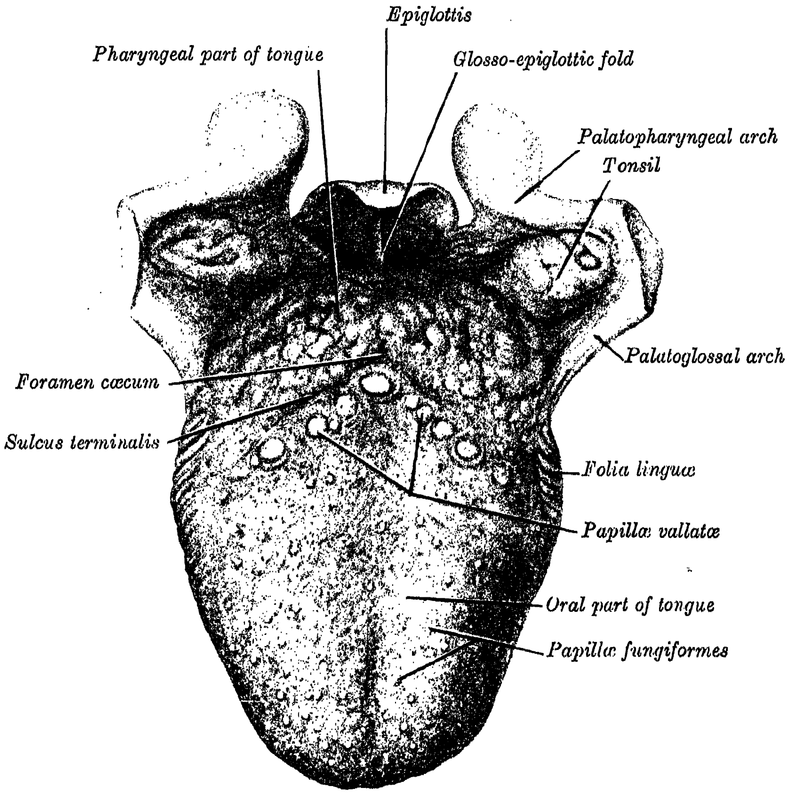
* Cecil M. West (Contributions to Embryology, No. 79. Publication 361 of the Carnegie Institution of Washington, 1925.)

and erosions ; this is particularly the case with the incisors. A characteristic malformation of the two upper central permanent incisors is seen in patients with inherited syphilis, and was first described by Hutchinson. Here there is a crescentic notch in the anterior surface and at the cutting edge of the tooth, which is peg-shaped, stunted, and set obliquely in the gum, pointing either medially or laterally.

The Tongue [Lingua] (figs. 1140 to 1142)

The **tongue** is a muscular organ intimately associated with the functions of taste, speech and deglutition ; it is situated partly in the mouth, and partly in the pharynx. Through the medium of its constituent muscles it is attached to the hyoid bone, the mandible, the styloid processes, the soft palate and the wall of the pharynx. It possesses a root, a tip, a curved dorsum and an inferior surface.

Fig. 1140.—The dorsum of the tongue.

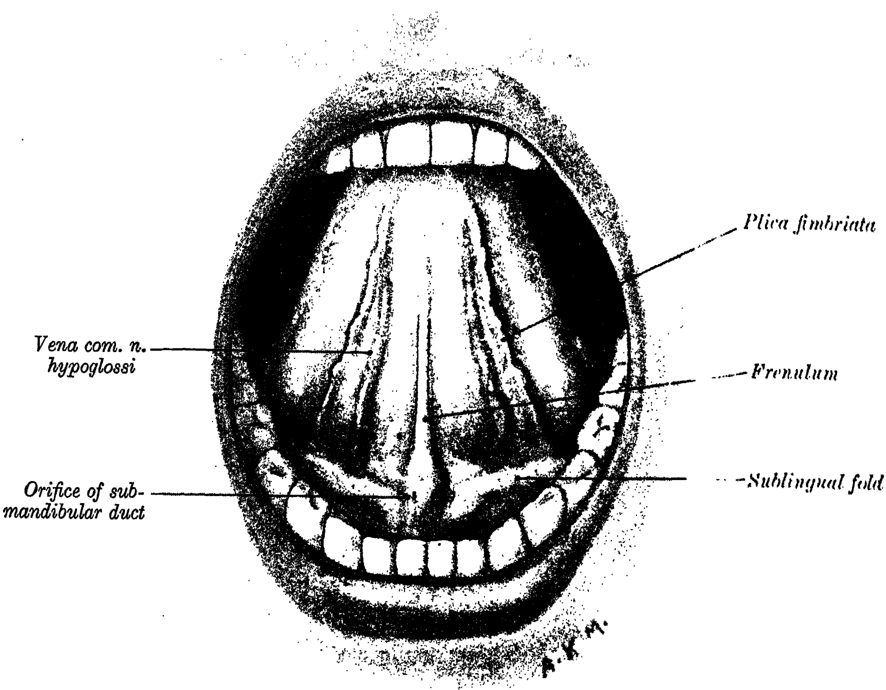


The *root* of the tongue (fig. 1117) is attached to the hyoid bone and the mandible, and between these bones is in contact with the Geniohyoid and the Mylohyoid muscles. The *dorsum* is convex from before backwards, and from side to side, and is divided into an anterior part which faces upwards, and a posterior part which faces backwards. These two parts are separated by a V-shaped furrow, termed the *sulcus terminalis*, the limbs of which run laterally and forwards from a median pit, named the *foramen cæcum*, to the palatoglossal arches (fig. 1140). The foramen cæcum marks the site of the upper end of the thyroid diverticulum (p. 165), and the sulcus terminalis serves as the boundary between the oral part or anterior two-thirds, and the pharyngeal part or posterior one-third, of the tongue. These two parts differ in the structure of their covering mucous membrane, in their nerve supply and in their development.

The *oral part* of the tongue (figs. 1140, 1142) is placed in the cavity and floor of the mouth ; its *apex* rests against the incisor teeth ; its *margin* is free and in contact with the gums and teeth ; its *superior surface* is in relation with the hard and soft palates. On each border, just in front of the palatoglossal

arch, there are four or five vertical folds, named the *folia linguæ* (fig. 1140), which correspond to the papillæ foliatæ of the rabbit's tongue. The mucous membrane of the superior surface of the oral part is marked by a median furrow (figs. 1140, 1142), is intimately adherent to the subjacent muscle, and is covered with papillæ. The mucous membrane on the inferior surface is smooth, and of a purplish colour ; it is reflected from the tongue to the floor of the mouth and the gums. In the median plane it is connected to the floor of the mouth by the frenulum linguæ (fig. 1141). Lateral to the frenulum, the lingual vein is seen shining through the mucous membrane, and at the lateral side of the vein there is a fringed fold of mucous membrane, named the *plica fimbriata*, which is directed forwards and medially towards the apex. The oral part of

FIG. 1141.—The cavity of the mouth. The tip of the tongue is turned upwards.



Note.—In the model from whom the drawing was made the two sublingual papillæ formed a single median elevation.

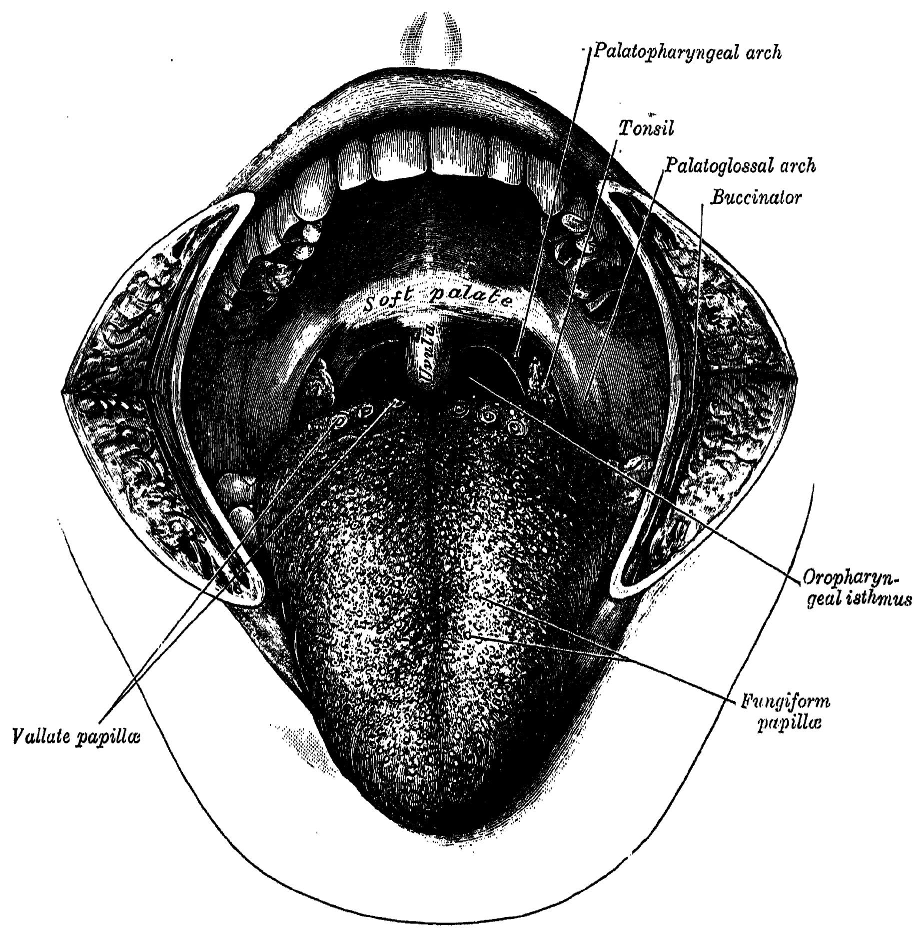
the tongue is developed from the lingual swellings of the mandibular arch, and to a small extent from the tuberculum impar (p. 163). Its nerve of ordinary sensation is the lingual ; its nerve of taste, the chorda tympani.

The *pharyngeal part* of the tongue (fig. 1140) lies behind the palatoglossal arches and the oropharyngeal isthmus ; its posterior surface (sometimes named the *base* of the tongue) forms the anterior wall of the oral part of the pharynx. The mucous membrane covering it is reflected laterally on to the tonsils and the pharyngeal wall, and posteriorly on to the epiglottis, where it forms a median [glosso-epiglottic] fold, and two lateral [pharyngo-epiglottic] folds. It is devoid of papillæ, but exhibits a number of low elevations, due to the presence of underlying nodules of lymphoid tissue, which are imbedded in the submucous tissue and collectively constitute the *lingual tonsil*. The pharyngeal part of the tongue is developed from the hypobranchial eminence, which is described on p. 164. Its nerves of ordinary sensation and of taste are derived from the glossopharyngeal.

The *papillæ of the tongue* (figs. 1140, 1142) are projections of the corium. They are thickly distributed over the anterior two-thirds of the dorsum, giving to this part its characteristic roughness. They are grouped under the terms papillæ vallatæ, papillæ fungiformes, papillæ filiformes and papillæ simplices.

The *vallate papillæ* (figs. 1140, 1142) are of large size, and vary from eight to twelve in number. They are situated on the dorsum of the tongue, and form a V-shaped row immediately in front of and parallel with the sulcus terminalis. Each papilla is from 1 mm. to 2 mm. in diamater, and is attached within a

FIG. 1142.—The cavity of the mouth. The cheeks have been slit transversely and the tongue pulled forwards.

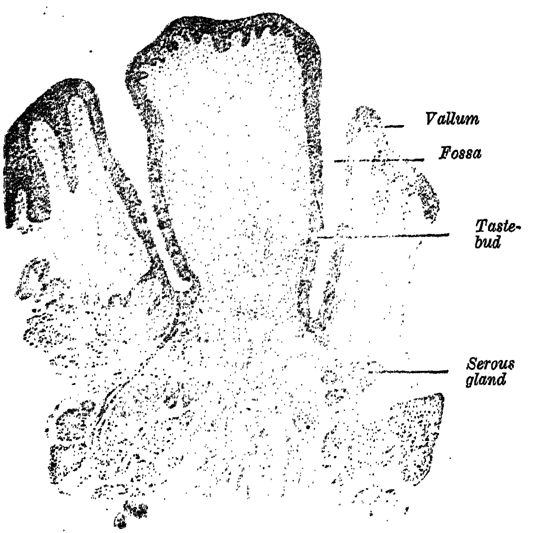


circular depression of the mucous membrane; each depression is surrounded by a wall (vallum) separated from the papilla by a circular sulcus. The papilla is shaped like a truncated cone, the smaller end being attached to the tongue; the broader end projects a little above the surface of the tongue, and is studded with numerous small secondary papillæ subjacent to the epithelial layer. The entire papilla and the surrounding sulcus are covered with stratified squamous epithelium.

The *fungiform papillæ* (figs. 1140, 1142, 1144), more numerous than the preceding, are found chiefly at the sides and apex of the tongue, but are scattered irregularly and sparingly over the dorsum. They are easily distinguished from the filiform papillæ by their large size, round shape, and deep red colour; each exhibits secondary papillæ beneath the epithelium. On the sides of the tongue they are somewhat flattened.

The *filiform papillæ* (fig. 1145) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, conical or cylindrical in shape, and arranged in rows which run parallel with those of the papillæ vallatæ, excepting at the apex of the tongue, where their direction is transverse. The filiform papillæ present numerous, secondary, connective tissue papillæ, but these are more pointed and contain a larger proportion of elastic fibres than the secondary papillæ vallatæ and papillæ fungiformes. The epithelium covering the filiform papillæ may be split up into filamentous processes, each of which forms the apex of one of the secondary papillæ; these processes are of a whitish tint, owing to the thickness and density of the epithelium, the cells of which are elongated and cornified.

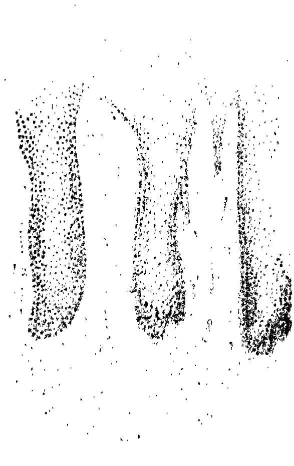
Fig. 1143.—A vertical section through a human vallate papilla. Stained with hæmatoxylin and eosin. ×15.



The *papillæ simplices* are similar to those of the skin, and cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set microscopic elevations of the corium; each contains a capillary loop, and is covered with epithelium.

Fig. 1144.—A section through a fungiform papilla from the human tongue, Stained with hæmatoxylin and eosin. ×15.

Fig. 1145.—A section through two filiform papillæ from the human tongue. Stained with hæmatoxylin and eosin. ×15.



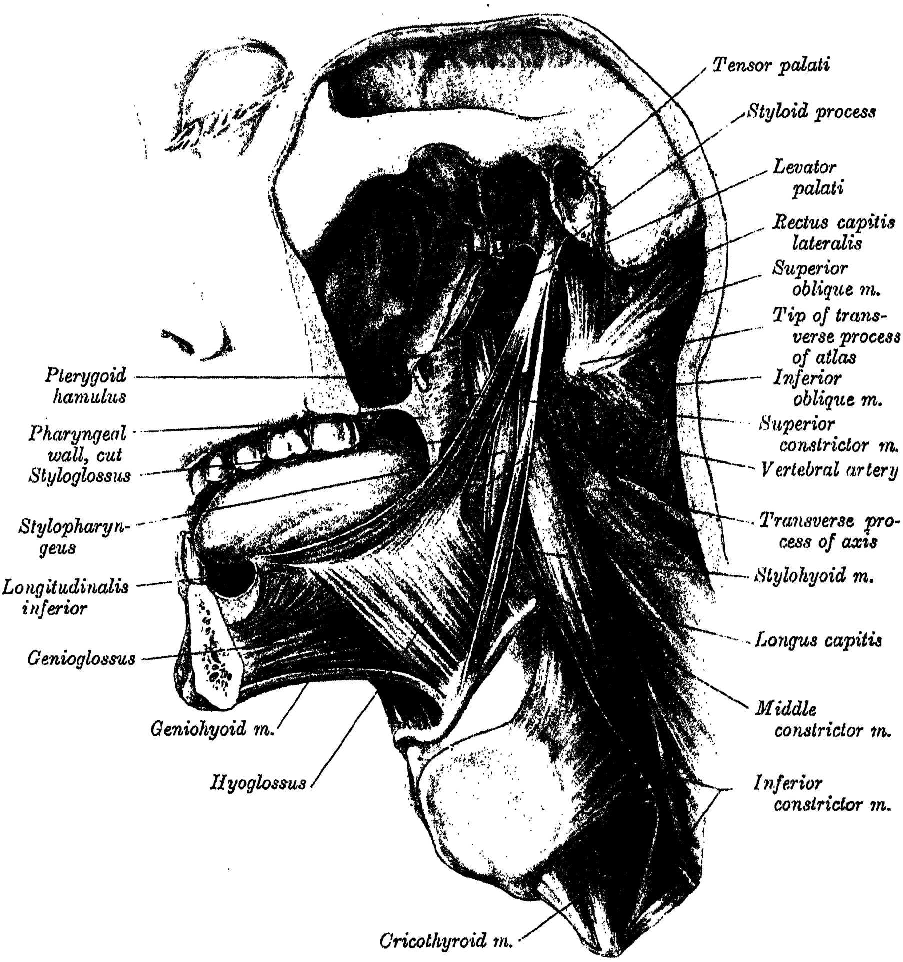
The muscles of the tongue.—The tongue is divided into right and left halves by a median fibrous septum, which is fixed below to the hyoid bone. In each half there are two sets of muscles, extrinsic and intrinsic; the former have their origins outside the tongue, the latter are contained within it.

The *extrinsic muscles* (fig. 1146) are :

Genioglossus. Chondroglossus.
Hyoglossus. Styloglossus.
Palatoglossus *

The **Genioglossus** is a triangular muscle placed close to and parallel with the median plane. It arises by a short tendon from the upper genial tubercle on the inner surface of the symphysis of the mandible, just above the origin of the Geniohyoid muscle, and spreads out in a fan-like form. The inferior

FIG. 1146.—A dissection of the left side of the head and neck, showing the muscles of the tongue and pharynx.



fibres are attached by a thin aponeurosis to the upper part of the body of the hyoid bone, a few passing between the Hyoglossus and Chondroglossus to blend with the Constrictors of the pharynx ; the middle fibres pass backwards, and the superior ones upwards and forwards, to enter the whole length of the under surface of the tongue, from the root to the apex. The muscles of opposite sides are separated posteriorly by the septum of the tongue (p. 1289) ; in front, they are more or less blended owing to the decussation of fasciculi in the median plane.

Actions.—The Genioglossus draws the tongue forwards and protrudes the

* The Palatoglossus, although one of the muscles of the tongue, is more closely associated with the soft palate both in situation and function ; it is consequently described with the muscles of that structure (p. 1265).

tip from the mouth. The two muscles acting in their entirety draw the median part of the tongue downwards so as to make the superior surface concave from side to side.

The **Hyoglossus**, thin and quadrilateral, arises from the whole length of the greater horn, and from the front of the lateral part of the body, of the hyoid bone; it passes almost vertically upwards and enters the side of the tongue, between the Styloglossus and Longitudinalis linguæ inferior. The fibres arising from the body of the hyoid bone overlap those from the greater horn.

Relations.—The Hyoglossus is in relation by its *superficial surface* with the tendon of the Digastric, the Stylohyoid, Styloglossus and Mylohyoid muscles, the lingual nerve and the submandibular ganglion, the sublingual gland, the deep portion of the submandibular gland and the submandibular duct, the hypoglossal nerve and its vena comitans. By its *deep surface* it is in relation with the stylohyoid ligament, the Genioglossus, the Longitudinalis linguæ inferior, and the glossopharyngeal nerve. In its lower and posterior part, it is separated from the Middle constrictor of the pharynx by the lingual vessels. This portion of the muscle lies in the lateral wall of the pharynx, a little below the tonsil.

Action.—The Hyoglossus depresses the tongue.

The **Chondroglossus** is sometimes described as a part of the Hyoglossus, but it is separated from that muscle by fibres of the Genioglossus which pass to the side of the pharynx. It is about 2 cm. long, and arises from the medial side and base of the lesser horn and contiguous portion of the body of the hyoid bone; it ascends and blends with the intrinsic muscular fibres of the tongue, between the Hyoglossus and Genioglossus.

A small slip arises occasionally from the cartilago triticea in the lateral thyrohyoid ligament and enters the tongue with the most posterior fibres of the Hyoglossus.

Action.—The Chondroglossus assists the Hyoglossus in depressing the tongue.

The **Styloglossus**, the shortest and smallest of the three styloid muscles, arises from the anterior and lateral surfaces of the styloid process, near its apex, and from the stylomandibular ligament. Passing downwards and forwards, it divides upon the side of the tongue into two portions; one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the fibres of the Longitudinalis linguæ inferior in front of the Hyoglossus; the other, oblique, overlaps the Hyoglossus and decussates with its fibres (fig. 1146).

Action.—The Styloglossus draws the tongue upwards and backwards.

Nerve-supply.—With the exception of the Palatoglossus (p. 1265) all the extrinsic muscles of the tongue are supplied by the hypoglossal nerve.

The *intrinsic muscles* are:

Longitudinalis linguæ superior.	Transversus linguæ.
Longitudinalis linguæ inferior.	Verticalis linguæ.

The **Longitudinalis linguæ superior** is a thin stratum of oblique and longitudinal fibres immediately underlying the mucous membrane on the dorsum of the tongue. It arises from the submucous fibrous layer close to the epiglottis, and from the median fibrous septum, and runs forward to the edges of the tongue, some of its fibres being inserted into the mucous membrane.

The **Longitudinalis linguæ inferior** is a narrow band situated on the under surface of the tongue between the Genioglossus and Hyoglossus. It extends from the root to the apex of the tongue, some of its posterior fibres being connected with the body of the hyoid bone; in front it blends with the fibres of the Styloglossus.

The **Transversus linguæ** consists of fibres which arise from the median fibrous septum and pass laterally to be inserted into the submucous fibrous tissue at the sides of the tongue.

The **Verticalis linguæ** is found at the borders of the fore part of the tongue. Its fibres extend from the upper to the under surface of the organ.

Applied Anatomy.—Owing to the presence of the median fibrous septum of the tongue, the anastomosis between the two lingual arteries is not very free. This is a point of considerable importance in connexion with removal of one-half of the tongue, an operation not infrequently resorted to for malignant disease. If the mucous membrane be divided exactly in the median plane, the tongue can be split into halves, without any appreciable hæmorrhage, and the diseased half can then be removed.

Nerve-supply.—The intrinsic muscles of the tongue are supplied by the hypoglossal nerve.

Actions.—The intrinsic muscles are mainly concerned in altering the shape of the tongue; thus, the Longitudinales linguæ, superior et inferior, tend to shorten it, but the former, in addition, turns the tip and sides upwards so as to render the dorsum concave, while the latter pulls the tip downwards and renders the dorsum convex. The Transversus linguæ narrows and elongates the tongue, and the Verticalis linguæ flattens and broadens it.

Structure of the tongue.—The tongue consists chiefly of muscular tissue, but is partly invested by mucous membrane and a submucous fibrous layer.

The mucous membrane covering the under surface of the tongue is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane of the pharyngeal part of the dorsum of the tongue is thick and freely movable over the subjacent parts. It contains a large number of follicles of lymphoid tissue; each follicle forms a rounded eminence, in the centre of which there is a minute orifice leading into a funnel-shaped cavity or recess; numerous round or oval nodules of lymphoid tissue, each enveloped by a capsule derived from the submucous fibrous layer, are grouped around this recess, which receives the openings of the ducts of some mucous glands in its floor. The mucous membrane on the oral part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and covered with numerous *papillæ* (p. 1285). It consists of a layer of connective tissue (the *corium*) covered with epithelium.

The epithelium is of the stratified squamous variety, similar to, but much thinner and less complex than that of the skin; it invests each papilla from root to summit.

The *corium* consists of a dense felt-work of fibrous connective tissue, with numerous elastic fibres, firmly united with the fibrous tissue between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymph vessels and the glands of the tongue.

Glands of the tongue.—The tongue is provided with mucous and serous glands.

The *mucous glands* are similar in structure to the labial and buccal glands. They are numerous in the posterior one-third of the tongue, i.e. behind the vallate papillæ, but are also present at the tip and margins. In this connexion the *anterior lingual glands* require special notice. They are situated on the under surface of the tip of the tongue (fig. 1141), one on each side of the frenulum, where they are covered by the mucous membrane and by a fasciculus of muscular fibres derived from the Styloglossus and Longitudinalis inferior. They are from 12 mm. to 20 mm. long, and about 8 mm. broad; each consists of mucous and serous alveoli, and opens by three or four ducts on the under surface of the tip of the tongue.

The *serous glands* occur in the neighbourhood of the taste-buds, their ducts opening for the most part into the sulci of the vallate papillæ. These glands are racemose; the duct of each branches into several minute ducts, which end in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in distributing the substance to be tasted over the taste area (Ebner).

The *septum* of the tongue is a median fibrous partition which extends throughout the length of the organ, but does not quite reach the dorsum; it gives origin to the Transversus linguæ, and is well displayed in a coronal section of the tongue. Posteriorly it expands in a transverse direction and forms what is sometimes known as the *hyoglossal membrane*; this membrane connects the root of the tongue to the hyoid bone, and gives insertion to the inferior fibres of the Genioglossi.

Taste-buds are scattered over the mucous membrane of the mouth and tongue at irregular intervals. They occur especially in the sides of the vallate papillæ. They are described under the organs of the senses (p. 1154).

Vessels and Nerves.—The main *artery* of the tongue is the lingual branch of the external carotid artery, but the facial (external maxillary) and ascending pharyngeal arteries also give branches to it. The *veins* open into the internal jugular vein.

The *lymph vessels of the tongue* are described on p. 856.

The *sensory nerves of the tongue* are: (1) the lingual branch of the mandibular nerve, which is the nerve of ordinary sensibility for the anterior two-thirds of the tongue; (2) the chorda tympani branch of the facial nerve, which runs in the sheath of the lingual nerve, and is generally regarded as the nerve of taste for the anterior two-thirds; this nerve is derived from the sensory root of the facial (nervus intermedius); (3) the lingual branch of the glossopharyngeal nerve, which is distributed to the mucous membrane at the base and sides of the tongue, and to the vallate papillæ, and is the nerve of taste and of general sensibility for this region; (4) the superior laryngeal nerve, which sends some fine branches to the part near the epiglottis.

Applied Anatomy.—Congenital cysts and fistulæ may develop from persistent remains of thyroglossal duct (p. 165).

It is the attachment of the Genioglossi to the genial tubercles on the inner surface of the symphysis of the mandible which prevents the tongue from falling back and obstructing respiration, and, therefore, anæsthetists always pull forward the mandible and so get the full benefit of this connexion.

A consideration of the lymph vessels of the tongue (p. 856) will indicate the extent of the operation necessary for the removal of cancer of the tongue.

The Oropharyngeal Isthmus (fig. 1141)

The aperture by which the mouth communicates with the pharynx is called the *oropharyngeal isthmus.* Above, it is bounded by the soft palate; below, by the dorsum of the tongue; and, at the sides, by the palatoglossal arches.

The *palatoglossal arch* runs downwards, laterally and forwards on each side from the inferior surface of the soft palate to the side of the tongue, and is formed by the projection of the Palatoglossus (p. 1265) with its covering mucous membrane. The approximation of the arches, which helps to shut off the mouth from the oral part of the pharynx, plays an important part in the mechanism of deglutition (p. 1299).

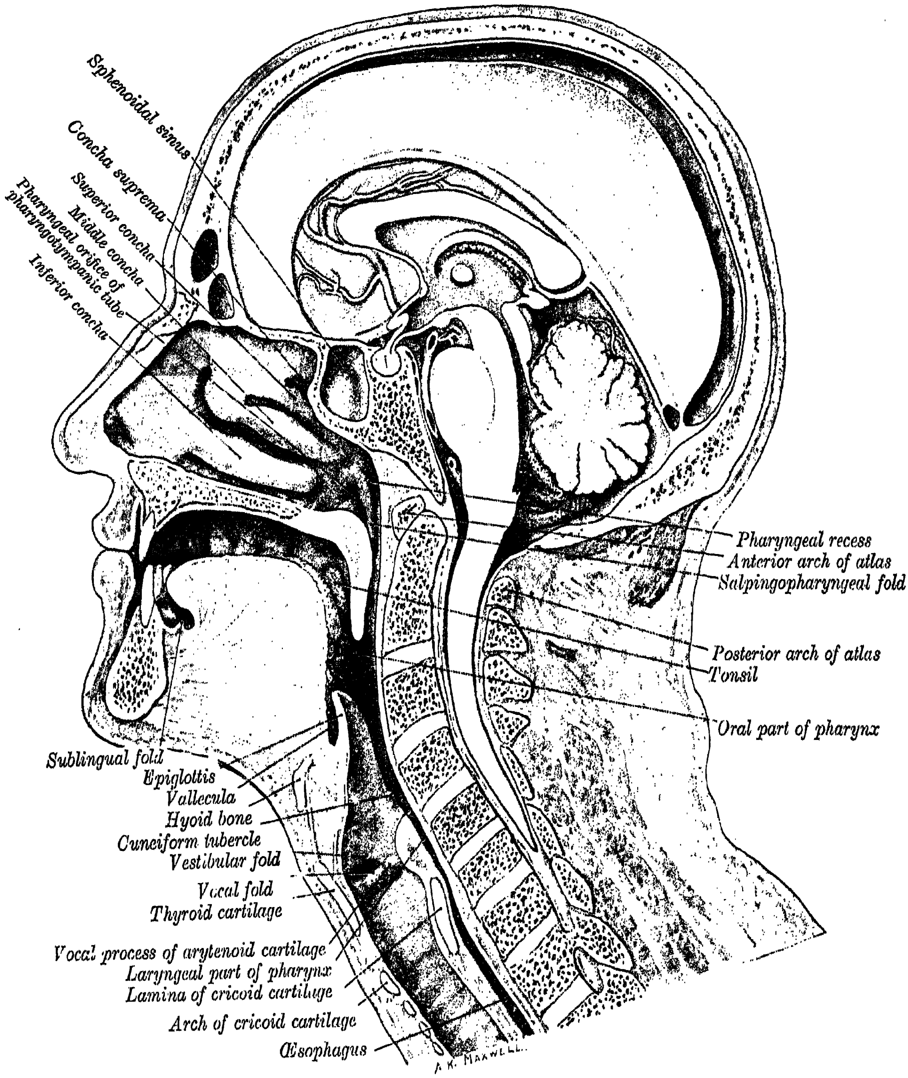
The Pharynx (figs. 1147, 1150, 1152)

The **pharynx** is the part of the digestive tube which is placed behind the nasal cavities, the mouth and the larynx. It is a musculomembranous tube, from 12 to 14 cm. long, which extends from the under surface of the skull to the sixth cervical vertebra opposite the lower border of the cricoid cartilage. Its width is greatest at its uppermost part, where it measures 3·5 cm.; at the junction of the pharynx with the œsophagus it is reduced to about 1·5 cm. The pharynx is limited, *above,* by the body of the sphenoid bone and the basilar part of the occipital bone; *below,* it is continuous with the œsophagus; *behind,* it is separated by loose areolar tissue from the cervical portion of the vertebral column and the prevertebral fascia covering the Longus cervicis (Longus colli) and Longus capitis muscles; *in front,* it opens into the nasal cavity, the mouth and the larynx, and therefore its anterior wall is incomplete. It is attached from above downwards, on each side, to the medial pterygoid plate, pterygomandibular ligament, mandible, tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally,* it communicates with the tympanic cavities through the pharyngotympanic (auditory) tubes, and is in relation with the styloid processes and their muscles, the common and external carotid arteries, and some of the branches of the latter artery. The pharynx consists of three parts: nasal, oral and laryngeal (fig. 1147).

The **nasal part of the pharynx** lies behind the nose and above the level of the soft palate. With the exception of the soft palate its walls are immovable, and consequently its cavity is never obliterated; in this respect it differs from the oral and laryngeal parts. *In front* (fig. 1147) it communicates with the nasal cavity through the posterior apertures of the nose; these measure about 25 mm. vertically, and 12·5 mm. transversely, and are separated by the posterior edge of the nasal septum. Between the free edge of the soft palate and the posterior wall of the pharynx the nasal and oral parts of the pharynx communicate through an opening, termed the *pharyngeal isthmus;* in the act of swallowing this opening is closed by the elevation of the soft palate and the contraction of the Palatopharyngeal sphincter (p. 1298). The *lateral wall,* on each side, presents the *pharyngeal opening of the pharyngotympanic* (*auditory*) *tube,* which lies behind and a little below the posterior end of the inferior nasal concha. Somewhat triangular in shape, this opening is bounded behind by the *tubal elevation* [torus tubarius], a firm prominence which is provided by the underlying pharyngeal end of the cartilage of the pharyngotympanic tube (p. 1199). A vertical fold of mucous membrane, termed the *salpingopharyngeal fold,* stretches from the lower part of the tubal elevation downwards to the wall of the pharynx; it contains the *Salpingopharyngeus* muscle. A second and smaller fold, termed the *salpingopalatine fold,* stretches from the upper part of the elevation to the palate. Behind the tubal elevation the mucous membrane

lines a recess of variable depth, termed the *pharyngeal recess.* The *roof* and *posterior wall* form a continuous sloping surface which inclines downwards and backwards. It is supported by the posterior part of the body of the sphenoid bone, the basilar part of the occipital bone and the anterior arch of the atlas. A collection of lymphoid tissue, best developed in children, lies in the mucous

FIG. 1147.—A sagittal section through the nose, mouth, pharynx and larynx.



membrane of the upper part of this surface and is known as the *nasopharyngeal tonsil.*

The nasopharyngeal tonsil is visible to the naked eye during the later months of fœtal life and usually increases in size up to the age of six or seven years, after which it not infrequently begins to atrophy. In a child of eighteen months it forms a triangular prominence the apex of which is near the nasal septum, and the base at the junction of the roof and posterior wall of the nasal part of the pharynx. The prominence consists of a number of folds which radiate forwards and laterally from a median recess, termed the *pharyngeal bursa.* The folds consist mainly of diffuse lymphoid tissue, but there are also some deeply

placed mucous glands. The pharyngeal bursa lies close to the base of the naso-pharyngeal tonsil and presents the appearance of a blind recess.*

The **oral part of the pharynx** reaches from the soft palate to the upper border of the epiglottis. It opens anteriorly, through the oropharyngeal isthmus, into the mouth. Its lateral wall presents the palatopharyngeal arch and the tonsil. Posteriorly, it is supported by the body of the second cervical vertebra and the upper part of the body of the third.

The *palatopharyngeal arch* (pharyngopalatine arch) lies behind and projects farther towards the median plane than the palatoglossal arch ; it runs downwards, laterally and backwards from the margin of the uvula to the side of the pharynx, and is formed by the projection of the Palatopharyngeus (Pharyngopalatinus) (p. 1265), covered with mucous membrane. On each side the palatopharyngeal and palatoglossal arches are separated below by a triangular recess, in which the tonsil is lodged.

The **tonsils** (palatine tonsils) (fig. 1142) are two masses of lymphoid tissue, situated in the lateral walls of the oral part of the pharynx. Each tonsil is placed in the triangular recess between the diverging palatoglossal and palatopharyngeal arches. Its medial surface is free and forms a conspicuous projection into the pharynx during childhood, but the size of this projection is not a true indication of the size of the organ. Its deep, or lateral, aspect extends upwards, downwards and forwards beyond the limits of the medial surface and is imbedded below the level of the mucous membrane. Inferiorly, it extends into the dorsum of the tongue ; superiorly, it invades the soft palate ; and, anteriorly, it may extend for some distance deep to the palatoglossal arch. The tonsil is variable in size and is frequently the seat of inflammatory changes involving hypertrophy. As a result it is difficult to decide which of the many varieties encountered is to be regarded as normal. In late fœtal life, a free fold of mucous membrane, which extends backwards from the palatoglossal arch, covers the anterior-inferior part of the tonsil and is termed the *plica triangularis*. In the child this fold is usually invaded by lymphoid tissue and becomes incorporated in the tonsil ; it is only rarely present as a small, free fold which extends backwards from the lower part of the palatoglossal arch.

The upper part of the tonsil contains a deep *intratonsillar cleft*, frequently and erroneously termed the *supratonsillar fossa*. This cleft does not lie above the tonsil, but actually in its substance, and its upper wall contains a quantity of lymphoid tissue which may reach a large size and extend into the soft palate. After puberty the imbedded part of the tonsil diminishes considerably in size and the projecting medial surface becomes flattened and much less prominent.

The *free surface* of the tonsil presents from twelve to fifteen orifices leading into small recesses, termed the *tonsillar pits*, from which numerous follicles branch out into the tonsillar substance.

The *lateral* or *deep surface* is covered by a layer of fibrous tissue, termed the *capsule*. In most of its extent the tonsil and its capsule can easily be separated from the muscular wall of the pharynx, which is formed in this situation by the Constrictor pharyngis superior with the Styloglossus on its lateral side (fig. 1150). At its antero-inferior part the capsule is firmly connected to the side of the tongue, and behind this point it receives the insertion of some muscular fibres. In the latter situation the tonsillar artery, which is a branch of the facial (external maxillary) artery, pierces the Constrictor pharyngis superior and at once enters the tonsil, accompanied by two venæ comitantes. An important, and sometimes large, palatine vein descends from the soft palate across the lateral aspect of the capsule of the tonsil before piercing the pharyngeal wall. It is this vessel which is responsible for the excessive venous hæmorrhage sometimes encountered in excision of the tonsil.† The muscular wall of the sinus tonsillaris separates the tonsil from the ascending palatine artery and, occasionally, from the facial artery itself (p. 707). The internal carotid artery lies 2·5 cm. behind and lateral to the tonsil.

* J. Symington, *British Medical Journal*, Oct. 15, 1910.

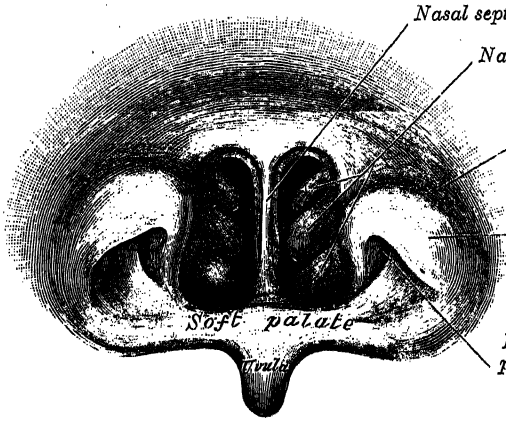
† D. Browne, *Journal of Anatomy*, vol. lxiii., 1928.

The tonsils form part of a circular band of lymphoid tissue which guards the opening into the digestive and respiratory tubes. The anterior and lower part of the ring is formed by the lingual tonsil; the lateral portions consist of the tonsils and the lymphoid collections in the vicinity of the pharyngotympanic (auditory) tubes; the ring is completed behind and above by the nasopharyngeal tonsil (p. 1291). Smaller collections of lymphoid tissue are found in the intervals between these main masses.

Structure.—The pits of the tonsil are lined by stratified squamous epithelium, which is continuous with that of the mucous membrane of the pharynx, and is invaded by numerous lymph-corpuscles; probably some of the latter pass into the mouth and form the so-called salivary corpuscles. The tonsil consists of lymphoid tissue which is arranged in nodules or follicles. The lymphocytes are less closely packed in the centre of each nodule, which is described as a *germ-centre*, because multiplication of the corpuscles goes on in this situation. A close plexus of lymph vessels surrounds each follicle and from it the lymph vessels pass to the upper deep cervical lymph-glands, and especially to the jugulodigastric lymph gland (p. 856).

Vessels and Nerves.—The chief *artery* supplying the tonsil is the tonsillar artery, a branch of the facial artery. In addition, it may receive occasional twigs from the dorsalis

Fig. 1148.—The front of the nasal part of the pharynx, as seen with the laryngoscope.



linguæ branches of the lingual artery, the ascending palatine branch of the facial artery, the ascending pharyngeal artery, and the greater palatine branch of the (internal) maxillary artery.

One or more *veins* leave the lower part of the deep aspect of the tonsil and at once pierce the superior constrictor muscle to join the pharyngeal or common facial veins.

The *nerves* are derived from the sphenopalatine ganglion, through the lesser palatine nerves, and from the glossopharyngeal nerve.

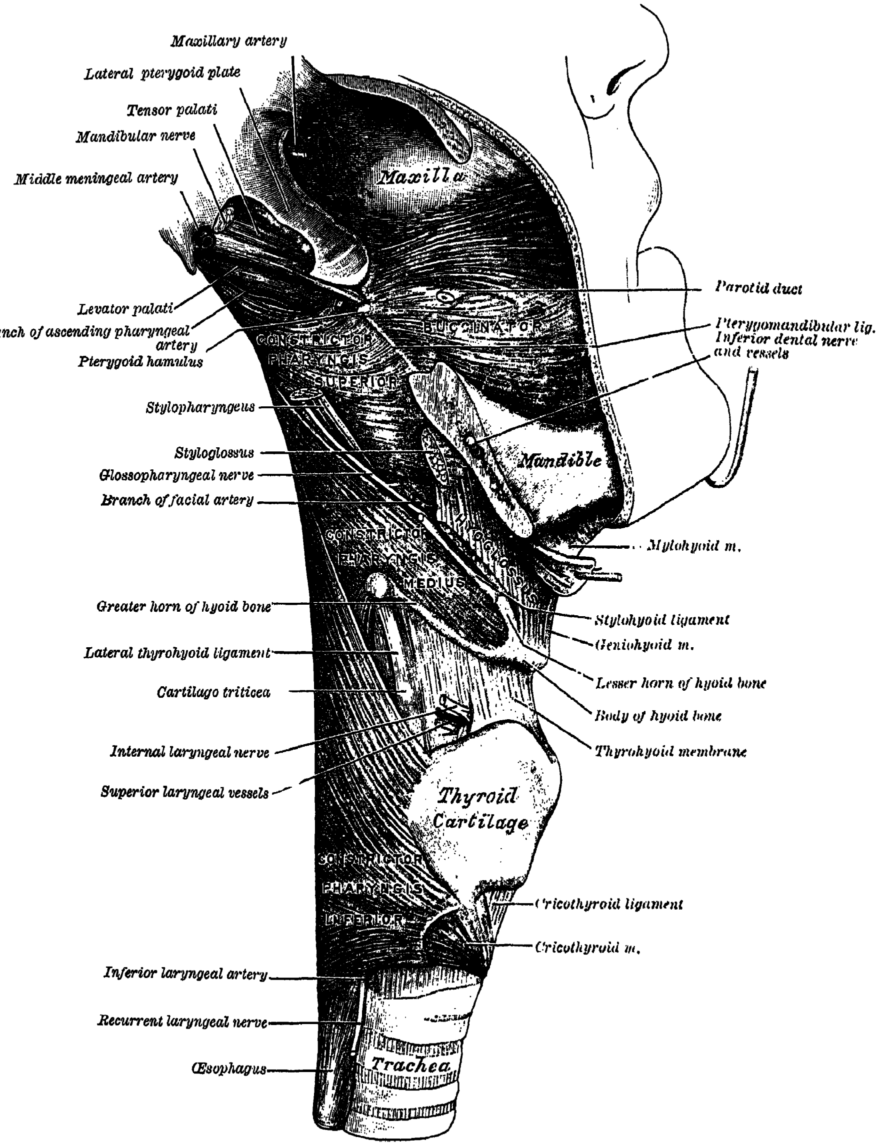
Applied Anatomy.—The tonsils can be inspected easily by instructing the patient to throw the head back and open his mouth widely, the tongue at the same time being depressed by a spatula or tongue-depressor. The normal tonsil should not project beyond the plane of the palatoglossal arch. They are prone to become enlarged, especially in tuberculous children; and when much increased in size they cause great trouble owing to obstruction to respiration and deglutition.

The laryngeal part of the pharynx reaches from the upper border of the epiglottis to the lower border of the cricoid cartilage, where it is continuous with the œsophagus. Its anterior wall presents, from above downwards, the inlet of the larynx (p. 1233), the posterior surfaces of the arytenoid cartilages and the posterior aspect of the cricoid cartilage. A small recess, termed the *piriform fossa*, lies on each side of the laryngeal orifice; it is bounded, medially, by the aryepiglottic fold and, laterally, by the thyroid cartilage and the thyrohyoid membrane. Posteriorly the laryngeal part of the pharynx is supported by the bodies of the third (lower part), fourth, fifth and sixth (upper part) cervical vertebrae.

Structure.—The pharynx is composed, from within outwards, of three coats; mucous, fibrous and muscular, the last being covered by the thin buccopharyngeal fascia, which covers the outer surface of the Constrictor muscles and extends forwards over the pterygomandibular ligament on to the Buccinator muscle.

The *mucous coat* is continuous with that of the pharyngotympanic tubes, nasal cavity, mouth and larynx. In the nasal part of the pharynx its epithelium is columnar and ciliated;

FIG. 1149.—The Buccinator and the muscles of the pharynx.



in the oral and laryngeal portions it is stratified squamous. Between the region covered by ciliated columnar epithelium and that covered by squamous epithelium, there is a narrow intermediate zone where the epithelium is cubical, and the cilia are imperfect or absent. Superiorly, this zone lies near the nasal septum: laterally it passes over the orifice of the pharyngotympanic tube and inclines backwards at the union of the soft palate with the lateral wall. Racemose glands are found beneath the mucous membrane, and are especially numerous at the upper part of the pharynx around the orifices of the pharyngotympanic tubes.

The *fibrous coat* is situated between the mucous and muscular layers. It is thick above (pharyngobasilar fascia) where the muscular fibres are wanting, and is firmly connected to the basilar portion of the occipital bone and the petrous portions of the temporal bones.

As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal tubercle on the under surface of the basilar portion of the occipital bone, and passes downwards as a median raphe which gives attachment to the Constrictor muscles (fig. 1152).

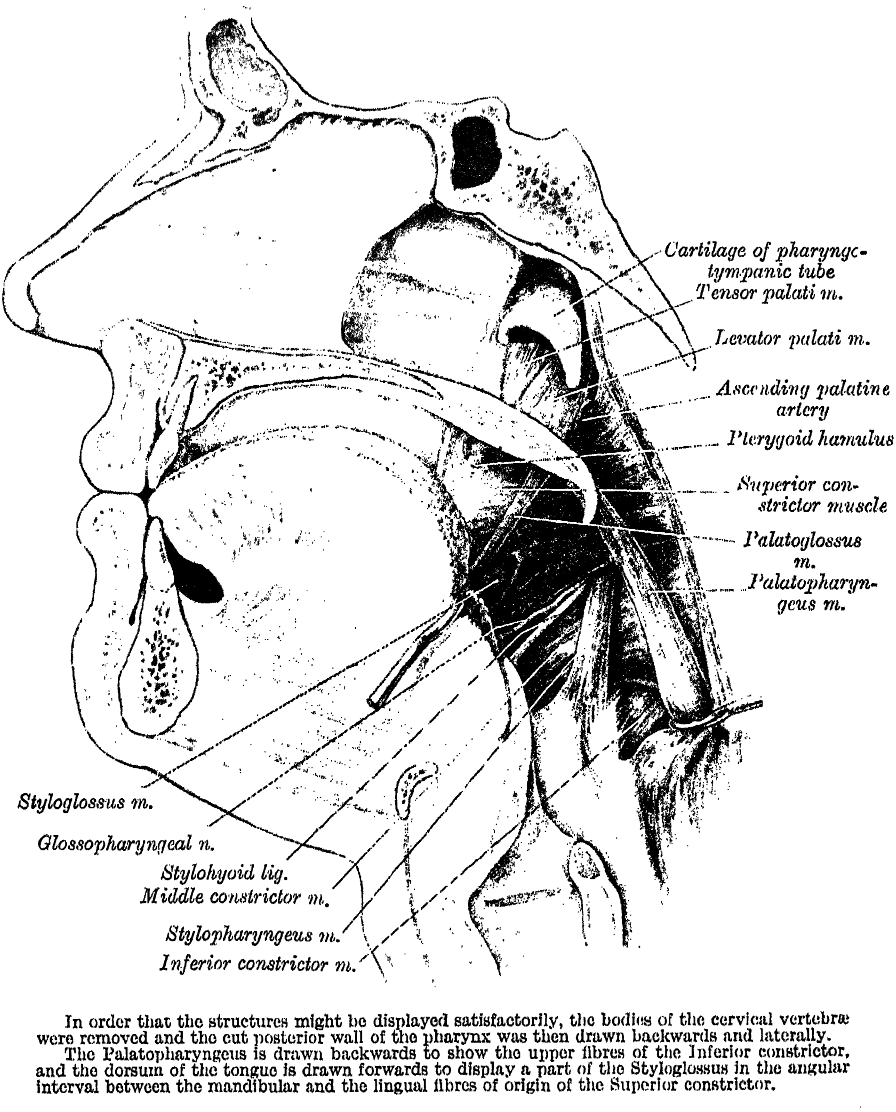
The *muscular coat* consists of the muscles of the pharynx.

The muscles of the pharynx (figs. 1146, 1149-52) are:

Constrictor pharyngis inferior.	Stylopharyngeus.
Constrictor pharyngis medius.	Salpingopharyngeus.
Constrictor pharyngis superior.	Palatopharyngeus.*

The **Constrictor pharyngis inferior** is the thickest of the constrictors. It arises from the cricoid cartilage in the interval between the origin of the Crico-

FIG. 1150.—Median sagittal section of the head, showing a dissection of the interior of the pharynx, after the removal of the mucous membrane.



In order that the structures might be displayed satisfactorily, the bodies of the cervical vertebræ were removed and the cut posterior wall of the pharynx was then drawn backwards and laterally. The Palatopharyngeus is drawn backwards to show the upper fibres of the Inferior constrictor, and the dorsum of the tongue is drawn forwards to display a part of the Styloglossus in the angular interval between the mandibular and the lingual fibres of origin of the Superior constrictor.

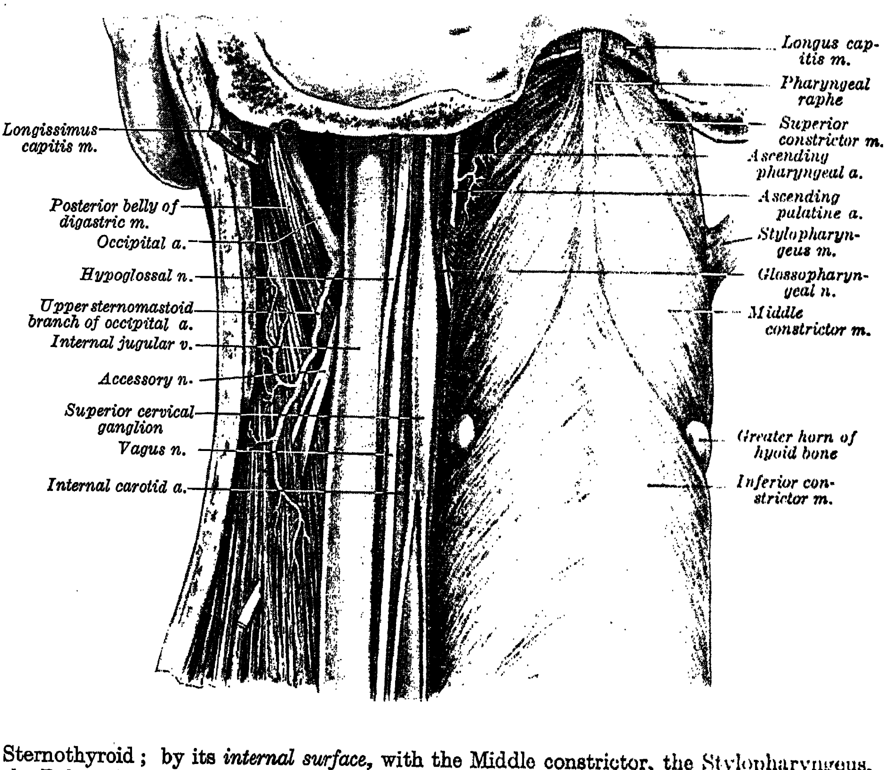
thyroid in front, and the articular facet for the inferior horn of the thyroid cartilage behind (*Cricopharyngeus*). It also arises from the oblique line of the lamina of the thyroid cartilage, from a strip of the surface of the lamina behind this line, from a fine tendinous band, which is thrown across the cricothyroid

* The Palatopharyngeus is described with the muscles of the palate (p. 1265).

muscle from the inferior thyroid tubercle to the cricoid cartilage (fig. 1094), and, by a small slip, from the inferior horn (*Thyreopharyngeus*). The fibres spread backwards and medially, and are inserted with the muscle of the opposite side into a fibrous raphe in the posterior median line of the pharynx. The inferior fibres, which are horizontal, are continuous with the circular fibres of the œsophagus and surround the narrowest part of the pharynx; the rest ascend obliquely, and overlap the Middle constrictor.

Relations.—The Inferior constrictor is covered with the buccopharyngeal fascia, which surrounds the entire pharynx. *Behind*, the muscle is in relation with the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the

FIG. 1151.—The pharynx, exposed from behind.



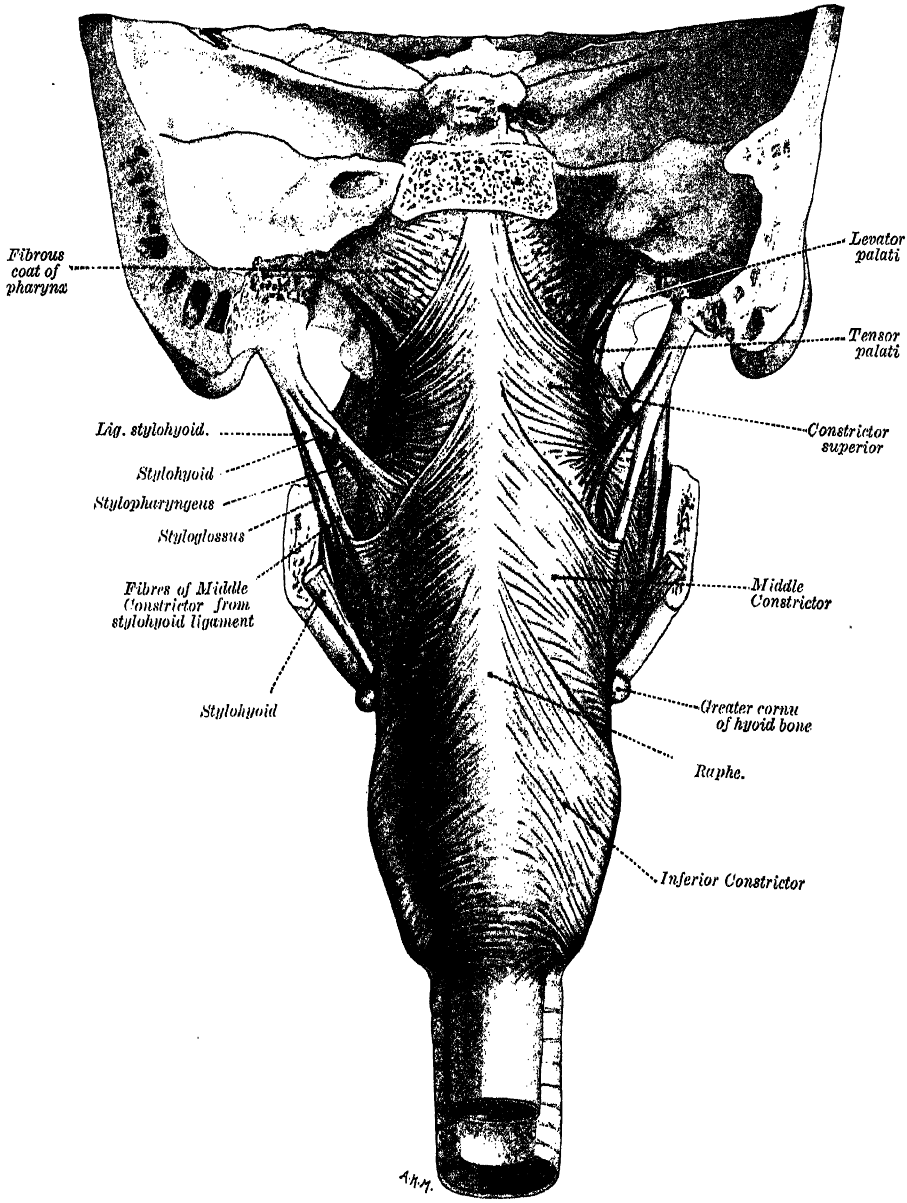
Sternothyroid; by its *internal surface*, with the Middle constrictor, the Stylopharyngeus, the Palatopharyngeus and the pharyngeal aponeurosis. The internal laryngeal nerve and the laryngeal branch of the superior thyroid artery run near the upper border, and the recurrent laryngeal nerve and the laryngeal branch of the inferior thyroid artery ascend deep to its lower border, before they enter the larynx.

The **Constrictor pharyngis medius** is a fan-shaped muscle which arises from the lesser horn and from the whole length of the upper border of the greater horn of the hyoid bone, and from the lower part of the stylohyoid ligament. The lower fibres descend deep to the Inferior constrictor, as far as the inferior end of the pharynx, the middle fibres pass transversely, and the upper fibres ascend and overlap the Superior constrictor. It is inserted, with the muscle of the opposite side, into the posterior median fibrous raphe.

Relations.—The Middle constrictor is separated from the Superior constrictor by a small interval, through which pass the glossopharyngeal nerve and the Stylopharyngeus muscle; and from the Inferior constrictor by the internal laryngeal nerve and laryngeal branch of the superior thyroid artery. *Behind*, it is related to the prevertebral fascia, the Longus cervicis and the Longus capitis. *Laterally*, it is in relation with the carotid vessels, the pharyngeal plexus of nerves and some lymph glands. Near its origin it is covered with the Hyoglossus, from which it is separated by the lingual vessels. Its *internal surface* lies upon the Superior constrictor, the Stylopharyngeus, the Palatopharyngeus and the pharyngeal aponeurosis.

The **Constrictor pharyngis superior** is a quadrilateral muscle, thinner and paler than the other two. It arises from the pterygoid hamulus, and sometimes from the adjoining part of the posterior margin of the medial pterygoid plate, from the pterygomandibular ligament, from the posterior end of the mylohyoid line on the inner surface of the mandible, and by a few fibres from the side of

FIG. 1152.—The muscles of the pharynx; posterior view. (From Quain's *Anatomy*, XI. Ed.)



the tongue (fig. 1150). The fibres curve backwards to be inserted into the median raphe, being also prolonged by means of an aponeurosis to the pharyngeal tubercle on the basilar part of the occipital bone. The superior fibres arch beneath the Levator palati and the pharyngotympanic (auditory) tube. An interval exists between the upper border of the muscle and the base of the skull to give passage to the pharyngotympanic (auditory tube). It is bounded in front by the medial pterygoid plate and is closed by the pharyngobasilar fascia (p. 1294).

A constant band of muscle fibres arises from the anterior and lateral part

of the palatine aponeurosis and sweeps backwards, lateral to the Levator palati, to blend with the inner surface of the Superior constrictor muscle near its upper border. Whillis * has termed this band the *Palatopharyngeal sphincter* and has pointed out that, when the soft palate is raised, it produces a rounded ridge on the pharyngeal wall. These fibres are much hypertrophied in cases of complete cleft palate.

Relations.—The Superior constrictor muscle is in relation by its *external surface* with the prevertebral fascia and muscles, the ascending pharyngeal artery and pharyngeal venous plexus, the glossopharyngeal and lingual nerves, the Styloglossus, Constrictor pharyngis medius and Pterygoideus medialis, the stylohyoid ligament and the Stylopharyngeus. The internal carotid artery, the sympathetic trunk, the hypoglossal nerve, the internal jugular vein and the styloid process are more distant relations. By its *internal surface* it is in relation with the Palatopharyngeus, the capsule of the tonsil, and the pharyngeal aponeurosis. Its *upper border* is separated from the base of the skull by a crescentic interval in which the Levator palati, the Tensor palati and the pharyngotympanic tube are situated. Its lower border is separated from the Middle constrictor by the Stylopharyngeus. *In front* it is separated from the Buccinator by the pterygomandibular ligament.

Nerve-supply.—The Constrictors of the pharynx are supplied by the pharyngeal plexus (p. 1069). In addition the Inferior constrictor receives branches from the external and recurrent laryngeal nerves.

The **Stylopharyngeus** (figs. 1146, 1151) is a long, slender muscle which is cylindrical above and flattened below. It arises from the medial side of the base of the styloid process of the temporal bone, descends along the side of the pharynx, passes between the Superior and the Middle constrictors, and spreads out beneath the mucous membrane. Some of its fibres are lost in the constrictor muscles and in the pharyngo-epiglottic fold, while others are inserted with the Palatopharyngeus into the posterior border of the thyroid cartilage. The glossopharyngeal nerve winds round the lateral side of the Stylopharyngeus muscle and passes through the interval between the Superior and the Middle constrictors to reach the tongue.

Nerve-supply.—The Stylopharyngeus is supplied by a branch from the glossopharyngeal nerve.

The **Salpingopharyngeus** (fig. 1118) arises from the inferior part of the cartilage of the pharyngotympanic (auditory) tube near its pharyngeal opening; it passes downwards and blends with the Palatopharyngeus.

Nerve-supply.—The Salpingopharyngeus is supplied by the pharyngeal plexus.

Actions.—The Salpingopharyngeus raises the upper part of the lateral wall of the pharynx, i.e. the part above the attachment of the Stylopharyngeus.

MOVEMENTS OF THE SOFT PALATE

The movements of the soft palate play an important part in deglutition, in speech and in the act of blowing, and involve a greater or lesser degree of closure of the pharyngeal isthmus, necessitated by these acts. The closure is maximal in blowing out through the mouth, when it is essential to prevent entirely the escape of air through the nose. In deglutition closure of the pharyngeal isthmus prevents the food from passing into the nasal part of the pharynx, whilst in speech the closure is maximal in the production of the explosive consonants.

Closure of the isthmus is brought about in the following way. The two Levatores palati pull the soft palate upwards and backwards towards the posterior pharyngeal wall. Coincident with this movement the fibres of the Palatopharyngeal sphincter raise a rounded ridge on the posterior pharyngeal wall, which meets the nasal surface of the soft palate over a considerable area, and it is at the upper limit of this area of contact that the mucous membrane on the upper surface of the palate changes from the respiratory to the pharyngeal type.

The Tensor palati is active in deglutition rather than in speech, and by producing a localised depression of the palate (p. 1265) squeezes the bolus against the tongue and so helps to project it through the oral pharynx.

* J. Whillis, *Journal of Anatomy*, vol. lxv., 1930.

The Mechanism of Deglutition

The first stage of the act of swallowing, or deglutition, is voluntary in character. The anterior part of the tongue is raised and pressed against the hard palate, the movement commencing at the tip of the tongue and spreading backwards rapidly. By this mechanism a bolus placed on the tongue behind the tip passes backwards to the posterior part of the mouth. The movements of the tongue are effected by the intrinsic muscles, especially the Longitudinales superiores and the Transversi linguæ. At the same time the hyoid bone moves forwards and upwards a little and becomes fixed owing to contraction of the Geniohyoid, Mylohyoid, Digastric and Stylohyoid muscles. By elevation of the posterior part of the tongue, which is drawn upwards and backwards by the Styloglossi, and by the approximation of the palatoglossal arches, caused by the contraction of the Palatoglossi, the bolus is now passed through the oropharyngeal isthmus into the oral part of the pharynx and the second, or involuntary, stage of the act of swallowing begins.

In the second stage, the soft palate is elevated (by the Levator muscles) and tightened (by the Tensor muscles). In addition it is closely and firmly approximated to the posterior pharyngeal wall by the contraction of the Palatopharyngeal sphincter (p. 1298) and the upper fibres of the Superior constrictor muscle. The pharyngeal isthmus is tightly closed and the bolus is prevented from passing upwards. At the same time the larynx is drawn upwards behind the hyoid bone and the pharynx ascends with it. This upward displacement is brought about by the Stylopharyngeus, Thyrohyoid and Palatopharyngeus muscles. Simultaneously the aryepiglottic folds are approximated and the arytenoid cartilages are drawn upwards and forwards by the contraction of the Aryepiglottic, Oblique arytenoid, Thyro-arytenoid and Thyroepiglottic muscles. Provision is thus made to prevent the bolus from entering the larynx. Partly under the influence of gravity—when the body is in the erect or sitting posture—and partly urged onwards by the successive contractions of the Superior and Middle constrictor muscles, the bolus slips over the posterior aspect of the epiglottis, the closed inlet of the larynx and the posterior surfaces of the arytenoid cartilages to gain the lowest part of the pharynx. During this stage its passage is facilitated by the action of the Palatopharyngei, which shorten the pharynx and pull it upwards. These two muscles, when contracting, convert the surface of the posterior pharyngeal wall into an inclined plane directed downwards and backwards and on its under surface the bolus descends.

The last stage in the act is effected by the Inferior constrictor muscle, which passes the bolus onwards into the œsophagus.

These stages follow one another in rapid succession, but it is not difficult for the student to satisfy himself, by palpation of the body of the hyoid bone and the laryngeal prominence during the act, that elevation and forward movement of the hyoid bone precede elevation of the larynx and that the amount of upward movement of the thyroid cartilage is considerable.

Applied Anatomy.—In young children the presence of adenoid growths in the nose and nasopharynx, with or without enlargement of the tonsils, produces a characteristic deformity of the face, the " adenoid facies," by obstructing respiration through the nose and making mouth-breathing more or less obligatory. As the child has to keep its mouth open in order to breathe, the bony palate and alveolar arch are habitually out of contact with the dorsum of the tongue ; lacking its pressure, they develop with an abnormally high arch and forward projection. Thus the hard palate becomes narrowed laterally, and the projecting alveolar processes afford insufficient room for the permanent teeth, which appear crowded, irregularly set, and overhang those in the lower jaw. The facial surfaces of the maxillæ become pinched together, with narrowing of the nasal fossæ and maxillary air-sinuses. The nose itself shows abnormality in shape of two chief types ; (1) The bridge remaining normal, the apex looks thin and pinched because the alæ fall inwards from disuse of the dilator muscles, and the nares become elongated, narrow, and barely capable of voluntary dilatation ; there is often a depression in the region of the lateral alar cartilage. (2) Less commonly the bones forming the bridge of the nose are pressed apart by the underlying adenoid growths, making it appear thicker and broader than normal ; the dilators of the nares atrophy from disuse, and the nares look unduly small and rounded. In all cases of adenoids the upper lip is drawn up, still further exposing the projecting

front upper teeth. The face is lengthened by dropping of the lower jaw; the whole expression of the child is highly characteristic, suggesting vacuity and inattention, the latter being due to the deafness so often associated with nasal obstruction and caused by blocking of the pharyngeal openings of the pharyngotympanic tubes.

The Œsophagus (fig. 1153). (Pl. XIV.)

Fig. 1153.—The œsophagus.

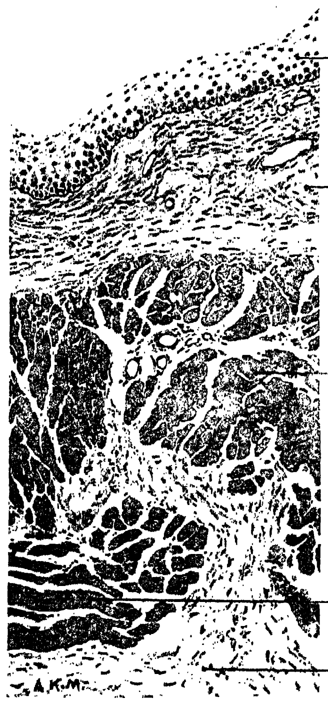
The œsophagus, or **gullet**, is a muscular canal, from 23 cm. to 25 cm. long, extending from the pharynx to the stomach. It begins in the neck at the lower border of the cricoid cartilage, opposite the sixth cervical vertebra, where it is continuous with the lower end of the pharynx. It descends along the front of the vertebral column, through the superior and posterior parts of the mediastinum, pierces the Diaphragm opposite the tenth thoracic vertebra, and ends at the cardiac orifice of the stomach at the level of the eleventh thoracic vertebra. The general direction of the œsophagus is vertical; but it presents two slight curves in its course. At its commencement it is placed in the median plane; but it inclines to the left side as far as the root of the neck, gradually passes again to the median plane, which it reaches at the level of the fifth thoracic vertebra, and again deviates to the left as it passes forwards to the œsophageal opening in the Diaphragm. The œsophagus presents also anteroposterior flexures corresponding to the curvatures of the cervical and thoracic portions of the vertebral column. It is the narrowest part of the digestive tube, and is constricted (*a*) at its commencement, (*b*) where it is crossed by the left bronchus, and (*c*) where it pierces the Diaphragm.

Relations.—The **cervical part** of the œsophagus (fig. 1098) is in relation, *in front*, with the trachea, and at the lower part of the neck, where it projects to the left side, with the left lobe of the thyroid gland; *behind*, it lies on the vertebral column and Longus cervicis muscles; *laterally*, it is in relation with the common carotid arteries (especially the left), and with parts of the lobes of the thyroid gland; the recurrent laryngeal nerves ascend, one on each side, in the groove between it and the trachea; the thoracic duct ascends for a short distance along its left edge.

The **thoracic part** of the œsophagus (figs. 1098-99, 1106-07, 1110, 1153) is at first situated in the superior mediastinum between the trachea and the

vertebral column, a little to the left of the median plane. It passes behind and to the right of the aortic arch and descends in the posterior mediastinum along the right side of the descending thoracic aorta. Below, as it inclines to the left, it crosses in front of the aorta, and enters the abdomen through the Diaphragm at the level of the tenth thoracic vertebra. It is in relation, *in front*, with the trachea, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longus cervicis muscles, the right posterior (aortic) intercostal arteries, the thoracic duct, the azygos vein and the terminal parts of the hemiazygos veins; and below, near the Diaphragm, upon the front of the aorta. In the posterior mediastinum an elongated recess of the right pleural sac intervenes between the œsophagus and the vena azygos and vertebral column. On its *left* side, in the superior mediastinum the terminal part of the aortic arch, the left subclavian artery, the thoracic duct, and left pleura are immediate relations, while the left recurrent laryngeal nerve runs upwards in the groove between it and the trachea; in the posterior mediastinum it is in relation with the descending thoracic aorta and the left pleura. On its *right* side it is related to the right pleura, the azygos vein intervening as it arches forwards above the right bronchus to join the superior vena cava. Below the roots of the lungs the vagus nerves descend in close contact with it, the right nerve chiefly behind, and the left chiefly in front of it; the two nerves unite to form a plexus around the tube (p. 1071).

Fig. 1154.—Longitudinal section through the upper part of the œsophagus.



In the lower part of the posterior mediastinum the thoracic duct lies behind and to the right of the œsophagus; higher up, it is placed behind it, and crossing to the left about the level of the fourth thoracic vertebra, is continued upwards on its left side.

The abdominal part of the œsophagus lies in the œsophageal groove on the posterior surface of the left lobe of the liver. It measures about 1·25 cm. in length, and is covered with peritoneum in front and on its left side. It is conical in shape, and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach (fig. 1153).

Structure (fig. 1154).—The œsophagus has four coats: an external or fibrous, a muscular, a submucous or areolar, and an internal or mucous.

The *fibrous coat* consists of a layer of areolar tissue, containing many elastic fibres.

The *muscular coat* is composed of two layers of considerable thickness: an external of longitudinal and an internal of circular fibres.

The *longitudinal fibres* form a complete investment for nearly the whole of the œsophagus, but at the upper part of the back of the tube, at a point between 3 cm. and 4 cm. below the cricoid cartilage, they diverge from the median plane and form two longitudinal fasciculi which incline upwards and forwards to the front of the tube. Here they pass deep to the lower border of the Constrictor pharyngis inferior and end in a tendon which is attached to the upper part of the ridge on the posterior surface of the lamina of the cricoid cartilage (fig. 1095). The V-shaped interval between the diverging longitudinal fasciculi is filled by the circular fibres of the œsophagus, thinly covered below by some decussating longitudinal fibres, and above by the overlapping lower edge of the Constrictor pharyngis inferior.

Accessory slips of muscular fibres sometimes pass between the œsophagus and the left pleura, or between the œsophagus and the root of the left bronchus.

The *circular fibres* are continuous superiorly, on the posterior surface, with the Constrictor pharyngis inferior; anteriorly, the uppermost are inserted into the lateral margins of the tendon of the two longitudinal fasciculi.*

The muscular fibres in the upper part of the œsophagus are of a red colour, and consist chiefly of the striped variety; but in the lower part they consist for the most part of involuntary fibres.

The *areolar* or *submucous coat* connects loosely the mucous and muscular coats. It contains the larger blood-vessels and nerves, as well as mucous glands.

The *mucous coat* is thick, of a reddish colour above, and pale below. It is disposed in longitudinal folds (Pl. XIV), which disappear on distension of the tube. It consists of (1) a layer of stratified squamous epithelium, lining the tube, (2) a layer of connective tissue, papillæ from which project into the epithelium, and (3) the muscularis mucosæ, a layer of longitudinally arranged non-striped muscular fibres. At the commencement of the œsophagus the muscularis mucosæ is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are small, compound racemose glands of the mucous type; they are lodged in the submucous tissue, and each opens into the tube by a long duct.

Vessels and Nerves.—The *arteries* supplying the œsophagus are derived from the inferior thyroid branch of the thyrocervical trunk, from the descending thoracic aorta, from the left gastric branch of the cœliac artery, and from the left (inferior) phrenic branch of the abdominal aorta. They have for the most part a longitudinal direction. The *veins* from the lower end of the œsophagus open into the left gastric vein, which is a tributary of the portal vein; those from the upper part join the azygos or the hemiazygos veins. The *lymph vessels* are described on p. 879.

The *nerves* are derived from the vagus nerves and from the sympathetic trunks; they form a plexus containing groups of ganglion-cells between the two layers of the muscular coat, and a second plexus in the submucous tissue.

Applied Anatomy.—The œsophagus may be obstructed by foreign bodies, and also by changes in its coats producing stricture, or by pressure on it from without by new growths or aneurysm, etc.

The mucous membrane of the œsophagus may become herniated through the muscular coat, giving rise to an œsophageal diverticulum. This condition occurs most frequently on the posterior surface of the beginning of the tube, where the wall is weakened by the absence of longitudinal muscle fibres (*vide supra*).

THE ABDOMEN

The **abdomen** is the largest cavity in the body. The roof of the cavity is formed by the Diaphragm, which extends as a dome over the abdomen, so that the cavity ascends into the bony thorax, reaching on the right side, in the mammary line, to the upper border of the fifth rib; on the left side it falls below this level by about 2·5 cm. The floor is formed by the muscles and fasciæ of the pelvic diaphragm (pp. 573 to 576).

In order to facilitate description the abdomen is artificially divided into two parts: an upper, larger part, the *abdomen proper*; and a lower, smaller part, the *pelvis*. These two parts are continuous with each other through the inlet of the true (lesser) pelvis.

The **abdomen proper** differs from the other cavities of the body in being bounded for the most part by muscles and fasciæ, so that its capacity and shape can vary according to the conditions of the viscera which it contains.

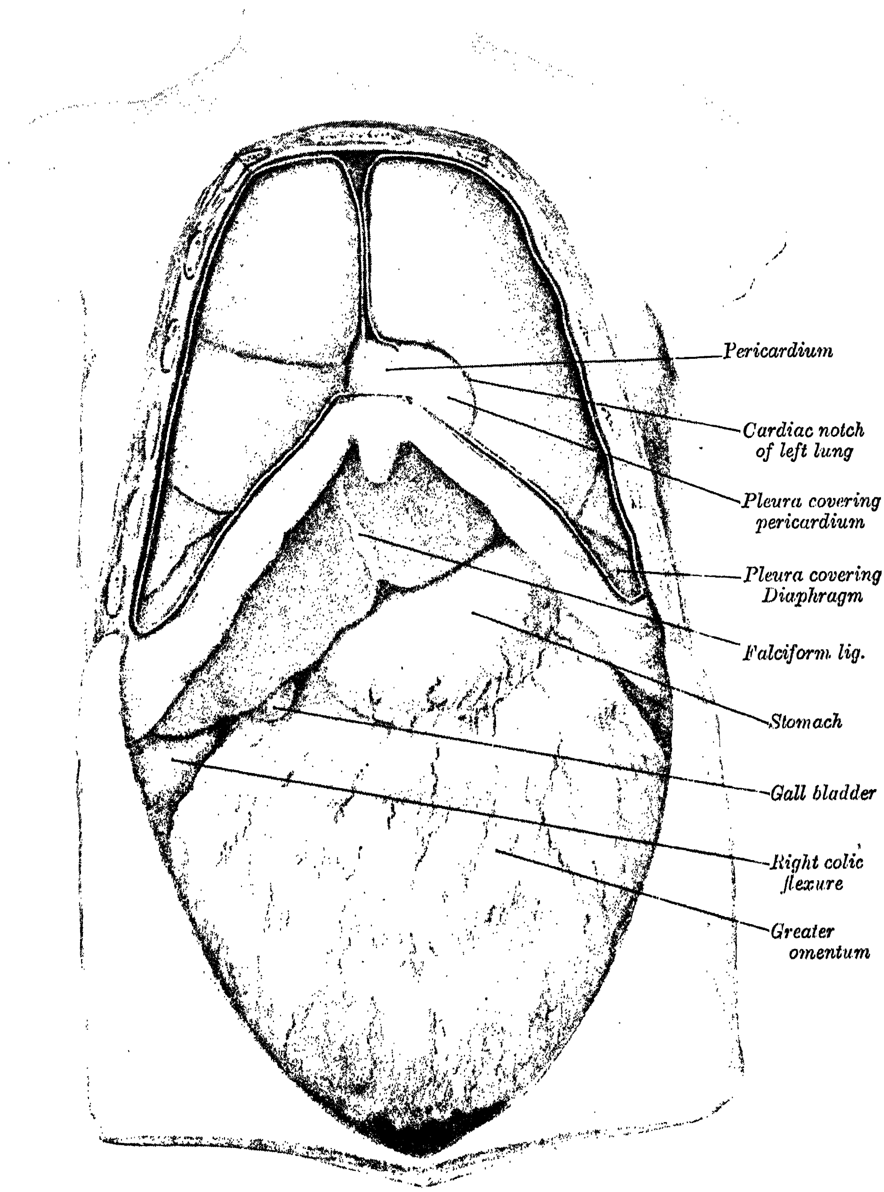
It is bounded *in front* and *at the sides* by the abdominal and Iliacus muscles, and the iliac bones; *behind*, by the lumbar part of the vertebral column and by the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the plane of the inlet of the true pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surfaces by a layer of fascia.

The abdomen contains the greater part of the digestive tube; it also contains the liver, pancreas, spleen, kidneys and suprarenal glands. Most of these structures, as well as the wall of the cavity in which they are contained, are more or less covered by an extensive and complicated serous membrane, termed the *peritoneum*.

* Williamina Abel, *Journal of Anatomy and Physiology*, vol. xlvii.

Regions.—For convenience of description of the viscera the abdomen is divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines drawn on the surface of the body (fig. 1156). The upper horizontal plane, or *transpyloric plane* (of Addison), is indicated by a line encircling the body at a

FIG. 1155.—A front view of the thoracic and abdominal viscera.

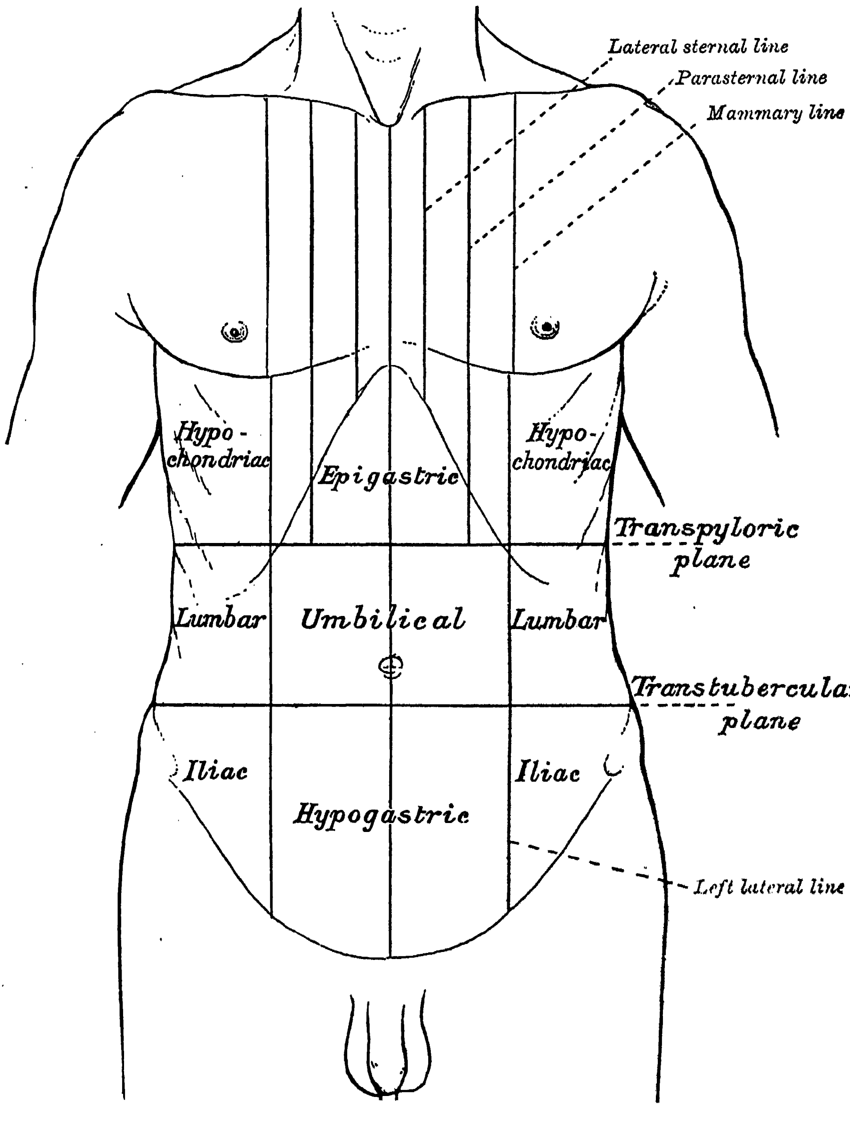


level midway between the suprasternal (jugular) notch and the symphysis pubis ; it cuts the front of the body of the first lumbar vertebra near its lower border. The lower horizontal plane is indicated by a line carried round the trunk at the level of the tubercle on the iliac crest (p. 368) and is termed the *transtubercular plane* ; it cuts the front of the body of the fifth lumbar vertebra near its upper border. By means of these planes the abdomen is cut into three zones ; each of these is further subdivided into three regions by the *right* and *left lateral planes*, which are indicated on the surface by lines drawn vertically

through points halfway between the anterior superior iliac spines and the symphysis pubis.*

The median region of the upper zone is the *epigastric*, and the lateral regions, the *right* and *left hypochondriac*. The median region of the middle zone is the *umbilical*, and the lateral regions are the *right* and *left lumbar*. The median

Fig. 1156.—The surface lines on the front of the thorax and abdomen.



region of the lower zone is the *hypogastric*, and the lateral regions are the *right* and *left iliac* or *inguinal* (fig. 1156).

A third horizontal plane is frequently utilised in describing the topography of the abdominal viscera. It is drawn through the body on a level with the most dependent parts of the tenth costal cartilages and is termed the *subcostal plane*. It cuts the front of the body of the third lumbar vertebra near its upper border. It is frequently utilised instead of the transpyloric plane for the purpose of dividing the abdomen into the regions named above.

The pelvis is that portion of the abdominal cavity which lies below and behind a plane passing through the promontory of the sacrum, the arcuate

* D. J. Cunningham, *Journal of Anatomy and Physiology*, vols. xxxiii., xxxiv., xxxv.

lines of the hip-bones, and the pubic crest; it contains the urinary bladder, the pelvic colon, the rectum, a few coils of the small intestine, and some of the generative organs.

When the anterior abdominal wall is removed (fig. 1155), the viscera are partly exposed as follows: above and to the right side the liver is visible, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the median plane, and reaching for some distance below the level of the xiphoid process. The stomach is exposed in the angle between the left costal margin and the lower border of the liver. From its lower border an apron-like fold of peritoneum, termed the *greater omentum*, descends for a varying distance, and obscures the other viscera to a greater or lesser extent. Below the greater omentum, however, some of the coils of the small intestine can generally be seen, while in the right iliac region the cæcum, and in the left iliac region the lower portion of the descending colon, are partly exposed. The urinary bladder occupies the anterior part of the pelvis, and, if distended, projects above the symphysis pubis; the rectum is placed in the concavity of the sacrum, but is usually hidden by coils of the small intestine. The pelvic colon may lie between the rectum and the bladder.

When the stomach is followed from left to right it is seen to be continuous with the first part of the small intestine [duodenum], the point of continuity being marked by a thickened ring, which indicates the position of the pyloric sphincter. The duodenum passes towards the under surface of the liver, and then, curving downwards, is lost to sight. If, however, the greater omentum and transverse colon be thrown upwards over the chest, the inferior part of the duodenum can be traced across the vertebral column towards the left side, where it becomes continuous with the coils of the jejunum and ileum. These measure about six metres in length, and if followed downwards the ileum is seen to end in the right iliac fossa by opening into the cæcum, which is the commencement of the large intestine. From the cæcum the large intestine takes an arched course, passing at first upwards on the right side, then across the median plane, and then downwards on the left side, forming respectively the ascending, transverse, and descending parts of the colon. In the pelvis it assumes the form of a loop, termed the pelvic colon, and ends in the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be exposed in part by pulling the stomach over towards the right side.

The glistening appearance of the deep surface of the abdominal wall and of the surfaces of the exposed viscera is due to the fact that the former is lined, and the latter are more or less completely covered, with a serous membrane, termed the *peritoneum*.

The Peritoneum

The **peritoneum** is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which lines the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the free ends of the uterine tubes open into the peritoneal cavity. The portion which lines the parietes is named the *parietal* portion of the peritoneum; that which is reflected over the contained viscera constitutes the *visceral* portion of the peritoneum. The *free surface* of the membrane is smooth, covered with a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide on the wall of the cavity or on one another with the least possible amount of friction. The *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue, termed the *extraperitoneal tissue*. The parietal portion is loosely connected with the fascial lining of the abdomen and pelvis, but is more closely adherent to the under surface of the Diaphragm and to the linea alba.

The parietal and visceral layers of the peritoneum are in actual contact, but the potential space between them is named the *peritoneal cavity*. The peritoneal cavity consists of (1) a main portion, termed the *greater sac*, and (2) a large diverticulum, termed the *lesser sac* (omental bursa), which is situated behind the stomach and adjoining structures; the neck or communication

between the greater sac and the lesser sac is termed the *aditus of the lesser sac* (epiploic foramen).

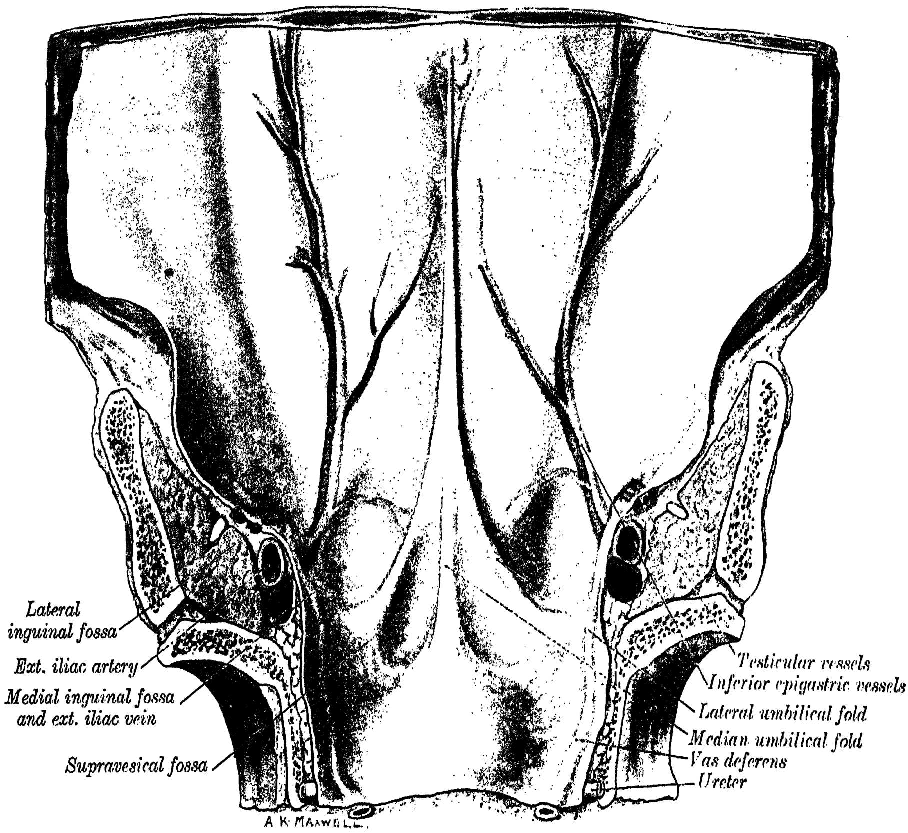
The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement, and one that can only be clearly understood by following the development of the digestive tube (pp. 168-177).

To trace the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its continuity in the vertical and horizontal directions, and it is simpler to describe the greater sac and the lesser sac separately.

Vertical disposition of the greater sac (fig. 1160).—It is convenient to trace this from the back of the anterior abdominal wall at the level of the umbilicus. On following the peritoneum upwards from this level it is seen to be reflected around a fibrous cord, termed the *ligamentum teres*, or *obliterated umbilical vein*, which reaches from the umbilicus to the under surface of the liver. This reflection forms a somewhat triangular fold, which is known as the *falciform ligament of the liver*, and attaches the upper and anterior surfaces of the liver to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the whole of the under surface of the anterior part of the Diaphragm, and is reflected from it on to the upper surface of the right lobe of the liver as the *superior layer of the coronary ligament*, and on to the upper surface of the left lobe as the *superior layer of the left triangular ligament* of the liver. From the upper and anterior surfaces of the liver, it is continued round the sharp margin of the liver to the under surface, where it has the following relations : (*a*) *To the right of the gall-bladder.* It covers the inferior surface of the right lobe and is reflected from the posterior part of this lobe to the right suprarenal gland and the upper end of the right kidney, forming the *inferior layer of the coronary ligament* ; a special fold, termed the *hepatorenal ligament*, is frequently present between the inferior surface of the liver and the front of the right kidney. From the right kidney it is carried downwards to the duodenum and right colic flexure (fig. 1161), and medially in front of a short segment of the inferior vena cava, where it is continuous with the posterior wall of the lesser sac (fig. 1161). Between the two layers of the coronary ligament there is a large, triangular, surface on the back of the liver devoid of peritoneal covering : this is sometimes named the *bare area* of the liver, and is attached to the Diaphragm by areolar tissue. Towards the right margin of the liver the two layers of the coronary ligament gradually approach each other, and ultimately fuse to form a small triangular fold connecting the right lobe of the liver to the Diaphragm, and named the *right triangular ligament* of the liver (fig. 1202). The apex of the bare area corresponds with the point of meeting of the two layers of the coronary ligament, its base with the groove for the inferior vena cava. (*b*) *To the left of the gall-bladder.* It covers the lower surface of the quadrate lobe of the liver, the under and lateral surfaces of the gall-bladder, and the under surface and posterior border of the left lobe of the liver ; it is then reflected from the upper surface of the left lobe to the Diaphragm as the *inferior layer of the left triangular ligament.* The line of reflection next passes down in the deepest part of the fissure for the ligamentum venosum (figs. 1160 and 1203), and curves to the right along the anterior margin of the porta hepatis. At the right extremity of the latter it becomes continuous with the peritoneum of the lesser sac and will be considered later. From this ⅃-shaped line the peritoneum passes to the lesser curvature of the stomach and the first 2 cm., or less, of the duodenum as the anterior layer of the *hepatogastric* and *hepatoduodenal ligaments*, which together constitute the *lesser omentum.* If this layer of the lesser omentum be followed to the right it will be found to turn round the hepatic artery, bile-duct, and portal vein, and become continuous with the anterior wall of the lesser sac, forming a free folded edge of peritoneum. Traced downwards, the anterior layer of the lesser omentum covers the anterosuperior surface of the stomach and the commencement of the duodenum, and is carried down beyond them into a large free fold, known as the *greater omentum.* Reaching the lower free margin of this fold, it is reflected upwards to cover the under and posterior surfaces of the transverse colon, and thence to the posterior abdominal wall as the inferior

layer of the *transverse mesocolon*. It reaches the abdominal wall at the head and anterior border of the pancreas (fig. 1160), is then carried down over the lower part of the head and over the inferior surface of the pancreas on the superior mesenteric vessels, and thence to the small intestine as the anterior layer of the *mesentery*. It encircles the intestine, and subsequently may be traced, as the posterior layer of the mesentery, upwards and backwards to the abdominal wall. From this it sweeps down over the aorta into the pelvis, where it invests the pelvic colon, and attaches it to the pelvic wall by a fold named the *pelvic mesocolon*. Leaving first the sides and then the front of the rectum, it is reflected

FIG. 1157.—The lower part of the anterior abdominal wall of a male subject. Posterior surface. The peritoneum is in place.



on to the upper ends of the seminal vesicles and the fundus of the urinary bladder, and after covering the upper surface of that viscus, is carried along the median and lateral umbilical ligaments (fig. 1157) on to the back of the abdominal wall to the level from which a start was made.

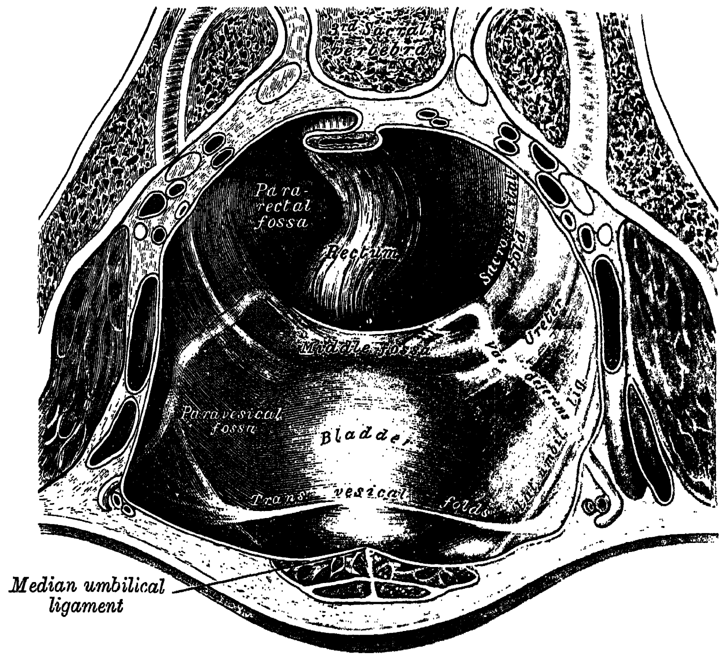
Between the rectum and the bladder it forms, in the male, a pouch, termed the *rectovesical pouch*, the bottom of which is slightly below the level of the upper ends of the seminal vesicles, and about 7·5 cm. from the orifice of the anus. When the bladder is distended, the peritoneum is carried up with it so that a considerable part of the anterior surface of the bladder lies directly against the abdominal wall without the intervention of peritoneal membrane (p. 1372). In the female, the peritoneum is reflected from the rectum over the posterior vaginal fornix to the cervix and body of the uterus, forming the *recto-uterine pouch*. It is continued over the intestinal surface and fundus of the uterus on to its vesical surface, which it covers as far as the junction of the body and neck of the uterus, and then to the bladder, forming here a second, but shallower, pouch, termed the *utero-vesical pouch*. It is also reflected from the side of the uterus to the lateral wall of the pelvis, on each side, as an expanded fold, termed

the *broad ligament of the uterus*, which contains the uterine tube in its free margin.

Horizontal disposition of the greater sac.—Below the transverse colon the arrangement is simple, and it may be considered in the two regions, viz. in the pelvis and in the abdomen proper.

(1) *In the pelvis.*—The peritoneum here follows closely the surfaces of the pelvic viscera and the inequalities of the pelvic walls, and presents important differences in the two sexes. (*a*) *In the male* (fig. 1158) it encircles the pelvic colon, from which it is reflected to the posterior wall of the pelvis as a fold, termed the *pelvic mesocolon*. It leaves the sides and, finally, the front of the rectum, and is continued over the upper parts of the seminal vesicles to the upper surface of the bladder ; on each side of the rectum it forms a *pararectal*

Fig. 1158.—The peritoneum of the male pelvis. (Dixon and Birmingham.)



fossa, which varies in size with the distension of the rectum. In front of the rectum the peritoneum forms the rectovesical pouch, which is limited laterally by peritoneal folds extending from the sides of the bladder to the rectum and sacrum. These folds are known, from their position, as the *sacrogenital folds*. The peritoneum of the anterior pelvic wall covers the superior surface of the bladder, and on each side of this viscus forms a depression, termed the *paravesical fossa*, which is limited laterally by the fold of peritoneum covering the vas deferens. The size of this fossa is dependent on the state of distension of the bladder, and when the bladder is empty, a variable fold of peritoneum, termed the *plica vesicalis transversa*, divides the fossa into two portions. On the peritoneum between the paravesical and pararectal fossæ the only elevations are those produced by the ureters and the internal iliac (hypogastric) vessels. (*b*) *In the female*, pararectal and paravesical fossæ similar to those in the male are present ; the lateral limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical pouch is, however, divided by the uterus and vagina into a small, anterior utero-vesical and a deep, posterior, recto-uterine pouch (fig. 1245). The sacrogenital folds form the margins of the latter, and are continued on to the back of the uterus and the posterior fornix of the vagina as a transverse fold. The *broad ligaments* extend from the sides of the uterus to the lateral walls of the pelvis ; the uterine tubes are contained in their free margins, and the ovaries are attached to their

posterior layers. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. In the angle between the elevations produced by the obliterated umbilical artery and the ureter on the lateral pelvic wall, there is a shallow fossa, known as the *ovarian fossa,* in which the ovary lies in the nulliparous female. It is situated behind the lateral attachment of the broad ligament.

(2) *In the lower abdomen.*—The peritoneum lining the lower part of the anterior abdominal wall is raised into five ridges or folds which converge as they pass upwards. One of these is placed in the median plane and extends from the apex of the urinary bladder to the umbilicus. It contains the urachus (p. 194) and is termed the *median umbilical fold.* To the lateral side the obliterated umbilical artery forms the *lateral umbilical fold,* as it ascends from the pelvis towards the umbilicus. The depression between the two umbilical folds is termed the *supravesical fossa.* Further to the lateral side, the inferior epigastric artery raises a fold below the point at which it enters the sheath of the Rectus muscle. The *medial inguinal fossa* is the depression situated between the epigastric and the lateral umbilical folds ; the *lateral inguinal fossa,* which overlies the deep inguinal ring, lies to the lateral side of the epigastric fold. A fourth depression is placed below and slightly medial to the lateral inguinal fossa and is separated from it by the medial end of the inguinal ligament. It overlies the femoral ring (p. 785) and is termed the *femoral fossa.*

Traced from the linea alba, below the level of the transverse colon, and followed in a horizontal direction to the right, the peritoneum covers the inner surface of the abdominal wall almost as far as the lateral border of the Quadratus lumborum ; it encloses the cæcum and vermiform appendix, and is reflected over the sides and front of the ascending colon ; it may then be traced over the duodenum, Psoas major, and inferior vena cava towards the median plane, whence it passes along the mesenteric vessels to invest the small intestine, and back again to the large vessels in front of the vertebral column, forming the *mesentery* (figs. 1160 and 1161), the layers of which enclose the jejunum, ileum, the mesenteric blood-vessels, nerves, lacteals and lymph glands. It is then continued over the left Psoas major ; it covers the sides and front of the descending colon, and, reaching the abdominal wall, is carried on it to the median plane.

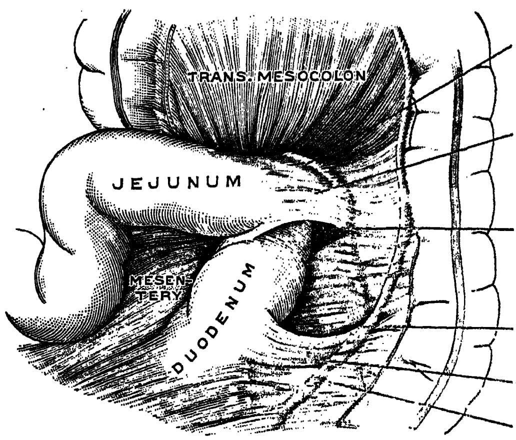
(3) *In the upper abdomen* (fig. 1162).—Above the transverse colon, the peritoneum on the posterior abdominal wall at the inferior vena cava may be followed to the right over the front of the right suprarenal gland and upper part of the right kidney to the anterolateral abdominal wall. From the anterior median line a double fold passes backwards and to the right, to become continuous with the peritoneum investing the liver, and forms the falciform ligament. Continuing to the left, the peritoneum lines the anterolateral abdominal wall and covers the lateral part of the front of the left kidney, and is reflected to the posterior border of the hilum of the spleen as the posterior or lateral layer of the *lienorenal ligament* (fig. 1162). It can be traced over the surfaces of the spleen to the front of the hilum, and thence to the cardiac end of the greater curvature of the stomach as the left layer of the *gastrosplenic ligament.* It covers the anterosuperior surface of the stomach and commencement of the duodenum, and ascends from the lesser curvature of the stomach to the liver as the anterior layer of the lesser omentum.

The lesser sac of peritoneum (omental bursa).—The *lesser sac* is a large recess of irregular outline which lies behind the stomach and extends beyond its limits. Its anterior and posterior walls are extensive and they are limited by variable lower, right, left and upper borders. The recess is completely shut off from the greater sac except in the upper part of its right border where a free communication is established through a slit-like opening. In its upper part the posterior wall of the lesser sac is formed by a single layer of peritoneum, closely applied to the posterior abdominal wall (fig. 1160), but below the pancreas, the sac is carried into the interior of the greater omentum and its posterior wall is formed by the posterior two layers of that structure and the transverse mesocolon (fig. 1160).

The *aditus to the lesser sac* (epiploic foramen) is a short, slit-like passage which leads out from the upper part of the right border of the lesser sac into

the greater sac. Its *anterior wall* is formed by the right margin of the lesser omentum, which contains between its two layers in this situation the bile-duct, the portal vein and the hepatic artery (fig. 1162). Traced upwards, the two layers separate and the posterior layer covers the caudate process, forming the *roof* of the aditus (fig. 1164), and then descends in front of the inferior vena cava, forming the *posterior wall* of the aditus. At, or a little below, the upper border of the first part of the duodenum, this layer passes forwards to become continuous with the posterior layer of the lesser omentum, and in this situation, it forms the *floor* of the aditus. The medial end of the floor * is continuous with the right border of the lower part of the sac (fig. 1161), and it is by passing forwards below the medial end of the floor that the hepatic artery is able to insinuate itself between the two layers of the lesser omentum. Traced laterally, i.e. to the right, all the boundaries of the aditus to the lesser sac become continuous with peritoneum of the greater sac. The roof is continuous with the peritoneal covering of the inferior surface of the right lobe of the liver (fig. 1203); the posterior wall with the peritoneum on the right suprarenal gland (fig. 1161); the anterior wall with the anterior layer of the lesser omentum round the bile-

Fig. 1159.—The superior and inferior duodenal recess. (After Jonnesco.) From Poirier and Charpy's *Traité d'Anatomie humaine*. (Masson et Cie.)



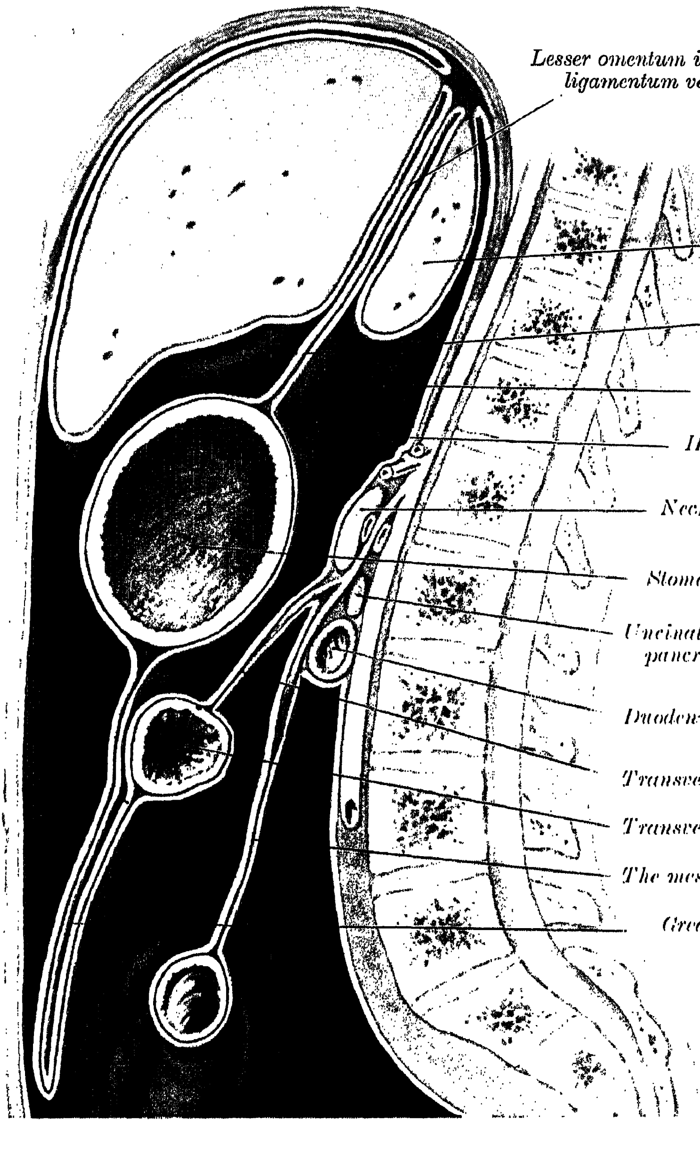
duct (fig. 1162); the floor with the peritoneum covering the lower part of the right suprarenal gland and the adjacent parts of the duodenum and right kidney.

The *lesser sac of peritoneum* (omental bursa) and its boundaries can now be considered in detail. The *anterior wall* is formed (1) by the peritoneum which covers the postero-inferior aspect of the stomach and the first 2 cm., or less, of the duodenum. Traced downwards this layer becomes the posterior of the anterior two layers of (2) the greater omentum; traced upwards and to the right, it leaves the stomach along the lesser curvature and the duodenum at its upper border, and becomes the posterior layer of (3) the lesser omentum. The lesser sac is usually described as passing upwards *behind* the caudate lobe of the liver, but this description is scarcely accurate, for the caudate lobe projects into the bursa from its right border and is covered by peritoneum on its anterior as well as on its posterior surface (fig. 1160).

The *posterior wall* is formed by the anterior of the posterior two layers of the greater omentum (when its constituent layers are not fused with one another), the peritoneum on the anterior aspect of the transverse colon, and the upper layer of the transverse mesocolon (fig. 1160). Above the inferior border of the pancreas, the posterior wall of the omental bursa lines the posterior abdominal wall, covering a small part of the front of the head, and the whole of the front of the neck and body of the pancreas, a small part of the anterior aspect of the left kidney and most of the anterior aspect of the left suprarenal gland, the

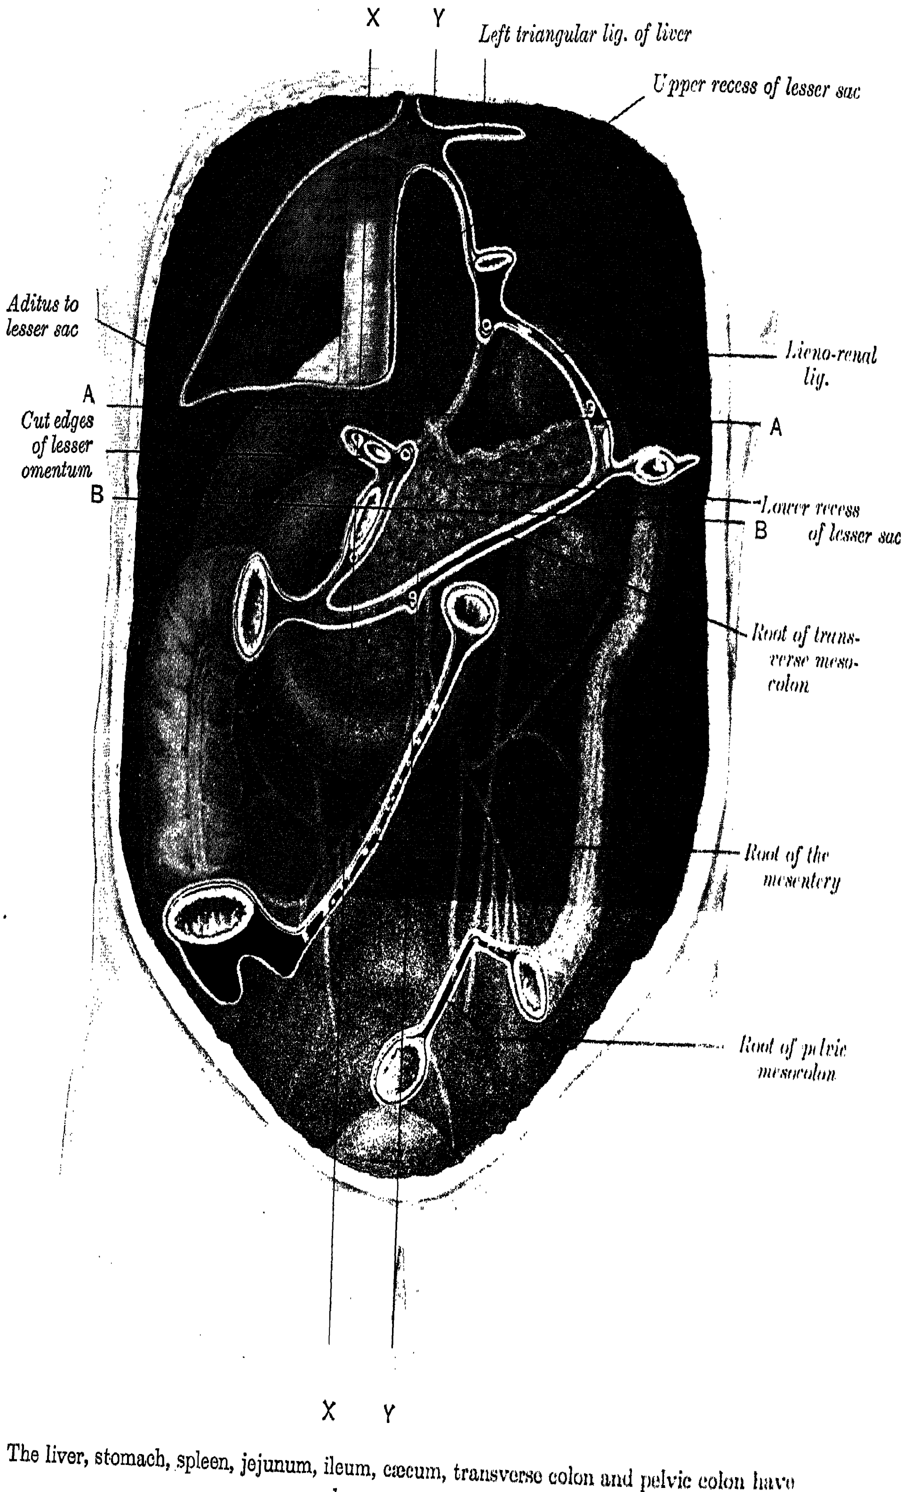
* In the B.N.A. the medial part of the aditus to the lesser sac is termed the *vestibule* of the omental bursa.

FIG. 1160.—A sagittal section through the abdomen, approximately in the median plane. Diagrammatic.



The section cuts the posterior abdominal wall along the line YY in Fig. 1161. The peritoneum is shown in *blue* except along cut edges, which are left *white*.

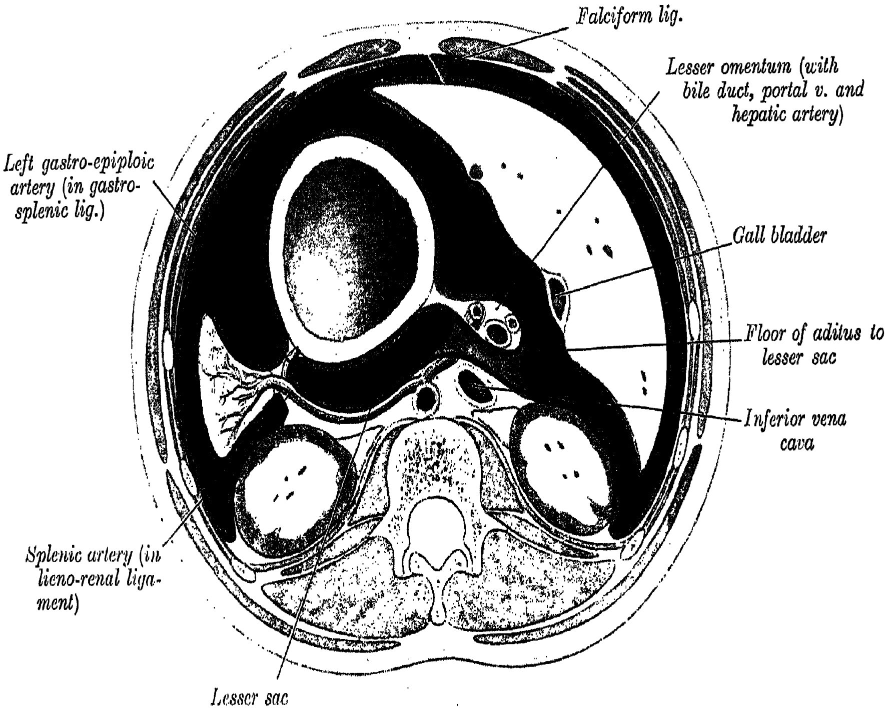
Fig. 1161.—The posterior abdominal wall, showing the lines of peritoneal reflexion.



The liver, stomach, spleen, jejunum, ileum, cæcum, transverse colon and pelvic colon have been removed.

Line YY represents the plane of Fig. 1160.
Line XX represents the plane of Fig. 1164.
Line AA represents the plane of Fig. 1162.
Line BB represents the plane of Fig. 1163.

Fig. 1162.—A transverse section through the abdomen, at the level of line AA, Fig. 1161, viewed from above. Diagrammatic.



The peritoneal cavity is shown in *dark blue*; the peritoneum and its cut edges in *lighter blue*.

Fig. 1163.—A transverse section through the abdomen, at the level of line BB in Fig. 1161, viewed from above. Diagrammatic. Colours as above.

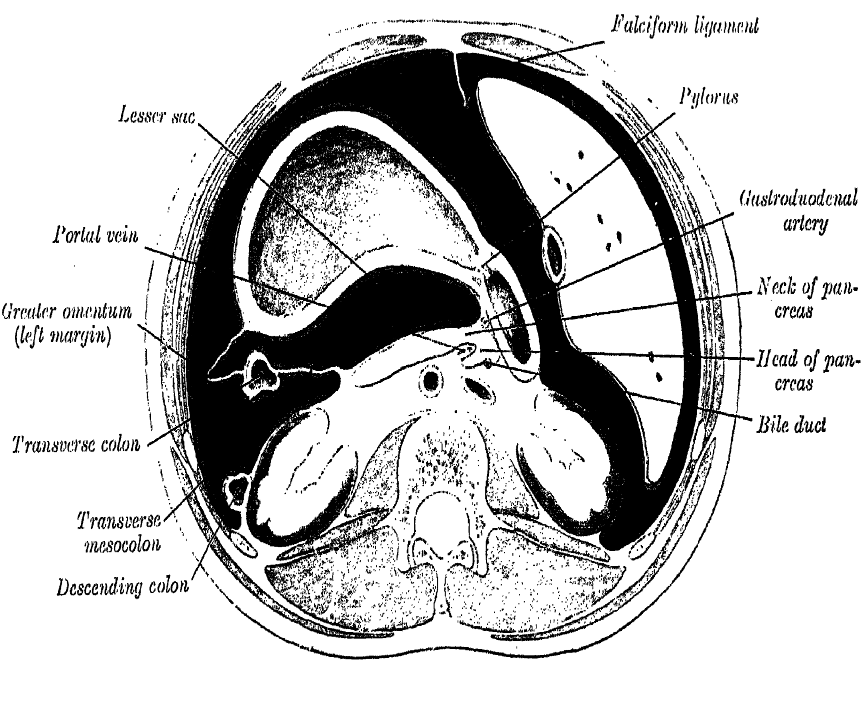


FIG. 1164.—A sagittal section through the upper part of the abdominal cavity, along the line XX in Fig. 1161.

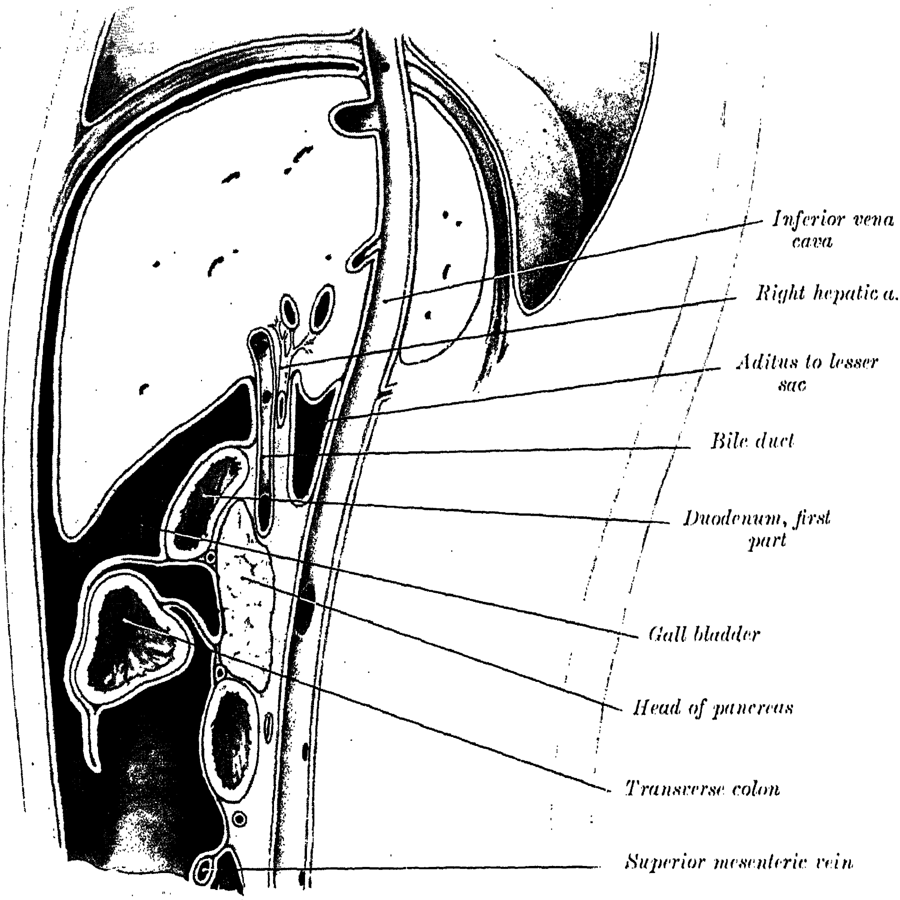


The boundaries of the aditus to the lesser sac are shown, and a small recess of the lesser sac is displayed in front of the head of the pancreas.

commencement of the abdominal aorta and the coeliac artery, and a considerable area of the Diaphragm. In addition, the (inferior) phrenic, the splenic, the left gastric and, to a much smaller extent, the hepatic arteries course behind the lesser sac (figs. 1161 and 1162).

The borders of the lesser sac of peritoneum are formed by the lines along which the peritoneal posterior wall is reflected to become continuous with the peritoneal anterior wall, and they are subject to considerable variation. The *lower border* is, developmentally (p. 177), the lower border of the greater omentum, but partial fusion of the constituent layers of this fold makes the border very irregular in the adult, and, as a rule, it does not extend much below the transverse colon. The *upper border* of the lesser sac is narrow and extends between the right side of the œsophagus and the upper end of the fissure for the ligamentum venosum of the liver. In this interval the peritoneal posterior wall of the sac is reflected forwards from the Diaphragm and becomes continuous with the posterior layer of the lesser omentum.

The *right border* of the lesser sac corresponds below to the right free border of the greater omentum. Above the upper end of the latter it is formed by the reflexion of the peritoneum from the neck and head of the pancreas on to the posterior surface of the duodenum (fig. 1163). The line of this reflexion passes upwards and to the left along the medial side of the gastroduodenal artery. Near the upper border of the duodenum the right border becomes continuous with the floor of the aditus to the lesser sac round the hepatic artery (fig. 1161). Above the opening, which interrupts its continuity, the right border is formed by the reflexion of the peritoneum from the Diaphragm to the right margin of the caudate lobe of the liver and it follows the left edge of the inferior vena cava (fig. 1161).

The *left border* of the lesser sac is formed, below, by the left free margin of the greater omentum. Above the root of the transverse mesocolon (fig. 1161) the left border is broader. It is formed by the *lienorenal* and the *gastrosplenic ligaments*, which together represent a part of the original dorsal mesogastrium (p. 168). The lienorenal ligament extends from the front of the left kidney to the hilum of the spleen as a two-layered fold, in which the splenic vessels and the tail of the pancreas (figs. 1161 and 1162) are enclosed. From the hilum of the spleen these two layers are continued forwards to the greater curvature of the stomach as the gastrosplenic ligament. There is no breach in the continuity of the inner layer (fig. 1162), but the continuity of the outer layer is interrupted by the spleen, which projects it into the greater sac. At their upper ends the lienorenal and the gastrosplenic ligaments merge into a short fold, termed the *gastrophrenic ligament*, which passes from the Diaphragm, behind, to the posterior aspect of the fundus of the stomach, in front. The two layers of this ligament diverge as they approach the œsophagus and a part of the posterior surface of the stomach is left devoid of peritoneal covering (fig. 1161). In this situation the upper end of the left border becomes continuous with the left extremity of the roof and the left gastric artery turns forwards to gain the lesser omentum.

The interior of the lesser sac is encroached on by two, more or less sickle-shaped, folds of peritoneum which are drawn into the sac by the hepatic and left gastric arteries. The upper or *left gastropancreatic fold* is formed by the left gastric artery as it passes from the posterior abdominal wall to reach the lesser curvature of the stomach ; the lower or *right gastropancreatic fold* is formed by the hepatic artery as it passes forwards from the posterior abdominal wall to gain the lesser omentum. The folds show considerable variation in their depths but, when well marked, they constrict the lesser sac and enclose a foramen which is sometimes called the *foramen bursæ omenti majoris*. The *superior recess* of the lesser sac lies above the foramen and communicates through it with the *inferior recess*, which represents the true *bursa omenti majoris* of the embryo (p. 174).

During a considerable part of fœtal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the posterior two layers of the greater omentum passing at this stage in front of the colon (fig. 215). This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the greater omentum, with the result that the colon appears to receive its

peritoneal covering by the splitting of the posterior two layers of the latter fold. In the adult the lesser sac intervenes between the stomach and the structures on which that viscus lies, and performs therefore the functions of a serous bursa for the stomach.

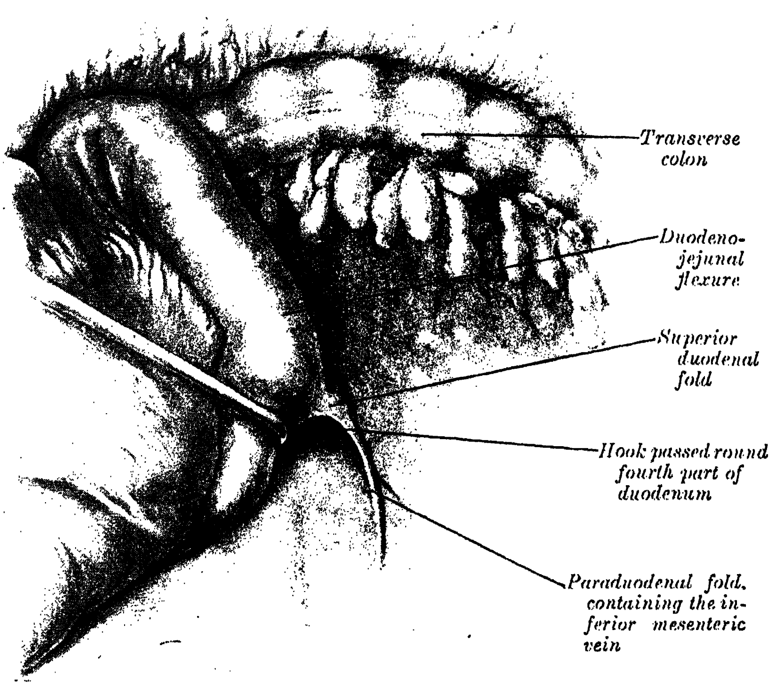
Numerous peritoneal folds extend between the various organs or connect them to the parietes; they serve to enclose the vessels and nerves proceeding to the viscera and, although they are clearly not designed to sustain any weight, they help to retain certain of the viscera in contact with one another. They are grouped as ligaments, omenta and mesenteries.

The **ligaments** will be described with their respective organs.

There are two **omenta**, the lesser and the greater.

The *lesser omentum* is the fold of peritoneum which extends to the liver from the lesser curvature of the stomach and the commencement of the duodenum. It is continuous with the two layers which cover the antero-superior

Fig. 1165.—The superior duodenal recess.

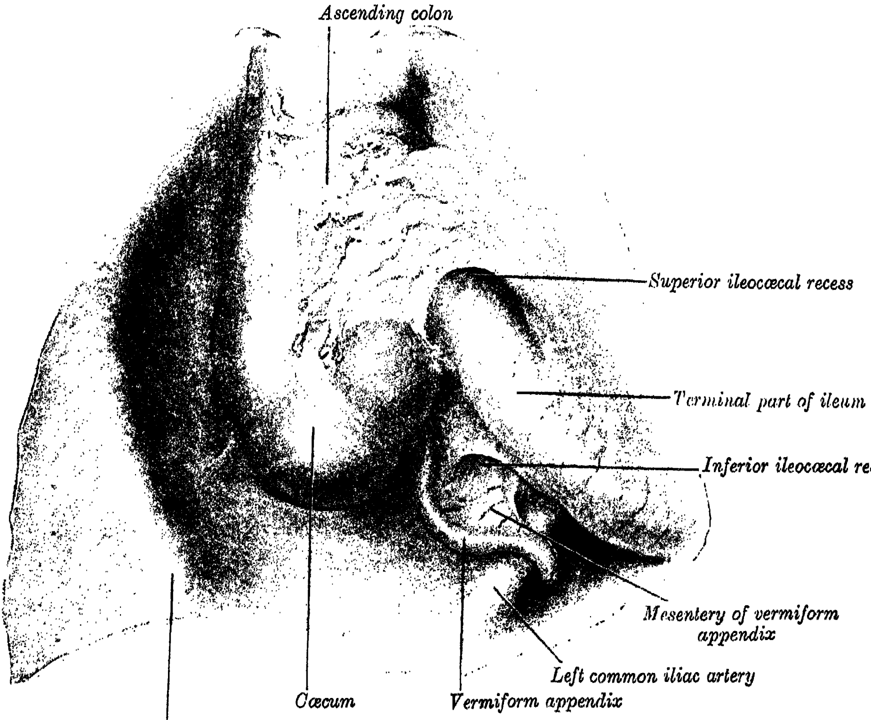


and postero-inferior surfaces of the stomach and the first 2 cm., or less, of the duodenum. From the lower part of the lesser curvature of the stomach and the upper border of the duodenum, these two layers ascend as a double fold to the porta hepatis; from the upper part of the lesser curvature, the two layers pass to be attached to the bottom of the fissure for the ligamentum venosum. The hepatic attachment of the lesser omentum is, therefore, ⅃-shaped, the horizontal limb corresponding to the margins of the porta hepatis, and the vertical limb to the floor of the fissure for the ligamentum venosum. At the upper end of the latter, the lesser omentum reaches the Diaphragm, where the two layers separate to embrace the end of the œsophagus. At the right border of the omentum the two layers are continuous, and form a free margin which constitutes the anterior boundary of the aditus to the lesser sac (epiploic foramen). The portion of the lesser omentum extending between the liver and stomach is sometimes named the *hepatogastric ligament*, and that between the liver and duodenum the *hepatoduodenal ligament*. Close to its right free margin the two layers of the lesser omentum enclose the hepatic artery, portal vein and bile duct, a few lymph glands and lymph vessels, and the hepatic plexus of nerves—all these structures being enclosed in a fibrous capsule, termed the *hepatobiliary capsule*

(Glisson's capsule). The right and left gastric arteries, the corresponding veins and some of the superior gastric lymph glands and their vessels, run between the layers of the lesser omentum, where these are attached to the stomach.

The *greater omentum* is the largest peritoneal fold. It consists of a double sheet, folded on itself so that it is made up of four layers. The two layers which descend from the stomach and commencement of the duodenum pass downwards in front of the small intestine for a variable distance; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These individual layers may be demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the greater omentum is continuous above with the gastrosplenic ligament; its right border extends as far as the

FIG. 1166.—The terminal part of the ileum, the cæcum and the vermiform appendix. Viewed from in front.



commencement of the duodenum. The greater omentum is usually thin, and presents a cribriform appearance, but it always contains some adipose tissue, which in fat people is present in considerable quantity. Between its anterior two layers, about a finger's breadth from the greater curvature of the stomach, the right and left gastro-epiploic vessels anastomose with each other.

The mesenteries are :—the mesentery (mesentery proper), the mesentery of the vermiform appendix, the transverse mesocolon and the pelvic mesocolon. In addition to these an ascending and a descending mesocolon are sometimes present.

The *mesentery* is a broad, fan-shaped fold of peritoneum connecting the coils of the jejunum and ileum with the posterior wall of the abdomen. Its root —the border connected with the posterior abdominal wall—is about 15 cm. long, and is directed obliquely from the duodeno-jejunal flexure at the left side of the second lumbar vertebra to the right sacroiliac joint (fig. 1161). Its intestinal border is about 6 metres long; and here the two layers separate to enclose the intestine and form its peritoneal coat. The mesentery is short at the upper part of the jejunum, but lengthens rapidly to about 20 cm. and is thrown into

numerous pleats or folds. It connects the jejunum and ileum to the posterior abdominal wall, and contains between its layers the jejunal and ileal branches of the superior mesenteric artery, with their accompanying veins and plexuses of nerves, the lymph vessels (lacteals), the mesenteric lymph glands and a varying amount of fatty tissue. At the upper end of the mesentery the fat tends to accumulate near its root, but as the fold is traced downwards, the fat extends farther towards the gut until, at the lower end of the ileum, it may entirely obscure the mesenteric border of the gut.

The *mesentery of the vermiform appendix* (fig. 1166) is a triangular fold of peritoneum which clothes the vermiform appendix, and is attached to the back of the lower end of the mesentery, close to the ileocæcal junction. Its layers enclose the blood-vessels, nerves and lymph vessels of the vermiform appendix, together with a lymph gland.

The *transverse mesocolon* is a broad fold connecting the transverse colon to the posterior wall of the abdomen. It is continuous with the posterior two layers of the greater omentum, which, after separating to surround the transverse colon, join behind it and are continued to the anterior border of the pancreas, where they separate (figs. 1160 and 1161). Between the layers of the transverse mesocolon the blood-vessels, nerves and lymphatics of the transverse colon are found. The middle colic artery passes downwards and to the right, leaving a large non-vascular area of the fold to its left, and a similar but smaller area to its right.

The *pelvic mesocolon* is a fold of peritoneum which attaches the pelvic colon to the pelvic wall. Its line of attachment has the form of an inverted V, the apex of which is near the point of division of the left common iliac artery (fig. 1161); the left limb descends on the medial side of the Psoas major; the right limb passes into the pelvis and ends in the median plane at the level of the third sacral vertebra. The inferior left colic (sigmoid) and superior rectal (superior hæmorrhoidal) vessels run between the two layers of the pelvic mesocolon.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon, but sometimes these are surrounded by peritoneum and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively (p. 1336*). A fold of peritoneum, termed the *phrenicocolic ligament*, is continued from the left colic flexure to the Diaphragm opposite the tenth and eleventh ribs; it passes below and lateral to the lateral end of the spleen, and is sometimes given the misleading name of *sustentaculum lienis*.

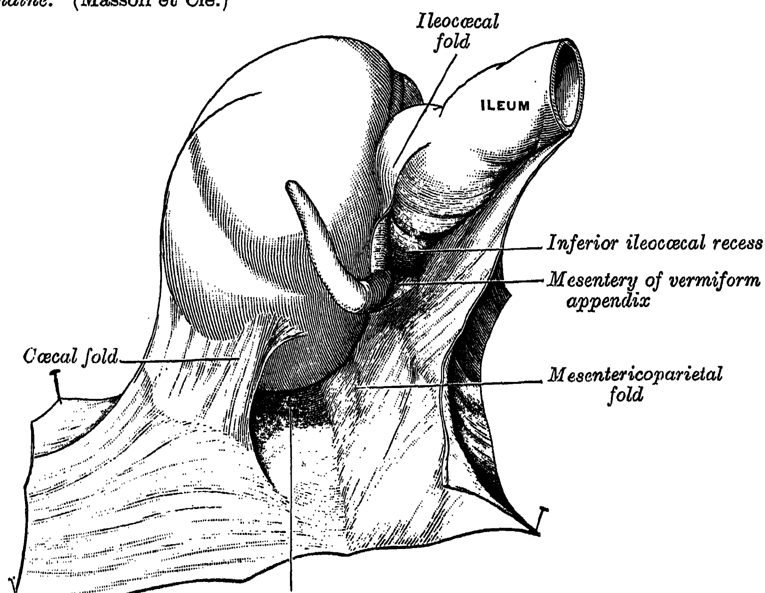
The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon; they are best marked on the transverse and pelvic parts of the colon.

Peritoneal recesses.—In certain parts of the abdominal cavity there are peritoneal recesses or pouches, which are of surgical interest in connexion with the possibility of the occurrence of 'internal' herniæ. The largest of these is the lesser sac (p. 1309), but others of smaller size require mention, and may be divided into three groups, viz.: duodenal, cæcal, and the recess of the pelvic mesocolon.

1. *Duodenal recesses* (figs. 1159 and 1165).—Five of these recesses are usually described, viz. a superior and an inferior duodenal, a paraduodenal, a retroduodenal and a duodenojejunal or mesocolic. The paraduodenal recess may occur together with the superior and inferior duodenal recesses, but the retroduodenal and duodenojejunal are not found in conjunction with the other varieties. (*a*) The *superior duodenal recess* (fig. 1165) is present in about 50 per cent. of bodies. It lies on the left side of the upper segment of the fourth part of the duodenum, behind a sickle-shaped fold of peritoneum, named the superior duodenal fold; the upper part of the inferior mesenteric vein usually runs between the layers of this fold. The fossa is about 2 cm. deep, and its orifice, directed downwards, admits a finger-tip. (*b*) The *inferior duodenal recess* (fig. 1159) is present in about 75 per cent. of bodies. It is placed on the left side of the lower segment of the fourth part of the duodenum behind a nonvascular triangular fold of peritoneum, named the inferior duodenal fold. This fossa has an average depth of 3 cm., and its orifice, which admits the tips of one or two

fingers, is directed upwards and faces that of the superior duodenal recess. In some cases the recess extends to the left in front of the ascending branch of the superior left colic artery, and the inferior mesenteric vein. (*c*) The *paraduodenal recess* (fig. 1165) lies a short distance to the left of the fourth part of the duodenum, and, though frequently present in the new-born child, is rarely found in the adult. It is placed behind a falciform fold [paraduodenal fold] of peritoneum, the free edge of which contains the ascending branch of the superior left colic artery, and frequently the inferior mesenteric vein, the fold forming a mesentery for these vessels. The free margin of the fold, and the wide orifice of the recess, are directed towards the right. (*d*) The *retroduodenal recess*, the largest of the duodenal recesses, is only occasionally present. It lies behind the third and fourth parts of the duodenum, and in front of the aorta, and extends upwards nearly as far as the duodenojejunal junction. The orifice of the recess looks

FIG. 1167.—The cæcal recesses. The ileum and cæcum are drawn backwards and upwards. (After Jonnesco.) From Poirier and Charpy's *Traité d'Anatomie humaine*. (Masson et Cie.)



downwards and to the left. (*e*) The *duodenojejunal* or *mesocolic recess* lies on the left side of the aorta, between the duodenojejunal junction and the root of the transverse mesocolon. It is present in about 20 per cent. of bodies, and has an average depth of from 2 cm. to 3 cm. Its orifice is directed forwards.

2. *Cæcal recesses.*—There are three principal pouches or recesses in the neighbourhood of the cæcum : (*a*) The *superior ileocæcal recess* (fig. 1166) is formed by a fold of peritoneum, named the vascular fold of the cæcum, arching over the branch of the ileocolic artery which supplies the ileocolic junction. The recess is a narrow chink situated between the mesentery of the small intestine, and the ileum and the small portion of the cæcum behind. Its mouth opens downwards. (*b*) The *inferior ileocæcal* recess (fig. 1166) is situated behind the angle of junction of the ileum and cæcum. It is formed by the *ileocæcal fold* of peritoneum (described by Treves as the ' bloodless fold '), the upper border of which is fixed to the ileum opposite its mesenteric attachment, while the posterior or right border joins the mesentery of the vermiform appendix, and sometimes the appendix itself or the cæcum. Between this fold and the mesentery of the vermiform appendix the inferior ileocæcal recess lies. It is bounded above by the posterior surface of the ileum and the mesentery ; in front by the ileocæcal fold, and behind by the upper part of the mesentery of the vermiform appendix. (*c*) The *cæcal recess* (fig. 1167) is situated immediately behind the cæcum, which has to be raised to bring it into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger ; in others it is merely

a shallow depression. It is bounded on the right by the cæcal fold, which extends downwards and to the right into the iliac fossa from the posterolateral aspect of the lower part of the ascending colon, or upper part of the cæcum. The *retrocæcal recess* is an occasional extension of the cæcal recess upwards behind the ascending colon.

3. The *recess of the pelvic mesocolon* (intersigmoid recess) is constant in the fœtus and during infancy, but may disappear as age advances. It lies on the pelvic side of the apex of the root of the pelvic mesocolon (p. 1314) and forms a funnel-shaped recess of variable size, the mouth of which opens downwards. In some instances it is a mere dimple. The posterior wall of the recess covers the left ureter as it crosses the bifurcation of the left common iliac artery.

The Stomach [Ventriculus]

The **stomach** is the most dilated part of the digestive tube, and is situated between the end of the œsophagus and the beginning of the small intestine. It lies in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess bounded by the upper abdominal viscera, and completed in front and on the left side by the anterior abdominal wall and the Diaphragm.

The *shape* and *position* of the stomach are so greatly modified by changes within itself and in the surrounding viscera that no one form and no single position can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage which the digestive process has reached, (3) the degree of development of the gastric musculature, and (4) the condition of the adjacent intestines ; but certain features are more or less common to all.

The stomach has two openings, two borders or curvatures, and two surfaces.

Openings.—The opening by which the œsophagus communicates with the stomach is known as the *cardiac orifice*, and is situated on the left of the median plane, behind the seventh costal cartilage one inch from its junction with the sternum, and at the level of the eleventh thoracic vertebra. The short abdominal portion of the œsophagus is conical in shape and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach. The right margin of the œsophagus is continuous with the lesser curvature of the stomach, while the left margin joins the greater curvature at an acute angle, termed the *cardiac notch* [incisura cardiaca].

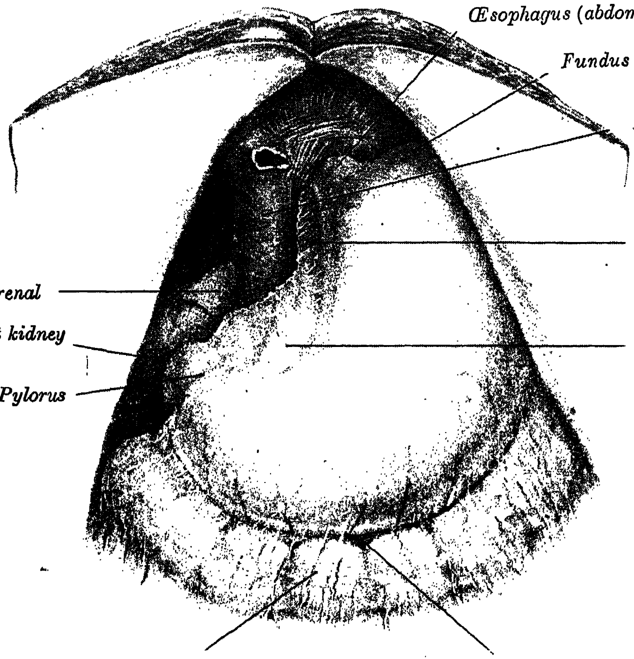
The opening by which the stomach communicates with the duodenum is named the *pyloric orifice*, and its position is usually indicated (fig. 1168) by a circular groove on the surface of the organ, termed the *pyloric constriction*, which indicates the position of the pyloric sphincter. In the living subject, at operation, it can be identified by the prepyloric vein, which runs vertically across its anterior surface. The pyloric orifice lies 1·5 cm. to the right of the median plane at the level of the lower border of the first lumbar vertebra, *when the body is in the supine position.*

Curvatures.—The *lesser curvature*, extending between the cardiac and pyloric orifices, forms the right or posterior border of the stomach. It descends as a continuation of the right margin of the œsophagus in front of the decussating fibres of the right crus of the Diaphragm, and then, turning to the right, it curves below the omental tuberosity of the pancreas and ends at the pylorus (fig. 1168). The deepest part of the curve forms a notch, named the *angular notch* [incisura angularis], which varies somewhat in position with the state of distension of the viscus ; it serves to separate the stomach into a right and a left portion. The lesser curvature gives attachment to the lesser omentum, the two layers of which contain the right and left gastric vessels.

The *greater curvature* is directed mainly forwards, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the cardiac notch, it forms an arch backwards, upwards, and to the left ; the highest point of the convexity is on a level with the left fifth intercostal space. From this level it may be followed downwards and forwards, with a slight convexity to the left almost as low as the cartilage of the tenth rib, when the body is in the supine position ; it then turns to the right, to end at the pylorus. Directly opposite

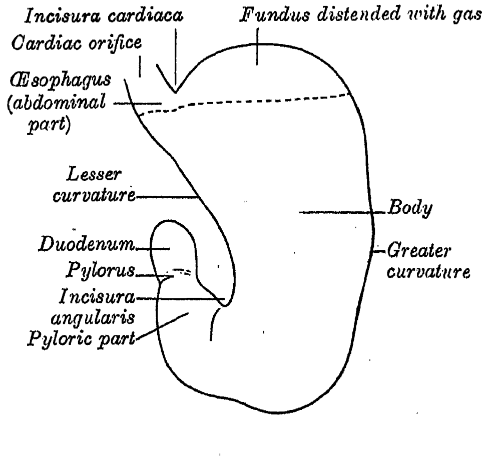
the incisura angularis of the lesser curvature the greater curvature presents a bulging, which is the left extremity of the *pyloric part* of the stomach ; this is limited on the right by a slight groove, which indicates the subdivision of the

Fig. 1168.—The stomach *in situ*, after the removal of the liver.



pyloric part into a pyloric antrum and a pyloric canal. The latter is only 2 to 3 cm. in length and terminates at the pyloric constriction. At its commencement the greater curvature is covered by peritoneum continuous with that on the front of the stomach. On the left side of the fundus and the adjoining part of the body, the greater curvature gives attachment to the gastrosplenic ligament, while its lower portion gives attachment to the two layers of the greater omentum, separated from each other by the gastro-epiploic vessels.

Fig. 1169.—An outline of the normal full stomach. (From a model by A. E. Barclay.)



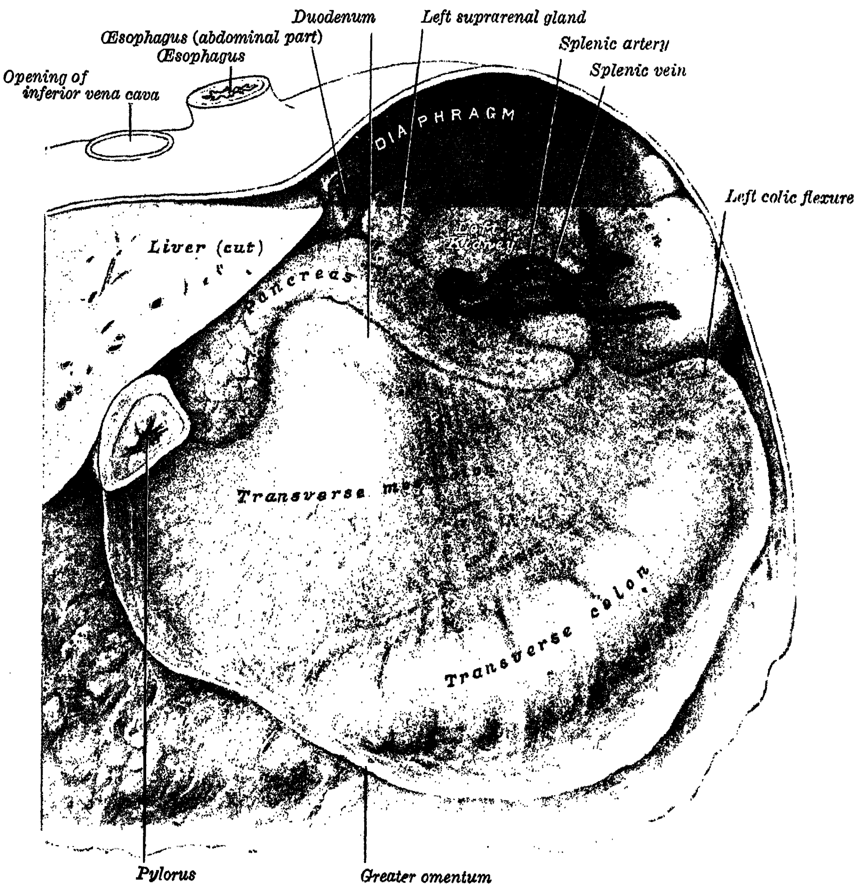
Surfaces.—When the stomach is empty and its walls contracted, its surfaces are directed upwards and downwards respectively, but when it is distended they look forwards and backwards. They may therefore be described as antero-superior and postero-inferior.

Anterosuperior surface. — The left part of this surface lies under cover of the left costal margin. It is in contact with the Diaphragm, which separates it from the left pleura, the base of the left lung, the pericardium, and the sixth, seventh, eighth and ninth ribs and intercostal spaces of the left side. It is also in contact with the upper fibres of origin of the transversus abdominis, which intervene between it and the seventh, eighth and ninth costal cartilages. The right half is in relation with the left and quadrate lobes of the liver and with

the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the front part of this surface. The whole surface is covered with peritoneum.

The *postero-inferior surface* is in relation with the Diaphragm, the gastric surface of the spleen, the left suprarenal gland, the upper part of the front of the left kidney, the splenic artery, the anterior surface of the pancreas, the left colic flexure, and the upper layer of the transverse mesocolon. These structures form the shallow *stomach-bed*, on which the viscus rests (fig. 1170). The transverse mesocolon separates the stomach from the duodenojejunal

Fig. 1170.—The 'stomach-bed.'



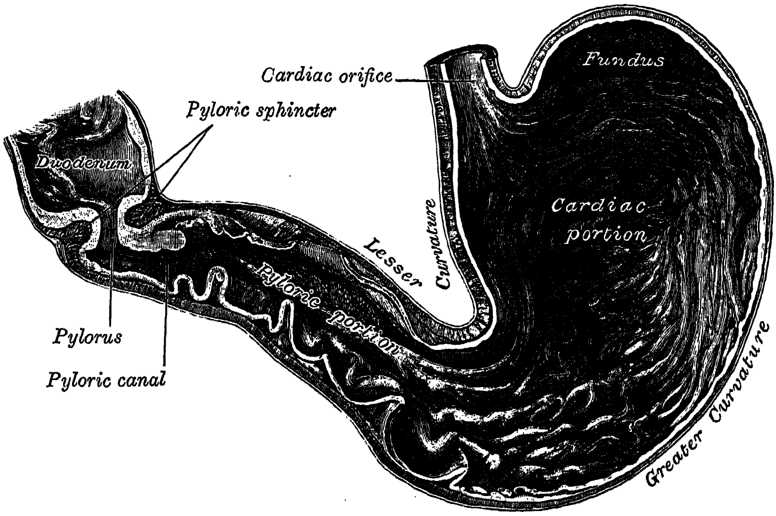
flexure and small intestine. The postero-inferior surface is covered with peritoneum, except near the cardiac orifice, where there is a small, somewhat triangular, area, about 5 cm. wide, in direct contact with the left crus of the Diaphragm, and sometimes with the left suprarenal gland. The left gastric vessels reach the lesser curvature of the stomach at the right extremity of this area, and from its left side a short peritoneal fold, termed the *gastrophrenic ligament*, which is continuous below with the lienorenal and gastrosplenic ligaments, passes to the inferior surface of the Diaphragm.

A plane passing through the incisura angularis on the lesser curvature and the left limit of the opposed bulging on the greater curvature divides the stomach into a large, left portion or *body* and a small, right, or *pyloric portion*. The upper portion of the body is known as the *fundus* and is marked off from the remainder of the body by a plane passing horizontally through the cardiac orifice.

By means of *x*-rays the form and position of the stomach can be studied in the living subject after the administration of a meal containing bismuth (Pl. XV). During the process of digestion, it is divided by a muscular constriction into a large, dilated, left portion, and

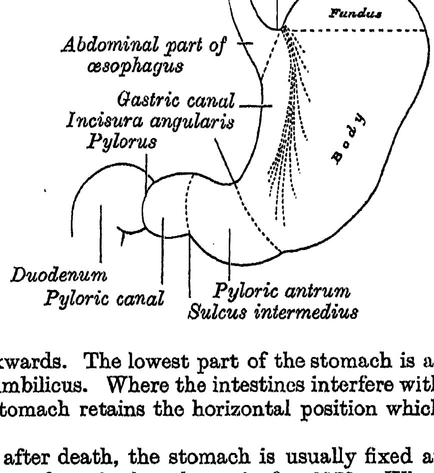
a narrow, contracted, tubular, right portion. The constriction is in the body of the stomach, and does not follow any of the anatomical landmarks; indeed, it shifts gradually towards the left as digestion progresses. The position of the stomach varies with the posture, with the amount of the stomach contents and with the condition of the intestines on which it rests. In addition there is a wide range of individual varia-

FIG. 1171.—The interior of the stomach.



tion. In the erect posture the empty stomach is somewhat J-shaped; the fundus is usually distended with gas; the pylorus descends to the level of the second or the upper part of the third lumbar vertebra, and the most dependent part of the stomach is below the level of the umbilicus. Variation in the amount of its contents affects mainly the body of the stomach, the pyloric portion remaining in a more or less contracted condition during the process of digestion. As the stomach fills it tends to expand forwards and downwards in the direction of least resistance, but when this is interfered with by a distended condition of the colon or intestines the fundus presses upwards on the liver and Diaphragm and gives rise to the feelings of oppression and palpitation complained of in such cases. By hardening the viscera *in situ* His * and Cunningham † have shown that the contracted stomach has a sickle shape, the fundus looking directly backwards. The surfaces are directed upwards and downwards, the upper surface having, however, a gradual downward slope to the right. The greater curvature is in front and at a slightly higher level than the lesser.

FIG. 1172.—A diagram showing the subdivisions of the human stomach. (F. T. Lewis.)



The position of the full stomach depends, as already indicated, on the state of the intestines: when the latter are empty the fundus expands vertically and also forwards, the pylorus is displaced towards the right, and the whole organ assumes an oblique position, so that its surfaces are directed more forwards and backwards. The lowest part of the stomach is at the pyloric antrum, which reaches below the umbilicus. Where the intestines interfere with the downward expansion of the fundus the stomach retains the horizontal position which is characteristic of the contracted viscus.

Interior of the stomach.—When examined after death, the stomach is usually fixed at some stage of the digestive process. A common form is that shown in fig. 1171. When the viscus is laid open by a section through the plane of its two curvatures, it is seen to consist of two segments: (*a*) a large globular portion on the left and (*b*) a narrow tubular part on the right. The cardiac notch lies to the left of the abdominal part of the œsophagus: the projection of this notch into the cavity of the stomach increases as the organ

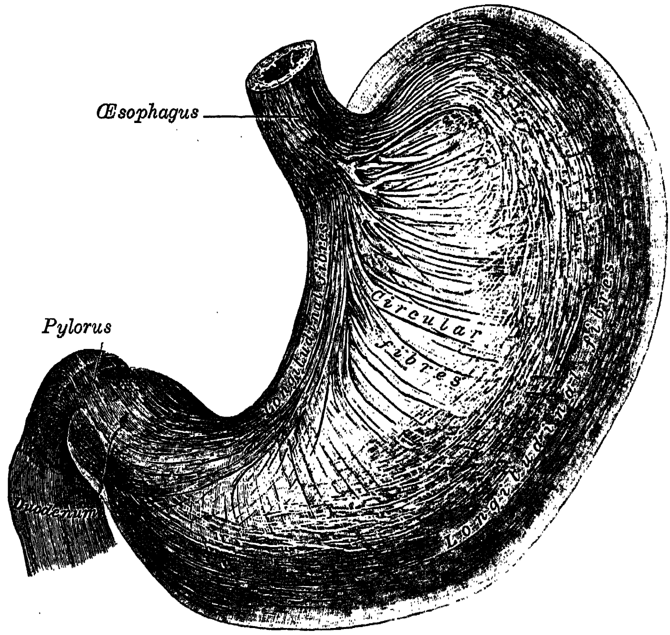
* *Archiv für Anatomie und Physiologie, anat. Abth.*, 1903.

† *Transactions of the Royal Society of Edinburgh*, vol. xlv. part i.

distends, and has been supposed to act as a valve preventing regurgitation into the œsophagus. The elevation corresponding to the incisura angularis is seen at the beginning, and the circular thickening of the pyloric sphincter at the end of the pyloric portion.

F. T. Lewis * has modelled the gastric epithelium in the human embryo, and has shown that a canal (named by him the *gastric canal*) extends along the lesser curvature from the cardiac orifice to the incisura angularis (fig. 1172), the distinctness of the canal being strikingly shown when the model is viewed from the inside. Jefferson † has brought forward radiographic evidence to show that such a canal exists in the adult. He found that in eighteen out of twenty-two cases examined whilst in the act of swallowing a mixture of oxychloride of bismuth and milk the fluid was confined to the lesser curvature. He is of the opinion that the oblique muscular coat of the stomach is so arranged that by its contraction it will cause a temporary cutting off of a canal along the lesser curvature.

FIG. 1173.—The longitudinal and circular muscular fibres of the stomach. Anterosuperior aspect. (Spalteholz.)



The *pyloric sphincter* is a muscular ring composed of a thickened portion of the circular layer of the muscular coat; this ring is covered with a reduplication of the mucous membrane. Some of the deeper longitudinal fibres turn in and interlace with the fibres of the sphincter.

Structure.—The wall of the stomach consists of four coats: serous, muscular, areolar and mucous, together with vessels and nerves.

The *serous coat* is derived from the peritoneum and covers the entire surface of the organ, excepting (*a*) along the greater and lesser curvatures at the lines of attachment of the greater and lesser omenta, where the two layers of peritoneum leave a small space, triangular on section, in which the vessels and nerves lie: and (*b*) a small area on the postero-inferior surface of the stomach, close to the cardiac orifice, where the stomach is in contact with the under surface of the Diaphragm.

The *muscular coat* (figs. 1173, 1174) is situated immediately beneath the serous covering, with which it is closely connected. It consists of three layers of unstriped muscular fibres: longitudinal, circular and oblique.

The *longitudinal fibres* are the most superficial, and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the œsophagus; they radiate from the cardiac orifice and end proximal to the pyloric portion. The second set commences on the body of the stomach and passes to the right, its fibres becoming more thickly arranged as they approach the pylorus. Some of the more superficial fibres of this set pass on to the duodenum, but the deeper fibres dip inwards and interlace with the fibres of the pyloric sphincter.

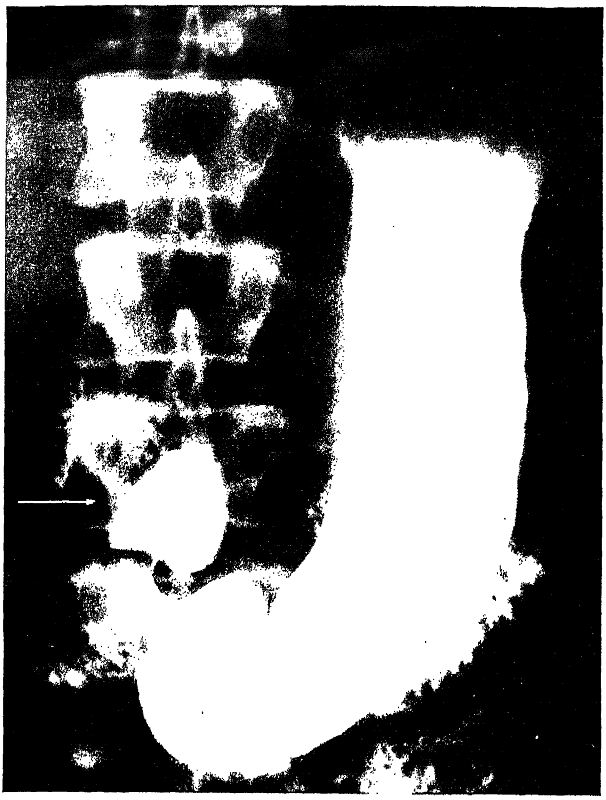

FIG. 1.—Radiograph of a normal stomach after a barium meal. The tone of the muscular wall is good and supports the weight of the column in the body of the organ. The arrow points to the duodenal cap, below which a gap in the barium indicates the position of the pylorus.

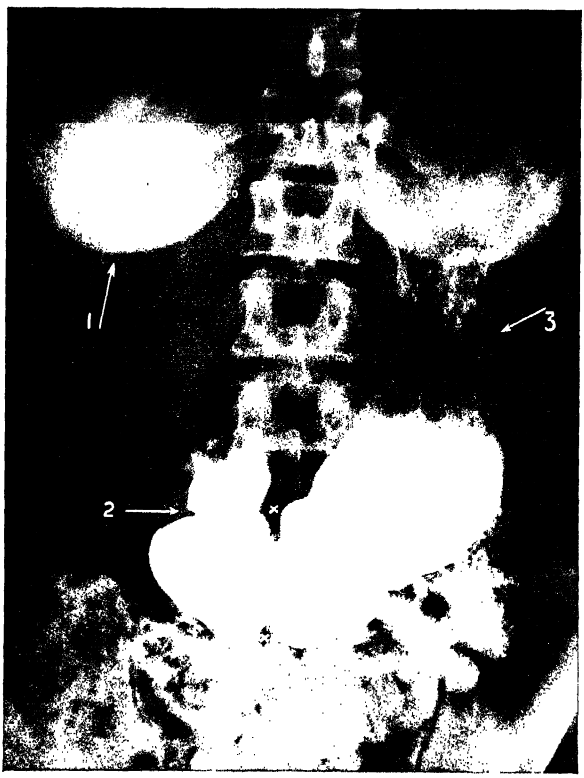

FIG. 2.—Radiograph of an atonic stomach after a barium meal. Note that this stomach contains the same amount of barium as the stomach in fig. 1. Arrow 1 points to the shadow of the right breast; arrow 2, to the pylorus; arrow 3, to the upper part of the body of the stomach, where longitudinal folds can be seen in the mucous membrane. XX marks a wave of peristalsis.

PLATE XVI

FIG. 1.—Radiograph of the small intestine after a barium meal. The 'feathery' appearance is due to the presence of the circular folds in the mucous coat.

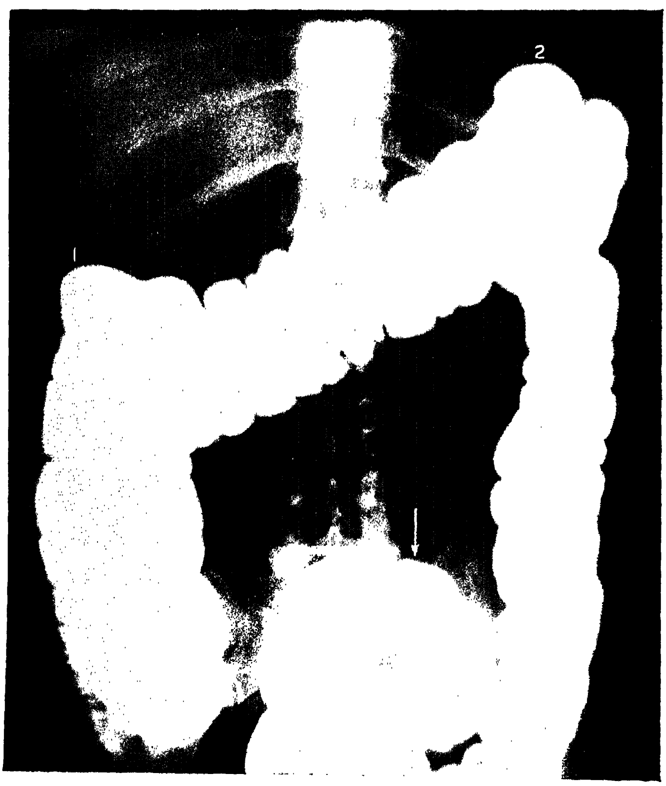

FIG. 2.—Radiograph of the large intestine after a barium enema. 1—right colic flexure; 2—left colic flexure. The arrow points to the pelvic colon. Note the sacculations of the gut, and the different levels of the two flexures.

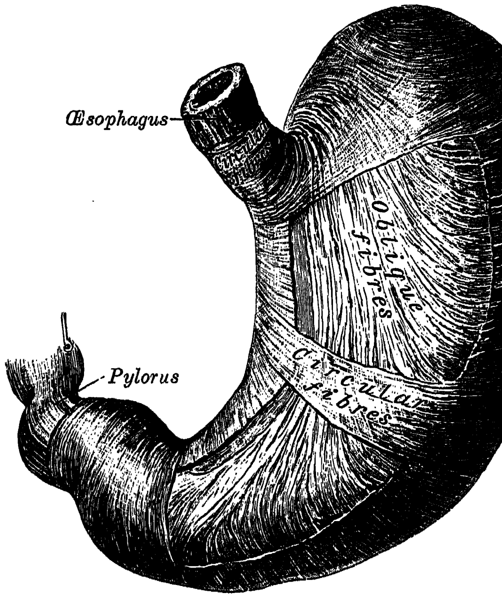
The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are there aggregated into a ring which forms the *pyloric sphincter*. The circular fibres of the stomach are con-

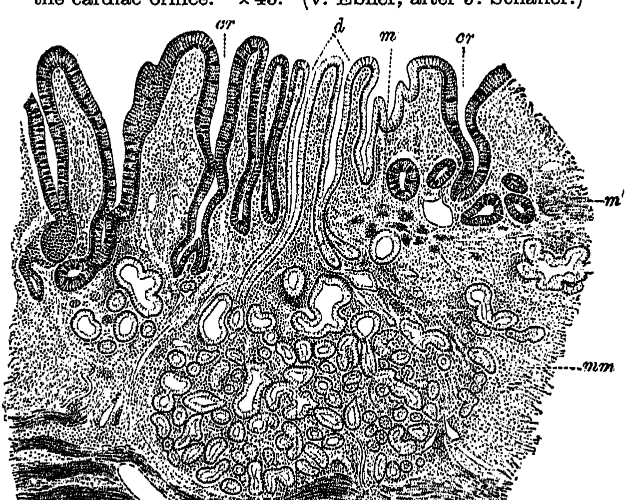
Fig. 1174.—The oblique muscular fibres of the stomach. Anterosuperior aspect. (Spalteholz.)



tinuous with the circular fibres of the œsophagus, but are sharply marked off from the circular fibres of the duodenum by a connective tissue septum.

The *oblique fibres*, internal to the circular layer, are limited chiefly to the body of the

Fig. 1175.—A section through the mucous membrane of a human stomach, near the cardiac orifice. ×45. (v. Ebner, after J. Schaffer.)



c. Cardiac glands. *d*. Their ducts. *cr*. Gland similar to the intestinal glands, with goblet cells. *mm*. Mucous membrane. *m*. Muscularis mucosæ. *m'*. Muscular tissue within the mucous membrane.

stomach. They sweep downwards from the incisura cardiaca and run more or less parallel with the lesser curvature. On the right they present a free and well-defined margin (fig. 1174); on the left they blend with the circular fibres.

The *areolar* or *submucous coat* consists of loose, areolar tissue, connecting the mucous and muscular layers.

The *mucous membrane* is thick and its surface is smooth, soft and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown colour over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker towards the pylorus. During the contracted state of the organ it is thrown into numerous folds or rugæ which for the most part have a longitudinal direction, and are best marked towards the pyloric end of the stomach, and along the greater curvature (fig. 1171). These folds are obliterated when the organ is distended.

Structure of the mucous membrane.—When examined with a lens, the inner surface of the mucous membrane presents a peculiar, honeycomb appearance owing to the fact that it

FIG. 1176.—A fundus gland.

m. Mouth. *n.* Neck. *tr.* A deep portion of a tubule cut transversely.

is covered with small, shallow depressions or alveoli, of a polygonal or hexagonal form, which vary from 0·12 mm. to 0·25 mm. in diameter. These are the ducts of the gastric glands, and at the bottom of each, one or more of the minute orifices of the gland-tubes may be seen. The surface of the mucous membrane is covered with a single layer of columnar epithelium with occasional goblet-cells. This epithelium commences very abruptly at the cardiac orifice, where there is a sudden transition from the stratified epithelium of the œsophagus. The epithelial lining of the gland-ducts is of the same character and is continuous with the general epithelial lining of the stomach.

The gastric glands are of three kinds: (*a*) *cardiac*, (*b*) *fundus* or *oxyntic*, and (*c*) *pyloric*. The *cardiac glands* (fig. 1184), few in number, occur close to the cardiac orifice. They are of two kinds: (1) simple tubular glands resembling those of the pyloric end of the stomach, but with short ducts; (2) compound racemose glands resembling the duodenal glands. The *fundus glands* (fig. 1176) are found in the body and fundus of the stomach; they are simple tubes, two or more of which open into a single duct. The duct is short, sometimes not amounting to more than one-sixth of the whole length of the gland. The epithelium of the fundus glands consists of (1) short columnar, glandular cells, known as the *chief* or *central cells*, which are responsible for the formation of pepsin, and (2) larger, oval cells, termed

parietal or *oxyntic cells*, which secrete the hydrochloric acid of the gastric juice. The latter lie between the chief cells and the basement-membrane, and stain deeply with eosin; they do not form a continuous layer, but occur at intervals and so give the tube a beaded appearance. They are connected with the lumen of the gland by fine channels which run in the substance of the cells. The *pyloric glands* (fig. 1177) are found in the pyloric portion of the stomach. Each consists of two or three short convoluted tubes opening into a funnel-shaped duct. The tubes are lined by cubical cells which are finely granular. Parietal or oxyntic cells are present in some of the pyloric glands. The ducts occupy about two-thirds of the depth of the mucous membrane.

Between the glands the mucous membrane consists of a connective tissue framework, and lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses which resemble the solitary lymphatic nodules of the intestine, and are termed the *gastric lymphatic nodules*. They are not, however, so distinctly circumscribed as the solitary nodules. The mucous membrane is bounded on its deep surface by a thin stratum of involuntary muscular fibres (muscularis mucosæ), which in some parts consists only of a single longitudinal layer; in others of two layers, an inner circular and an outer longitudinal.

Vessels and Nerves.—The *arteries* supplying the stomach are: the left gastric branch of the cœliac artery, the right gastric and right gastro-epiploic branches of the hepatic artery, and the left gastro-epiploic and short gastric branches of the splenic artery. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the deep ends of the gastric glands into a plexus of fine capillaries which run between the glands, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the glands, and also form hexagonal meshes around the gland-ducts. From these the *veins* arise, and pursue a straight course, between the glands, to the submucous tissue: they end either in the splenic and superior mesenteric veins, or directly in the portal vein. The *lymph vessels* are numerous; they consist of a superficial and a deep set, and pass to the lymph glands found along the two curvatures of the organ (p. 866). The *nerves* are the terminal branches of the right and left vagi, the former being distributed for the most part upon the back, and the latter for the most part upon the front part of the stomach. A great number of branches from the cœliac plexus of the sympathetic are also distributed to it. Nerve-plexuses are found in the submucous coat and between the layers of the muscular coat, as in the intestine. From these plexuses fibrils are distributed to the muscular tissue and the mucous membrane.

The Small Intestine [Intestinum Tenue]

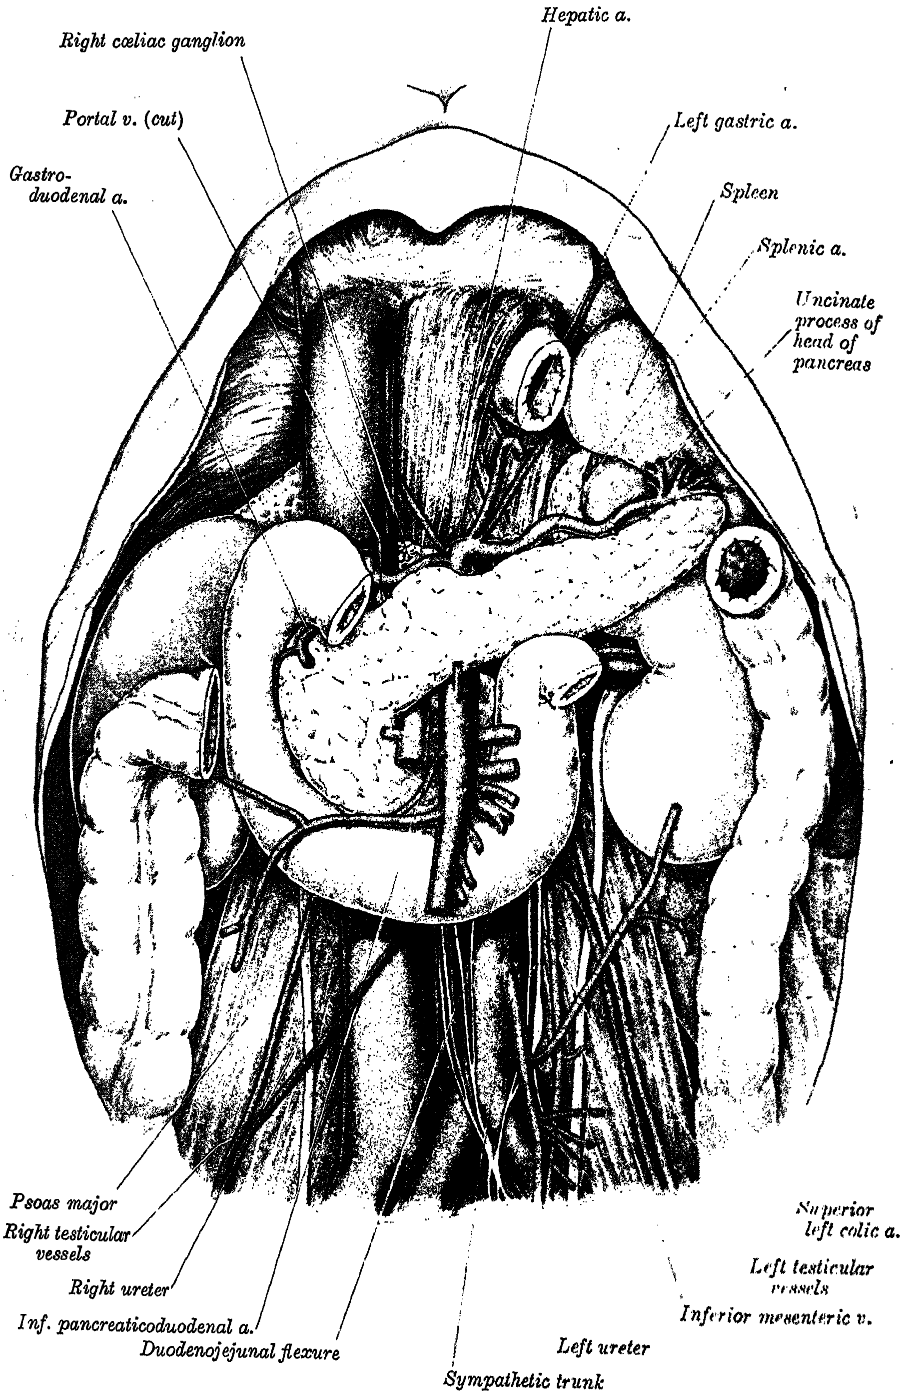
The **small intestine** is a convoluted tube, extending from the pylorus to the ileocolic valve, where it joins the large intestine. It is about 6·5 metres long, and gradually diminishes in diameter from its commencement to its termination. It is contained in the central and lower parts of the abdominal cavity and usually lies within the curve of the large intestine; it is in relation, in front, with the greater omentum and abdominal parietes; a portion of it extends down into the pelvis and lies in front of the rectum. The small intestine consists of (1) a short, curved portion which is devoid of a mesentery and is named the *duodenum*, and (2) a long, greatly coiled part which is attached to the posterior abdominal wall by the mesentery (p. 1313); the proximal two-fifths constitute the *jejunum* (*intestinum jejunum*), the distal three-fifths the *ileum* (*intestinum ileum*).

The **duodenum** (fig. 1178) is so named because its length is about equal to the breadth of twelve fingers (25 cm.). It is the shortest, widest and most fixed part of the small intestine; it has no mesentery, and is only partially covered with peritoneum. Its course presents a remarkably constant curve, somewhat of the shape of an imperfect circle, which encloses the head of the pancreas.

It begins at the pylorus, passes backwards, upwards and to the right, under cover of the quadrate lobe of the liver, to the neck of the gall-bladder, varying slightly in direction according to the degree of distention of the stomach; it then makes a sharp curve (*superior duodenal flexure*) and descends in front of the medial part of the right kidney, for a variable distance, generally to the level of the lower border of the body of the third lumbar vertebra. Here it makes a second bend (*inferior duodenal flexure*), and passes almost horizontally from right to left across the vertebral column, having a slight inclination upwards; it then ascends in front, or to the left, of the abdominal aorta for about 2·5 cm., and ends opposite the second lumbar vertebra in the jejunum. At its union with the jejunum it turns abruptly forwards, forming the *duodenojejunal flexure*. For descriptive purposes it is divided into first, second, third and fourth parts.

Relations.—The *first part* (superior portion) is about 5 cm. long, and is the most movable of the four portions; it begins at the pylorus, and ends at the

Fig. 1178.—A dissection to show the duodenum and pancreas.



neck of the gall-bladder. It is covered with peritoneum over the whole of its anterior aspect, but it is devoid of peritoneum posteriorly, *except near the pylorus*, where it takes a small part in the formation of the anterior wall of the lesser sac; the right part of the lesser omentum is attached to the upper border, and the

greater omentum to the lower border of the proximal half. It is in relation above and in front with the quadrate lobe of the liver and the gall-bladder; behind, with the gastroduodenal artery, the bile-duct and the portal vein, and below and behind, with the head and neck of the pancreas. It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface.

The *second part* (descending portion) from 8 cm. to 10 cm. long, descends from the neck of the gall-bladder along the right side of the vertebral column as low as the lower border of the body of the third lumbar vertebra. It is crossed by the transverse colon, the posterior surface of which is connected to the duodenum by a small quantity of areolar tissue. The parts above and below the transverse colon are covered in front with peritoneum. It is in relation, in front, from above downwards, with the duodenal impression on the right lobe of the liver, the transverse colon, and the small intestine; behind, it has a variable relation to the front of the right kidney in the neighbourhood of its hilum, and is connected to it by loose areolar tissue; the right renal vessels, edge of the inferior vena cava, and Psoas major are also behind it. Its medial side is related to the head of the pancreas and the bile-duct; its lateral side, to the right colic flexure. The bile-duct and the pancreatic duct come into contact at the medial side of this part of the duodenum. The two ducts enter the wall of the gut obliquely, and there unite to form a short, dilated duct which is named the *ampulla of the bile duct.* The narrow, distal end of this ampulla opens on the summit of a papilla, termed the *duodenal papilla,* which is situated within the second part of the duodenum at the junction of its medial and posterior walls (figs. 1179, 1199), from 8 cm. to 10 cm. distal to the pylorus. The accessory pancreatic duct, when present, opens about 2 cm. proximal to the duodenal papilla.

The *third part* (horizontal portion), about 10 cm. long, begins at the right side of the lower border of the third lumbar vertebra and passes from right to left, with a slight inclination upwards, in front of the inferior vena cava, and ends in the fourth part in front of the abdominal aorta. Its anterior surface is covered with peritoneum, except near the median plane, where it is crossed by the superior mesenteric vessels and the root of the mesentery. Its posterior surface is uncovered by peritoneum, except towards its left extremity, where the posterior layer of the mesentery sometimes covers it to a variable extent. This surface rests upon the right ureter, the right Psoas major, the right testicular (or ovarian) vessels, the inferior vena cava and the abdominal aorta. The upper surface is in relation with the head of the pancreas; the lower, with the coils of the jejunum.

The *fourth part* (ascending portion), about 2·5 cm. long, ascends on or immediately to the left of the aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forwards [*duodenojejunal flexure*] and is continuous with the jejunum. It lies in front of the left sympathetic trunk, left Psoas major, the left renal and testicular vessels. Along its right border it gives attachment to the upper part of the root of the mesentery, the left layer of which is continued over its anterior surface and left side.

The first part of the duodenum, as stated above, possesses a range of movement, but the rest is relatively fixed, and is bound down to neighbouring viscera and the posterior abdominal wall.

The fourth part of the duodenum and the duodenojejunal flexure are fixed by the Suspensory muscle of the duodenum, which arises from the right crus of the Diaphragm, close to the right margin of the œsophagus. It passes downwards and slightly forwards in close relation with the cœliac artery (sometimes dividing to enclose this vessel) and is attached to the posterior surface of the upper part of the duodenojejunal flexure, many fibres being continued into the mesentery.* This muscle consists of three parts, viz. an upper of striped muscular fibres, an intermediate elastic tendon, and a lower of unstriped muscular fibres.

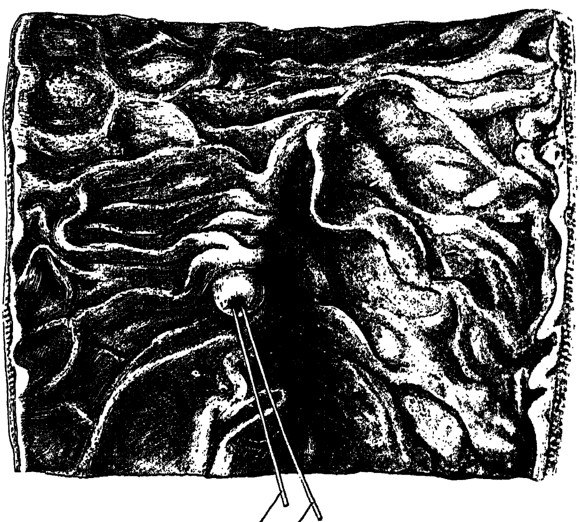
Vessels and Nerves.—The *arteries* supplying the duodenum are the right gastric and superior pancreaticoduodenal branches of the hepatic, and the inferior pancreaticoduodenal

* A. Low, *Journal of Anatomy and Physiology,* vol. xlii.

branch of the superior mesenteric. One, sometimes two, small branches descend from the hepatic artery as it lies in the lesser omentum and supply a limited area near the termination of the first part. The *veins* end in the splenic, superior mesenteric and portal veins. The *nerves* are derived from the cœliac plexus.

The rest of the small intestine, about 6 metres long, extends from the duodenojejunal flexure to the ileocolic valve, where it ends in the cæcum of the large intestine ; it is arranged in a series of coils or loops which are attached to the posterior abdominal wall by the mesentery. This part of the gut is completely covered with the peritoneum, except for a narrow strip along its mesenteric border, where the two layers of the mesentery diverge from each other to enclose it. It is divided into jejunum and ileum, the former name being given to the upper two-fifths and the latter to the lower three-fifths. There is no morphological line of distinction between these two parts, and the division is arbitrary ; but at the same time the character of the intestine gradually undergoes a change

FIG. 1179.—The interior of the second part of the duodenum, showing the duodenal papilla.



from the beginning of the jejunum to the end of the ileum, so that portions of the bowel taken from these two situations present characteristic differences.

The **jejunum** (intestinum jejunum) has a diameter of about 4 cm., and is thicker, redder and more vascular than the ileum. The circular folds (p. 1328) of its mucous membrane are large and thickly set, and its villi surpass those of the ileum in size. The aggregated lymphatic nodules (p. 1330) are almost absent in the upper part of the jejunum ; in the lower part they are less frequently found than in the ileum, and are smaller and tend to assume a circular form. When the jejunum is grasped between the finger and thumb the circular folds can be felt through the wall of the gut ; as these folds are absent from the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

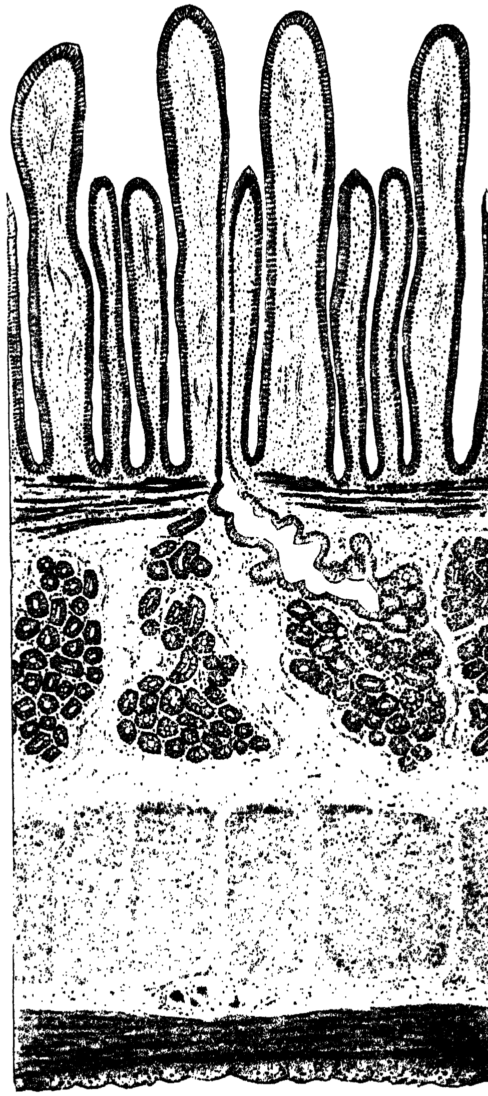
For the most part the jejunum lies in the umbilical region, but it may extend into any of the surrounding areas. The first coil occupies a recess between the left part of the transverse mesocolon and the anterior surface of the left kidney (p. 1345).

The **ileum** (intestinum ileum) has a diameter of 3·5 cm., and its coats are thinner than those of the jejunum. A few circular folds are present in the upper part of the ileum, but they are small and disappear almost entirely towards its lower end ; the aggregated lymphatic nodules are, however, larger and more numerous than in the jejunum. For the most part the ileum is situated in the hypogastric and pelvic regions. The terminal part of the ileum usually lies in

the pelvis, from which it ascends over the right Psoas major and right iliac vessels ; it ends in the right iliac fossa by opening into the medial side of the cæcum.

The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, termed the *mesentery,* which allows of very free

FIG. 1180.—A section through the duodenum of a cat. ×60. (From Sharpey-Schafer's *Essentials of Histology.*)



movement, so that each coil can accommodate itself to changes in form, and position. The mesentery is fan-shaped ; its vertebral border or root, about 15 cm. long, is attached to the posterior abdominal wall along a line running from the left side of the body of the second lumbar vertebra to the right sacro-iliac joint, and crossing successively the third part of the duodenum, the aorta, the inferior vena cava, the right ureter, and right Psoas major (fig. 1161). Its average breadth from the vertebral to the intestinal border is about 20 cm., but is greater in the middle than at its upper and lower ends ; according to Lockwood the breadth of the mesentery tends to increase as age advances. The two layers of the mesentery contain the jejunum, ileum, the jejunal and ileal

branches of the superior mesenteric blood-vessels, nerves, lacteals, and lymph glands, together with a variable amount of fat (p. 1314).

Meckel's diverticulum.—This is a pouch which projects from the lower part of the ileum in about 2 per cent. of subjects. Its average position is about 1 metre above the ileocolic valve, and its average length about 5 cm. Its calibre is generally similar to that of the ileum, and its blind extremity may be free or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. It represents the persistent proximal part of the vitello-intestinal duct, which connects the yolk-sac and the primitive digestive tube in early fœtal life (pp. 71, 168).

Structure.—The wall of the small intestine (fig. 1180) is composed of four coats: serous, muscular, areolar and mucous.

The *serous* coat is formed of peritoneum.

The *muscular coat* is thicker in the upper than in the lower part of the small intestine; it consists of an external longitudinal and an internal circular layer of non-striped muscular fibres. The *longitudinal layer* is thin; the *circular layer* is thick, and composed of fibres of considerable length.

The *areolar* or *submucous coat* unites the mucous and muscular layers. It consists of loose, areolar tissue containing blood-vessels, lymph vessels and nerves.

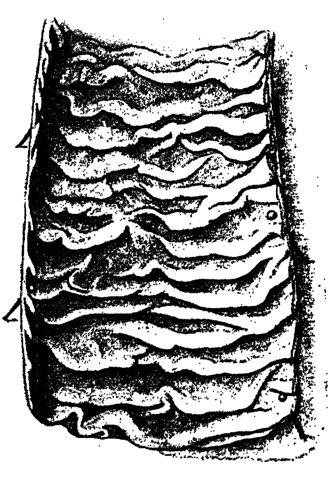
The *mucous membrane* is thick and highly vascular in the upper part of the small intestine, but thinner and less vascular in the lower part. It consists of the following structures: next to the areolar or submucous coat there is the *muscularis mucosæ*, which consists of an outer longitudinal and inner circular layer of unstriped muscular fibres; internal to the muscularis mucosæ there is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify; lastly, a basement membrane, supporting a single layer of tall columnar cells. The cells are granular in appearance, and each possesses a clear oval nucleus. Their superficial and unattached ends present a distinct layer of highly refracting material, marked by vertical striæ (the *striated border*). Goblet-cells occur at intervals in the epithelial layer.

The following structures are contained within or belong to the mucous membrane:

Circular folds.	Duodenal glands.
Villi.	Solitary lymphatic nodules.
Intestinal glands.	Aggregated lymphatic nodules.

The **circular folds** (fig. 1181) are large transverse folds of mucous membrane which project into the lumen of the bowel. They are composed of reduplications of the mucous membrane, the two layers of the fold being bound together by submucous tissue; unlike the folds in the stomach they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely round the intestine for about one-half or two-thirds of its circumference, but some form complete circles, some bifurcate and join adjacent folds, and others have a spiral direction; the latter usually extend a little more than once round the bowel, but occasionally two or three times. The larger folds are about 8 mm. in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. Circular folds are not found at the commencement of the duodenum, but begin to appear about 2·5 or 5 cm. beyond the pylorus. Distal to the point where the bile- and pancreatic ducts enter the duodenum, they are very large and closely approximated. In the upper one-half of the jejunum they are large and numerous, but from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they are almost entirely absent; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The circular folds retard the passage of the food and afford an increased surface for absorption (Pl. XVI, fig. 1).

Fig. 1181.—The interior of a portion of the upper part of the jejunum, showing the circular folds.



The **intestinal villi** are highly vascular processes, just visible to the naked eye; they project from the mucous membrane of the whole of the small intestine, and give to its surface a velvety appearance. They are large and numerous in the duodenum and jejunum, but are smaller and fewer in the ileum.

Structure of the villi (figs. 1182, 1183).—The essential parts of a villus are: the lacteal

vessel, the blood-vessels, the epithelium, the basement-membrane and the muscular tissue of the mucosa, all being supported and held together by retiform tissue.

The *lacteals* are in some cases double, and in some animals multiple, but usually there is a single vessel. Situated in the axis of the villus, each commences by a dilated blind extremity near to, but not quite at, the summit of the villus. The wall is composed of a single layer of endothelial cells.

The *muscular fibres* are derived from the muscularis mucosæ, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane and to the lacteal.

The *blood-vessels* (fig. 1184) form a plexus under the basement-membrane, and are enclosed in the reticular tissue.

These structures are surrounded by the *basement-membrane*, which is made up of a layer of endothelial cells, and upon this is placed a layer of *columnar epithelium*, the

FIG. 1182.—A vertical section through a villus of the small intestine of a dog. × 80.

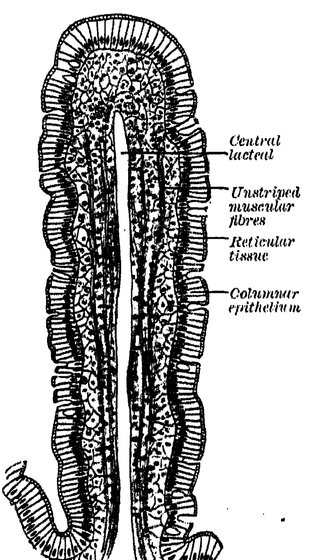


FIG. 1183.—A transverse section through a villus of the human intestine. × 350. (v. Ebner.)

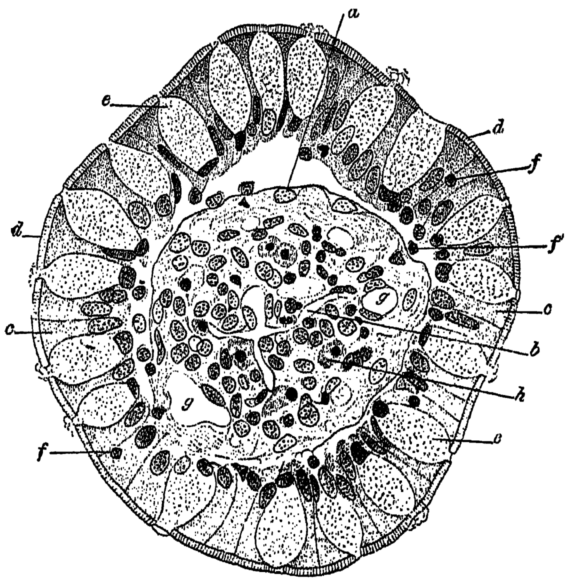

a. Basement-membrane, here somewhat shrunken away from the epithelium. *b*. Lacteal. *c*. Columnar epithelium; *d*. its striated border. *e*. Goblet-cells. *f*. Leucocytes in epithelium. *f'*. Leucocyte below epithelium. *g*. Blood-vessels. *h*. Muscle-cells cut across.

characteristics of which have been described above. The *retiform tissue* forms a network (fig. 1183) in the meshes of which a number of leucocytes are found.

The **intestinal glands** (fig. 1185) are found in considerable numbers over every part of the mucous membrane of the small intestine. They are simple tubular glands, arranged perpendicularly to the surface, upon which they open by small circular apertures. Their orifices may be seen with the aid of a lens as minute dots scattered between the villi. Their walls are thin, consisting of a basement-membrane lined with columnar epithelium, and covered on their exterior with capillary vessels. The deeper cells, especially in the duodenal glands, contain granules which stain characteristically with phosphotungstic haematoxylin and are termed *granules of Paneth*.

The **duodenal glands** are limited to the duodenum (fig. 1180), and are found in the submucous areolar tissue. They are largest and most numerous near the pylorus, forming an almost complete layer in the first part, and upper half of the second part, of the duodenum; beyond this they gradually diminish in number and disappear at the junction of the duodenum and jejunum. They are small, compound, acinotubular glands, each consisting of a number of alveoli lined with short columnar epithelium and opening by a duct on the inner surface of the intestine.

The **solitary lymphatic nodules** are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. Their free surfaces are covered with rudimentary villi, except at the summits, and each nodule is surrounded by the openings of the intestinal glands. Each consists of a dense, interlacing, retiform tissue closely packed with lymph-corpuscles, and permeated by an abundant, capillary network.

The interspaces of the retiform tissue are continuous with larger lymph-spaces which surround the nodule, and by this means they are enabled to communicate with the lacteal

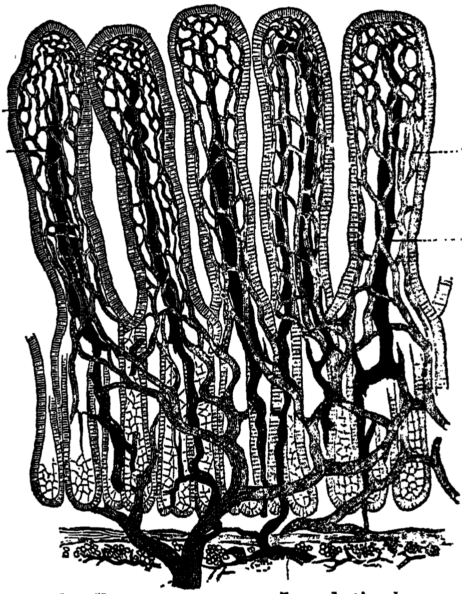

FIG. 1184.—The villi of the small intestine, showing the blood-vessels and the lymph vessels. (Cadiat.)

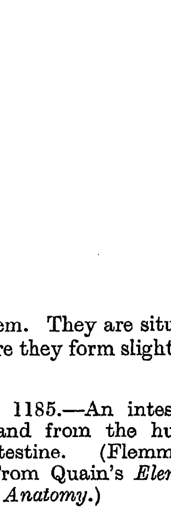
system. They are situated partly in the submucous tissue, and partly in the mucous coat, where they form slight projections of its epithelial layer.

FIG. 1185.—An intestinal gland from the human intestine. (Flemming.) (From Quain's *Elements of Anatomy*.)

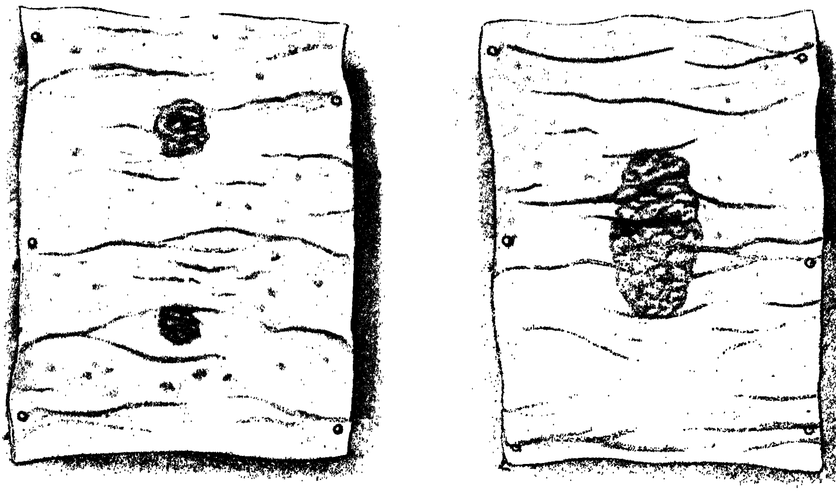


The **aggregated lymphatic nodules** (figs. 1186, 1187) form circular or oblong patches, from twenty to thirty in number, and varying in length from 2 cm. to 10 cm. Like the other collections of lymphoid tissue in the body, they are best marked in the young subject, become indistinct in middle age, and usually disappear altogether in advanced life. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, circular and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of solitary lymphatic nodules covered with columnar epithelium; the patches do not, as a rule, possess villi on their free surfaces. They are freely supplied with blood-vessels, which form an abundant plexus around each nodule and give off fine branches to permeate the lymphoid tissue in the interior of the nodule. The plexuses of lymph vessels are especially abundant around these patches.

Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the jejunal and ileal branches of which, having reached the attached border of the bowel, run between the serous and muscular coats. From these vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The anastomoses between the terminal intestinal branches are by no means free, and there is a distinct tendency for the alternate vessels to be distributed to opposite sides of the gut. The *veins* have a course and arrangement similar to the arteries. The *lymph vessels* of the small intestine [lacteals] are arranged in two sets, viz. those of the mucous membrane and those of the muscular coat. The lymph vessels of the villi commence in these structures in the manner

described on p. 1329. They form an intricate plexus in the mucous and submucous tissue, being joined by the lymph vessels from the lymph-spaces at the bases of the solitary nodules, and from there pass to larger vessels at the mesenteric border of the

FIG. 1186.—Aggregated lymphatic nodules. A, from the upper part, and B, from the lower part, of the ileum.



A B

gut. The lymph vessels of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a close plexus; throughout their course they communicate freely with those from the mucous membrane, and open in

the same manner as these into the origins of the lacteal vessels at the attached border of the gut.

The *nerves* of the small intestine are derived from the vagus and splanchnic nerves through the cœliac ganglia and the plexuses around the superior mesenteric artery. They run to the

myenteric plexus (*Auerbach's plexus*) of nerves and ganglia, situated between the circular and longitudinal layers; from this plexus filaments are distributed to the muscular coats of the intestine. From the myenteric plexus a secondary plexus, termed the *plexus of the submucosa* (*Meissner's plexus*), is derived, and is formed by branches which have perforated the circular muscular layer. This plexus also contains ganglia from which the nerve-fibres pass to the muscularis mucosæ and to the mucous membrane. The nerve-bundles of the submucous plexus are finer than those of the myenteric plexus.

Keith states that 'Auerbach's plexus is not composed simply of ganglionic cells and nerve-fibres; it contains numerous other cells to which Kölliker called attention, and which may be described as Kölliker's cells. These cells have small bodies which send out numerous branched processes, and differ from pure sheath-cells in staining reaction and structure. It is through these cells that Auerbach's tissue is linked up with the musculature of the bowel. The nerve-fibres which former authors have described as distributed to the muscular and other coats of the bowel are probably sensory in nature. Sections of the developing bowel show that the outer and inner muscular coats are developed from a germinal layer situated between them. Auerbach's plexus represents the residue of the germinal or developmental intermediate layer. Probably the ganglionic cells may be of central origin, but the cells of Kölliker are apparently undifferentiated muscle-cells.' He adds that in point of development Auerbach's plexus is similar in origin to that of the atrioventricular bundle, and is of opinion that they are homologous.*

The Large Intestine [Intestinum Crassum]

The **large intestine** extends from the end of the ileum to the anus, and is about 1·5 metres long. Its calibre is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. In appearance, structure, size and arrangement it presents certain differences from the small intestine. (1) It has a greater calibre. (2) For the most part, it is more fixed in position. (3) Its longitudinal muscular fibres do not form a continuous layer round the gut but are arranged in three longitudinal bands or *tæniæ coli*. (4) Since these tæniæ are shorter than the circular muscular coat, the colon is puckered and sacculated. (5) Little, peritoneum-covered, fatty projections, termed *appendices epiploicæ*, are found scattered over the free surface of the whole of the large intestine, with the exceptions of the cæcum, the vermiform appendix and the rectum.

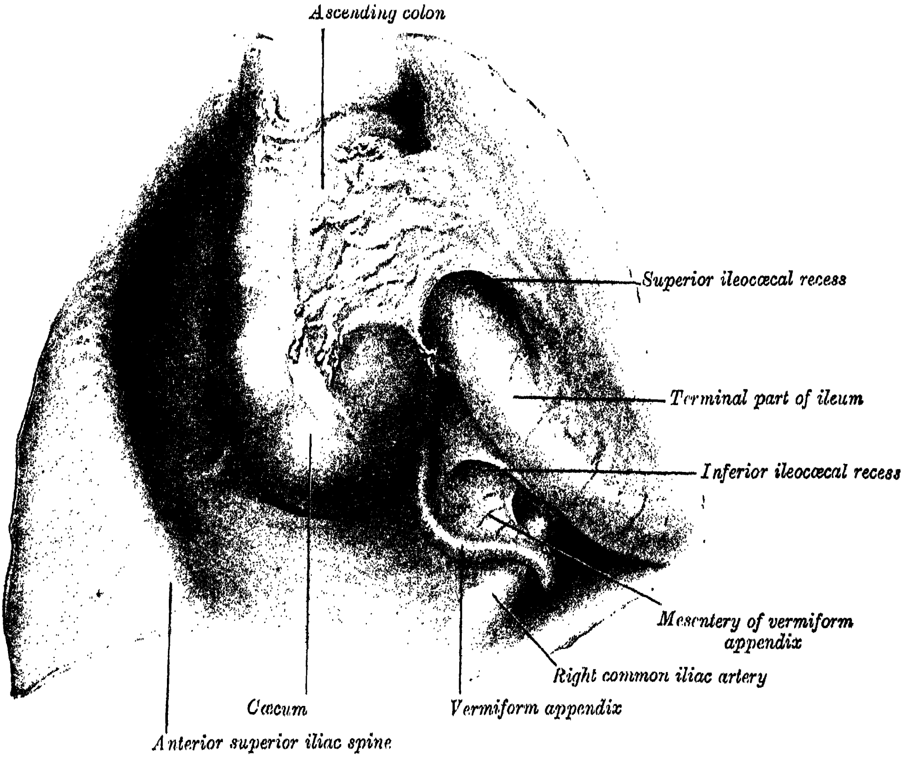
In its course the large intestine describes an arch which usually encloses the convolutions of the small intestine. It commences in the right iliac region, in a dilated part, termed the *cæcum* (fig. 1188). It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; here it bends [the *right colic flexure*] (fig. 1178) to the left, and, curving with a downward and a forward convexity, passes, as the *transverse colon*, across the abdomen to the left hypochondriac region; it then bends again [the *left colic flexure*] (fig. 1178), and descends through the left lumbar and iliac regions to the pelvis, where it forms a loop called the *pelvic colon* (fig. 1191); from this it is continued along the lower part of the posterior wall of the pelvis to the anus. It is divided into the cæcum, the colon, the rectum and the anal canal.

The **cæcum** (fig. 1188), which is the commencement of the large intestine, lies in the right iliac fossa. It is a large sac which has a blind lower end but is continuous above with the ascending colon, and at the point where the one passes into the other the ileum opens into the large intestine from the medial side. Its average length is about 6 cm. and its breadth about 7·5 cm. It is situated in the right iliac fossa above the lateral half of the inguinal ligament: it rests on the Iliacus, from which it is separated by its covering fascia and the lateral cutaneous nerve of the thigh, and on Psoas major. In front it is usually in contact with the anterior abdominal wall, but the greater omentum, and, if the cæcum is empty, some coils of small intestine, may lie in front of it. As a rule, it is entirely enveloped by peritoneum, but in about 5 per cent. of cases (Berry) the peritoneal covering is incomplete, the upper part of the posterior surface being uncovered, and connected to the iliac fascia by areolar tissue. The cæcum enjoys a considerable amount of movement, so that it may become herniated down the right inguinal canal, and it has occasionally been found in an inguinal hernia on the left side.

* *Proceedings of the Anatomical Society of Great Britain and Ireland*, January 1915.

The cæcum varies in shape, but, according to Treves, it may be classified under one of four types. In early fœtal life it is short, conical, and broad at the base, with its apex turned upwards and medially towards the ileocolic junction. It then resembles the cæcum of the mangabey monkey. As the fœtus grows, the cæcum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and lacks the broad base, but still has the same inclination of the apex towards the ileocolic junction. This form is seen in the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth the narrow vermiform appendix hangs from the apex of a conical cæcum. This is the infantile form, and as it persists throughout life in about 2 per cent. of subjects, it was regarded by Treves as the *first* of his four types of human cæca. The cæcum is conical and the appendix rises from its apex. The three tæniæ coli (p. 1340) start from the appendix and are equidistant from each other. In the *second* type, the conical cæcum has become quadrate by the outgrowth of a

FIG. 1188.—The terminal part of the ileum, the cæcum and the vermiform appendix. Viewed from in front.

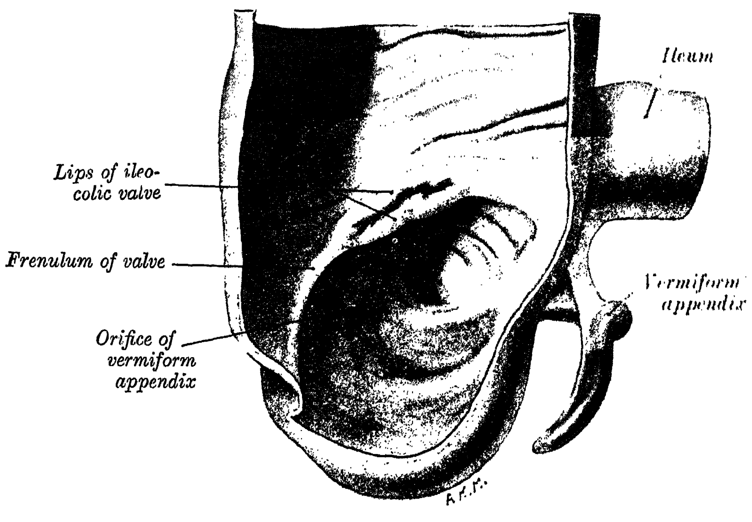


saccule on each side of the anterior tænia. These saccules are of equal size, and the appendix arises from the depression between them, instead of from the apex of a cone. This type is found in about 3 per cent. of subjects. The *third* type is the normal type for man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the downward growth of the right saccule, and the original apex, with the appendix attached, is pushed over to the left towards the ileocolic junction. The three tæniæ still start from the base of the vermiform process, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and posterolateral tæniæ, pushing them over to the left. This type occurs in about 90 per cent. of subjects. The *fourth* type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has become atrophied, so that the original apex of the cæcum, with the vermiform appendix, is close to the ileocolic junction, and the anterior tænia courses medially to the same situation. This type is present in about 4 per cent. of subjects.

The ileocolic valve (fig. 1189).—The lower end of the ileum opens into the medial and posterior aspect of the large intestine, at the point of junction of the cæcum with the colon. The opening is provided with a valve, consisting of two

segments or lips, which project into the lumen of the large intestine. If the intestine has been inflated and dried, the lips are of a semilunar shape. The upper lip, nearly horizontal in direction, is attached by its convex border to the line of junction of the ileum with the colon ; the lower lip, the longer and more concave, is attached to the line of junction of the ileum with the cæcum. At the ends of the aperture the two segments of the valve coalesce, and are continued as narrow membranous ridges around the canal for a short distance, forming the *frenula* of the valve. The left or anterior end of the aperture is rounded ; the right or posterior is narrow and pointed. In the fresh condition, or in specimens which have been hardened *in situ*, the circular muscular coat of the ileum is thickened to form a sphincter-like valve, while the lips of the valve project as thick folds into the lumen of the cæcum, and the opening between them may present the appearance of a slit or may be somewhat oval in shape.

FIG. 1189.—The interior of the cæcum and the lower end of the ascending colon, showing the ileocolic valve.



Each lip of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly from the small to the large intestine.

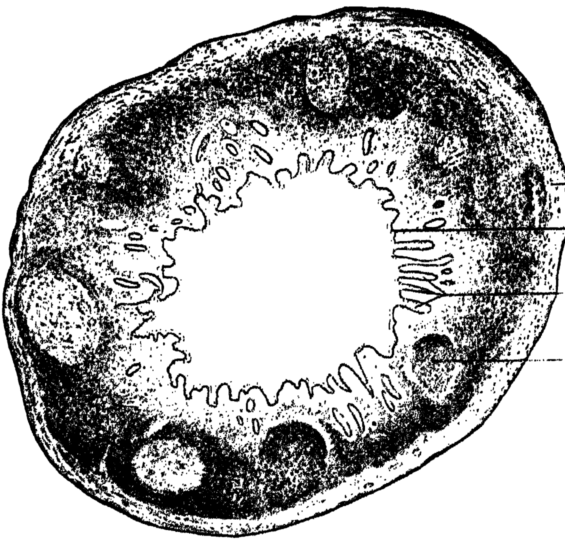
The surfaces of the valve directed towards the ileum are covered with villi and present the characteristic structure of the mucous membrane of the small intestine ; while those turned towards the large intestine are destitute of villi and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. It was formerly maintained that this valve prevented reflux from the cæcum into the ileum, but in all probability it acts as a sphincter round the end of the ileum and prevents the contents of the ileum from passing too quickly into the cæcum ; the valve is kept in a condition of tonic contraction by impulses which reach it through the splanchnic nerves.

The **vermiform appendix** (fig. 1188, Pl. XVII) is a long, narrow, worm-shaped tube, which springs from the posteromedial wall of the cæcum, 2 cm. or less below the end of the ileum, and may occupy one of several positions*: (*a*) it may lie behind the cæcum and the lower part of the ascending colon (*postcæcal and retrocolic*),

* R. J. Gladstone and Cecil P. G. Wakeley (*British Journal of Surgery*, vol. xi. No. 43, 1924) examined the positions of the vermiform appendix in 3000 subjects and found it to be postcæcal and retrocolic in 69·2 per cent., pelvic in 27·5 per cent., subcolic in 1·86 per cent., and pre- and postileal in 1·4 per cent. These percentages differ very markedly from those given by other observers.

(*b*) it may hang down over the brim of the pelvis (*pelvic* or *descending*), (*c*) it may lie below the cæcum (*subcolic*), (*d*) it may lie in front of the terminal part of the ileum and may then be in contact with the anterior abdominal wall, and (*e*) it may lie behind the terminal part of the ileum. It varies from 2 cm. to 20 cm. in length, the average being about 9 cm. It is connected by a short mesentery to the lower part of the mesentery of the ileum. This fold, in the majority of cases, is more or less triangular in shape, and as a rule extends along the entire length of the tube. The appendicular artery lies between the two layers of the appendicular mesentery, and close to its free margin. The canal of the vermiform appendix is small, and communicates with the cæcum by an orifice which is placed below and a little behind the ileocolic opening. The orifice is sometimes guarded by a semilunar valve formed by a fold of mucous membrane.

FIG. 1190.—A transverse section through the human vermiform appendix. ×20.



Structure.—The coats of the vermiform appendix are the same as those of the intestine: serous, muscular, submucous and mucous. The *serous* coat forms a complete investment for the tube, except along the narrow line of attachment of its mesentery. The *longitudinal muscular fibres* do not form three bands as in the greater part of the large intestine, but invest the whole organ, except at one or two points where both the longitudinal and circular layers are deficient, so that the peritoneal and submucous coats are contiguous over small areas. The *circular muscular fibres* form a thicker layer than the longitudinal fibres, and are separated from them by a small amount of connective tissue. The *submucous* coat is well developed, and contains a large number of masses of lymphoid tissue which cause the mucous membrane to bulge into the lumen and so render the latter of small size and irregular shape. The *mucous membrane* is lined with columnar epithelium and resembles that of the rest of the large intestine, but the intestinal glands are fewer in number (fig. 1190).

The **colon** is divided into four parts: the ascending, transverse, descending and pelvic.

The **ascending colon**, about 15 cm. long, is smaller in calibre than the cæcum. It begins at the cæcum, and ascends to the under surface of the right lobe of the liver, where it is lodged in a shallow depression, termed the colic impression; here it bends abruptly forwards and to the left, forming the *right colic flexure* (fig. 1178). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its sides and anterior surface, its posterior surface being connected by loose areolar tissue with the Iliacus, iliolumbar ligament, Quadratus lumborum, aponeurotic origin of Transversus abdominis, and with the front of the lower and lateral part of the right kidney. The lateral cutaneous nerve of the thigh, the fourth lumbar artery (as a rule) and, sometimes, the ilio-inguinal and iliohypogastric nerves cross behind it. Sometimes it is com-

pletely invested with peritoneum, and it then possesses a distinct but narrow mesocolon.* It is in relation, in front, with the convolutions of the ileum, the right edge of the greater omentum and the abdominal parietes.

The *right colic flexure* comprises the terminal part of the ascending colon and the commencement of the transverse colon, which turns downwards, forwards and to the left. Behind, it is in relation with the lower and lateral part of the anterior surface of the right kidney. Above and anterolaterally, it is related to the right lobe of the liver; anteromedially, to the second part of the duodenum and the fundus of the gall bladder.

The **transverse colon** (fig. 1168), about 50 cm. long, begins at the right colic flexure, in the right hypochondriac region, and, passing across the abdomen into the left hypochondriac region, curves sharply on itself, downwards and backwards, beneath the lower end of the spleen, forming the *left colic flexure*. In its course across the abdomen it describes an arch, the concavity of which is usually directed backwards and upwards; towards its splenic end there is often an abrupt U-shaped curve which may descend lower than the main curve. The precise position occupied by the transverse colon is difficult to define, for it not only shows variations from individual to individual but its position varies in the same individual from time to time. Very commonly it lies in the lower umbilical or upper hypogastric region, but it is often found at a higher level, especially in formalin-hardened subjects. The posterior surface of its right extremity is devoid of peritoneum, and is attached by areolar tissue to the front of the second part of the duodenum and the head of the pancreas. Between the head of the pancreas and the left colic flexure the transverse colon is almost completely invested by peritoneum, and is connected to the anterior border of the pancreas by the *transverse mesocolon*. It is in relation, by its upper surface, with the liver and gall-bladder, the greater curvature of the stomach, and the lateral end of the spleen; by its under surface, with the small intestine; by its anterior surface with the anterior layers of the greater omentum and the abdominal parietes; its posterior surface is in relation with the second portion of the duodenum, the head of the pancreas, the upper end of the mesentery, the duodenojejunal flexure and some of the coils of the jejunum and ileum.

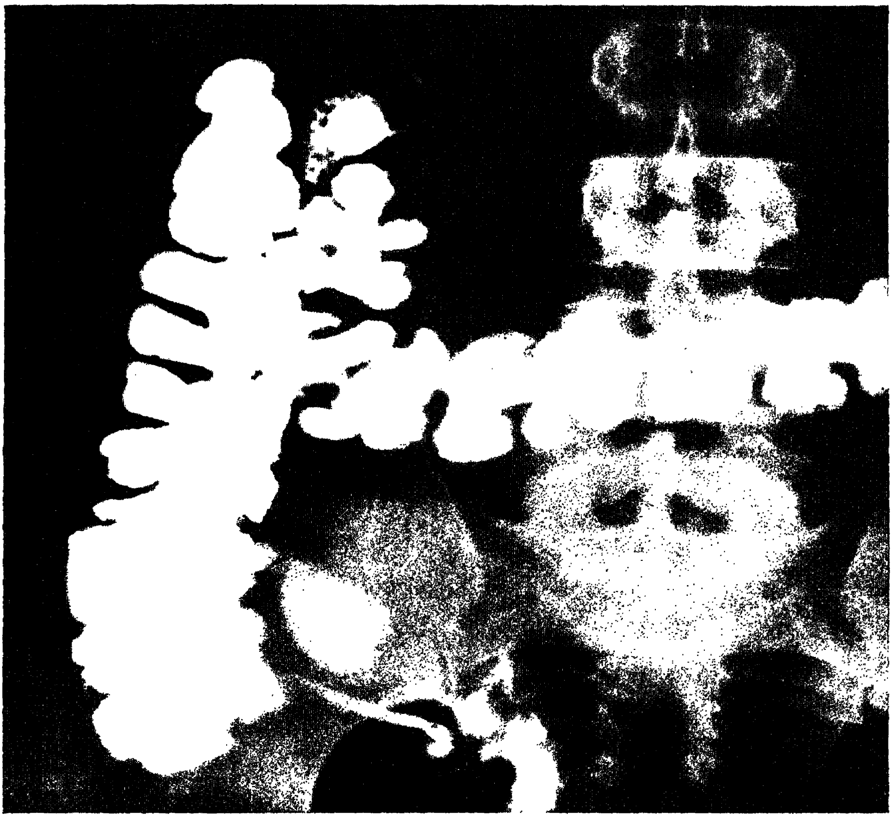
The *left colic flexure* (fig. 1178) is situated at the junction of the transverse and descending parts of the colon in the left hypochondriac region, and is in relation with the lateral end of the spleen and the tail of the pancreas, above, and with the anterior aspect of the left kidney, medially; the flexure is so acute that the end of the transverse colon usually lies in contact with the front of the descending colon. The left colic flexure lies at a higher level than, and on a plane posterior to, the right colic flexure (Pl. XVI, fig. 2), and is attached to the Diaphragm, opposite the tenth and eleventh ribs, by a peritoneal fold, named the *phrenicocolic ligament*, which lies in relation to the lateral end of the spleen (p. 1314).

The **descending colon** (fig. 1178), about 25 cm. long, passes downwards through the left hypochondriac and lumbar regions. At first it follows the lower part of the lateral border of the left kidney and then, at the lower pole of that organ, it descends, in the angle between Psoas major and Quadratus lumborum, to the crest of the ilium; it then curves downwards and medially in front of the Iliacus and Psoas major, and ends in the pelvic colon at the inlet of the true pelvis.† The peritoneum covers its anterior surface and sides, while its posterior surface is connected by areolar tissue with the lower and lateral part of the left kidney, the aponeurotic origin of the Transversus abdominis, the Quadratus lumborum, the Iliacus and the Psoas major (fig. 1191). Numerous structures cross behind it. They include :—the subcostal vessels and nerve, the iliohypogastric and ilio-inguinal nerves, the fourth lumbar artery (as a rule), the lateral femoral cutaneous, femoral and genitofemoral nerves, the testicular

* Treves examined one hundred subjects, and found that in fifty-two there was neither an ascending nor a descending mesocolon; in fourteen both were present; while in twelve there was an ascending, and in twenty-two a descending, mesocolon. It follows, therefore, that when lumbar colotomy is performed, a mesocolon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent.—*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.

† The descending colon is sometimes described as ending at the level of the iliac crest, the part between that level and the inlet of the true pelvis being named the *iliac colon*.

PLATE XVII



Radiograph of part of the large intestine after a barium meal.

Note the vermiform appendix, which passes from the medial side of the caecum medially and slightly downwards into the true pelvis. At a slightly higher level the terminal part of the ileum can be recognised. The first part of the transverse colon runs downwards in front of, and slightly medial to, the ascending colon, before it turns to the left.

PLATE XVIII

Radiograph of the genital tract in the female, after an injection of barium sulphate into the uterus.

X = body of uterus. Note the two cornua leading to the uterine tubes.

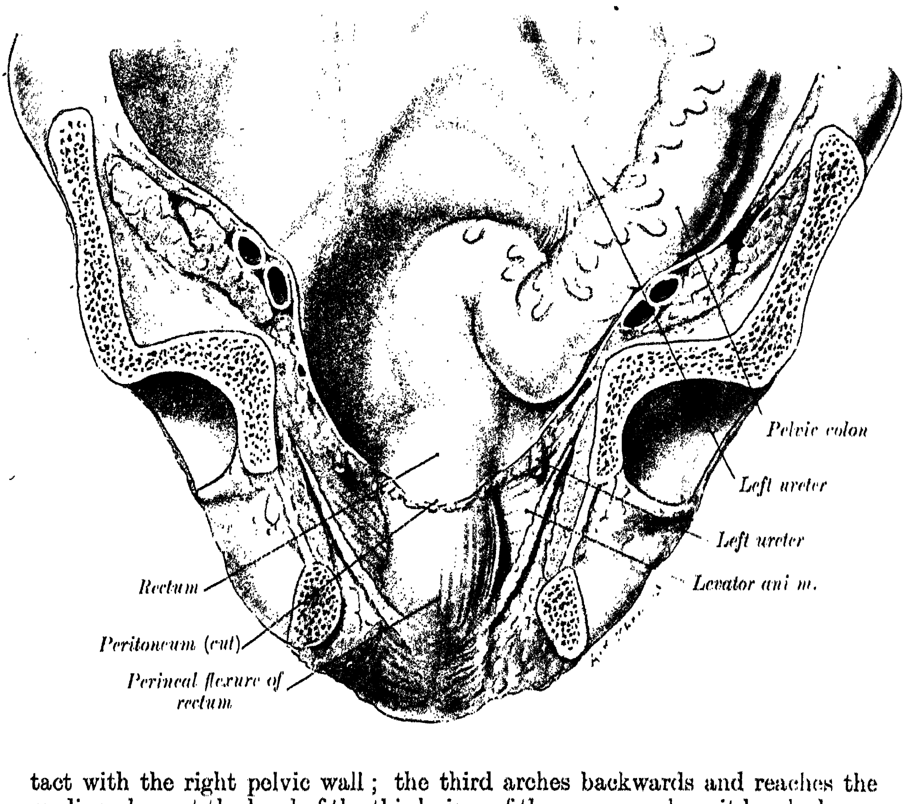
XX = speculum in vagina.

The arrows indicate the infundibula of the uterine tubes. Some of the barium has passed through the pelvic opening of the tube into the general peritoneal cavity.

(or ovarian) vessels and the external iliac artery, all of the left side. The descending colon is smaller in calibre, more deeply placed, and more frequently covered with peritoneum on its posterior surface, than the ascending colon (p. 1336 *). Anteriorly it is related to coils of the jejunum.

The **pelvic colon** (fig. 1191) begins at the inlet of the true pelvis, where it is continuous with the descending colon; it forms a loop which varies greatly in length, but averages about 40 cm., and normally lies within the pelvis. The loop consists of three parts; the first part descends in contact with the left pelvic wall; the second crosses the pelvic cavity, between the rectum and bladder in the male, and the rectum and uterus in the female, and may come into con-

FIG. 1191.—An oblique coronal section through the pelvis to expose the rectum from in front.

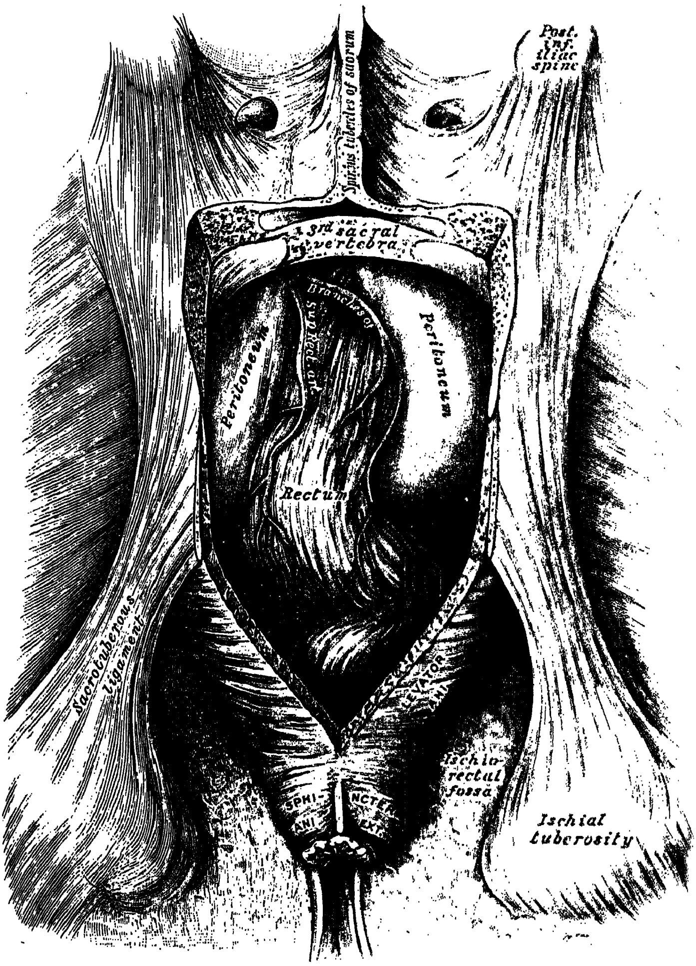


tact with the right pelvic wall; the third arches backwards and reaches the median plane at the level of the third piece of the sacrum, where it bends downward and ends in the rectum. The pelvic colon is completely surrounded by peritoneum, which forms a mesentery, termed the *pelvic mesocolon* (p. 1314); this diminishes in length from the centre towards the ends of the loop, where it disappears, so that the loop is fixed at its junctions with the descending colon and rectum, but enjoys a considerable range of movement in its central portion. Its relations are therefore subject to considerable variation. *Laterally* it is related to the external iliac vessels, the obturator nerve, the ovary (in the female), the vas deferens (in the male) and the lateral pelvic wall. *Posteriorly* it is related to the internal iliac (hypogastric) vessels, the ureter, the Piriformis and the sacral plexus, all of the left side. *Inferiorly* it rests on the bladder, in the male, and on the uterus and bladder, in the female. *Above* and on its *right side*, it is in contact with the terminal coil of the ileum.

The position and shape of the pelvic colon vary very much, and depend on (*a*) its length; (*b*) the length and freedom of its mesocolon; (*c*) the condition of distension; when distended it rises out of the pelvis into the abdominal cavity, and when empty it sinks again into the pelvis; (*d*) the condition of the rectum and bladder (and the uterus, in the female); when these organs are distended the pelvic colon tends to rise, and conversely.

The **rectum** (figs. 1191 to 1193) is continuous above with the pelvic colon, whilst below it ends in the anal canal. From its origin at the level of the third sacral vertebra it passes downwards, lying in the sacrococcygeal curve, and extends for 2 or 3 cm. in front of, and a little below, the tip of the coccyx, as far as the apex of the prostate. It then bends sharply backwards into the anal canal. It therefore presents two anteroposterior flexures: an upper or *sacral flexure* with its convexity backwards, and a lower or *perineal flexure* with its

FIG. 1192.—The rectum viewed from behind. Exposed by the removal of the lower part of the sacrum and the coccyx.



convexity forwards. Three lateral curves are also described, one convex to the right opposite the junction of the third and fourth sacral vertebræ, a second convex to the left, opposite the sacrococcygeal articulation, and a third, convex to the right, in front of the tip of the coccyx. As a result of these lateral curves the rectum is not exactly in the median plane, except at its upper and lower ends, the intermediate part bulging towards the left. The rectum is about 12 cm. long, and at its commencement its calibre is similar to that of the pelvic colon, but near its termination it is dilated to form the *rectal ampulla*. It has no sacculations comparable to those of the colon, but when the lower part of it is contracted its mucous membrane is thrown into a number of folds, which are longitudinal in direction and are effaced by the distension of the gut. Besides these there are certain permanent *horizontal folds* of a semilunar shape (fig. 1193). There are usually three of these horizontal folds, but sometimes four or five, and frequently only two, are present. One is situated near the commence-

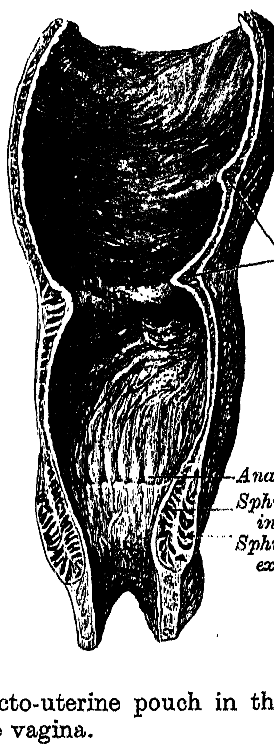
ment of the rectum, on the right side ; a second extends inwards from the left side of the tube at a slightly lower level ; a third, the largest and most constant, projects backwards from the fore part of the rectum, opposite the fundus of the urinary bladder. When a fourth is present, it is situated nearly 2·5 cm. above the anus, on the left and posterior wall of the tube. These folds are about 12 mm. in width and contain some of the circular fibres of the gut. In the empty state of the intestines they overlap each other so effectually that considerable manœuvring is required to conduct a bougie or the finger along the canal. Their use seems to be 'to support the weight of fæcal matter, and prevent its urging towards the anus, where its presence always excites a sensation demanding its discharge.' *

The peritoneum is related to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only ; from the latter it is reflected on to the bladder in the male and the posterior vaginal wall in the female.

The level at which the peritoneum is reflected from the rectum to the viscus in front of it is higher in the male than in the female. In the former the height of the rectovesical pouch is about 7·5 cm. (i.e. the height to which an ordinary index finger can reach) from the anus. In the female the height of the recto-uterine pouch is about 5·5 cm. from the anal orifice. The lower part of the rectum is surrounded by a dense tube of fascia which consists of a localised thickening and compression of the extraperitoneal tissue ; this fascial tube is loosely attached to the rectal wall by areolar tissue, in order to allow of distension of the viscus.

Relations of the rectum.—The upper part of the rectum is in relation, *behind*, with the lower three sacral vertebræ, the coccyx and the anococcygeal raphe, in the median plane, but the median sacral vessels, the ganglion impar and, at its upper end, the superior rectal vessels intervene. On each side of the median plane, but especially on the left side, the rectum lies in front of the Piriformis muscle, the third, fourth and fifth sacral and the coccygeal nerves, the sympathetic trunk, the lower lateral sacral vessels, the Coccygeus and the Levator ani muscles ; it is attached to the sacrum along the lines of the sacral foramina by fibro-areolar tissue which surrounds the sacral nerves and the branches of the superior rectal vessels passing to the bowel. *In front*, the rectum is related, above, to the rectovesical pouch of the peritoneum, in the male, to the recto-uterine pouch in the female. These pouches contain the terminal coils of the ileum, and frequently the pelvic colon. Below the rectovesical pouch in the male the anterior surface of the rectum is in relation with a portion of the base of the bladder, the vesiculæ seminales and vasa deferentia. The rectal ampulla is related in front to the posterior surface of the prostate, a loose, cellular interval separating it from the recto-vesical fascia, which forms the posterior wall of the prostatic sheath ; below the recto-uterine pouch in the female, it is in relation with the posterior wall of the vagina.

FIG. 1193.—A coronal section through the rectum and anal canal.



* Paterson (*Journal of Anatomy and Physiology*, vol. xliii.) utilised the third fold for the purpose of dividing the rectum into an upper and a lower portion ; he considered the latter 'to be just as much a duct as the narrower anal canal below,' and maintained that, under normal conditions, it does not contain fæces except during the act of defæcation. Hurst (*Constipation*, Oxford University Press, 1919) believes that the pelvic colon acts as a reservoir and that, in normal individuals, the passage of fæces from the pelvic colon into the rectum is always followed by the desire to defæcate.

The **anal canal** (fig. 1193) begins at the level of the apex of the prostate, is directed downwards and backwards through the pelvic floor, and ends at the anus. It forms an angle with the lower part of the rectum, and is from 2 to 3 cm. long. It has no peritoneal covering, but is invested by the Sphincter ani internus, supported by the Levatores ani, and surrounded at its termination by the Sphincter ani externus. In the empty condition it presents the appearance of an anteroposterior longitudinal slit. Behind, it is in contact with a mass of muscular and fibrous tissue, termed the *anococcygeal body* (Symington); in front, it is separated by the *perineal body* from the membranous part of the urethra and the bulb of the penis in the male, and from the lower end of the vagina in the female.

The upper half of the anal canal is lined by mucous membrane which presents from six to ten vertical folds known as the *anal* (rectal) *columns*. These columns are usually well marked in the new-born child (fig. 1194), but are often ill-defined in the adult. They are produced by infoldings of the mucous membrane and of some of the longitudinal muscular tissue, and each contains a small artery and vein. They are separated from one another by furrows, and end below in small crescentic valve-like folds, termed *anal valves*; these valves join together the lower ends of the anal columns, and each forms the inner wall of a small pouch or *anal sinus*.

The lower half of the anal canal is lined with skin (p. 172) and exhibits a series of folds extending upwards from the anus towards the anal columns. The junction of the skin and mucous membrane is indicated by a white line, which is somewhat wavy 'owing to the interlocking of the cutaneous and mucous folds' (Symington).

The **anus** or **anal orifice** is the lower aperture of the anal canal, and is situated in front of the apex of the coccyx in the cleft between the buttocks. The skin surrounding it is thrown into a series of folds which converge towards the orifice and are continued upwards into the lower part of the anal canal.

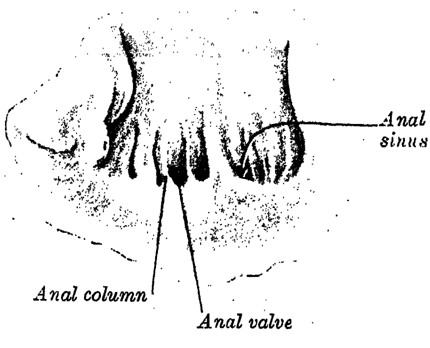
Structure of the large intestine.—The large intestine has four coats: serous, muscular, areolar and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent (*vide ante*). In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicæ*. They are most numerous on the transverse colon.

The *muscular coat* consists of an external longitudinal, and an internal circular layer of non-striped muscular fibres.

The *longitudinal fibres* do not form a continuous layer over the whole surface of the large intestine. In the cæcum and colon they are collected into three longitudinal bands (*tæniæ coli*), each of about 12 mm. in width; one (the *tænia mesocolica*) is placed along the attached border of the intestine; the second and largest (the *tænia omentalis*) corresponds, along the curve of the transverse colon, with the attachment of the greater omentum, but is placed anteriorly in the ascending, descending and pelvic parts of the colon; the third (the *tænia libera*) is found on the medial sides of the ascending and descending parts of the colon, and on the under surface of the transverse colon. These bands are shorter than the other coats of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the pelvic colon the longitudinal fibres become more scattered; and round the rectum they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, so that an anterior and a posterior band can be recognised. At the rectal ampulla, a few strands of the anterior longitudinal fibres pass forwards to the perineal body (fig. 608); they constitute the *recto-urethralis muscle*. In addition, two fasciculi of plain muscular tissue arise from the front of the second and third coccygeal vertebræ, and pass downwards and forwards to blend with the lon-

FIG. 1194.—The interior of the anal canal of a new-born child.



gitudinal muscular fibres on the posterior wall of the anal canal. These are known as the *Rectococcygeal muscles.* A thin stratum of involuntary muscular fibres radiates from the anal orifice and is named the *Corrugator cutis ani.* Centrally the fibres fade off into the subcutaneous tissue ; externally they blend with the true skin.

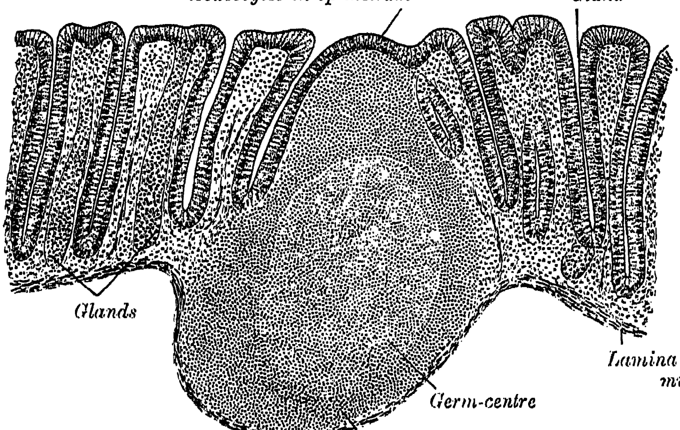
The *circular fibres* form a thin layer over the cæcum and colon, being especially accumulated in the intervals between the sacculi ; in the rectum they form a thick layer, and in the anal canal they become numerous, and constitute the Sphincter ani internus.

The Sphincter ani internus is a muscular ring which surrounds the upper 2·5 cm. of the anal canal ; below, it is in contact with the Sphincter ani externus and, posteriorly and on each side, it is covered by the Puborectalis. It assists the Sphincter ani externus and the Puborectalis to occlude the anal canal.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane* of the cæcum and colon is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond with the intervals between the sacculi ; that of the rectum is thicker, of a darker colour, more vascular and connected loosely with the muscular coat.

FIG. 1195.—A section through the mucous membrane of the human rectum. × 60. (Sobotta.)



As in the small intestine, the mucous membrane consists of a muscular layer [lamina muscularis mucosæ] ; a quantity of retiform tissue in which the vessels ramify ; a basement-membrane, and an epithelium which is of the columnar variety and resembles the epithelium found in the small intestine. The mucous membrane of the large intestine presents for examination glands and solitary lymphatic nodules.

The *glands* of the large intestine are minute tubular prolongations of the mucous membrane arranged perpendicularly to its surface ; they are longer, more numerous, and placed in much closer apposition than those of the small intestine ; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance. Each gland is lined with short columnar epithelium, the majority of the cells being goblet-cells.

The *solitary lymphatic nodules* (fig. 1195) of the large intestine are most abundant in the cæcum and vermiform appendix, but are irregularly scattered over the rest of the large intestine also. They are similar to those of the small intestine.

The structure of the vermiform appendix is described on p. 1335.

Vessels and Nerves —The *arteries* supplying the colon are derived from the colic branches of the mesenteric arteries. They give off large branches, which ramify between and supply the muscular coats, and after dividing into small vessels in the submucous tissue pass to the mucous membrane. The rectum is supplied by the superior rectal (hæmorrhoidal) branch of the inferior mesenteric, and the anal canal by the middle rectal from the internal iliac (hypogastric), and the inferior rectal from the internal pudendal artery. The superior rectal (the continuation of the inferior mesenteric) divides into two branches, which run down one on each side of the rectum ; they divide into a number of branches, which pierce the muscular coat and descend between it and the mucous membrane in the anal columns as far as the Sphincter ani internus, where they anastomose with the other rectal arteries and form a series of loops around the anus. The *veins* of the rectum commence in a plexus of vessels which surrounds the anal canal. In the vessels forming this plexus small saccular dilatations occur just within the margin of the anus ; from the plexus about six vessels of considerable size are given off. These ascend between the muscular and mucous coats,

running parallel to one another; at about the middle of the rectum they pierce the muscular coat, and, by their union, form a single trunk [the superior rectal vein]. This arrangement is termed the *rectal* (*hæmorrhoidal*) *plexus*; it communicates with the tributaries of the middle and inferior rectal veins, at its commencement, and thus a communication is established between the systemic and portal circulations. The *nerves* are derived from the second, third and fourth sacral nerves (parasympathetic), and from the sympathetic, through the pelvic plexuses. They are distributed in a similar way to those found in the small intestine.

The *lymph glands and vessels* of the large intestine are described on pp. 868, 870.

Applied Anatomy.—The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one coil glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of it may be ruptured, but probably the most common situation is the third part of the duodenum, because it is more fixed than other portions of the bowel, and because it is situated in front of the vertebral column, so that if this portion of the intestine is struck by a sharp blow, such as the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. Intussusception, most commonly an invagination of the small intestine into the large, may take place; it may attain great size, and it is possible in these cases to find the ileocolic valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may also lead to intestinal obstruction.

The vermiform appendix is very liable to become inflamed, because it contains a relatively large amount of lymphoid tissue, which is prone to bacterial infection. In many cases the inflammation is set up by the impaction in it of a solid mass of fæces or a foreign body, or by the inspissation of its mucous secretion in catarrhal conditions. The inflammation may result in ulceration and perforation, or if very acute in gangrene of the organ. These conditions generally require immediate operative interference.

In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved it is usually the cæcum or the pelvic colon. In some few cases the vermiform appendix has been the part implicated in strangulated hernia.

The calibre of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the pelvic colon with the rectum. At or a little below this point stricture most commonly occurs, and diminishes in frequency as one proceeds upwards to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the right and left colic flexures, which are more deeply placed; the distension is most obvious in the flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is the portion of the bowel which becomes most distended. It may assume enormous dimensions, and may rupture from the distension, leading to rapidly fatal peritonitis. The mobility of the pelvic colon renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. This generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesocolon is elongated.

Hernia.—The two chief sites at which external hernia may take place are the inguinal region and the femoral canal. The description of the inguinal canal and its relations will be found on p. 571 and that of the femoral canal on p. 785. The peritoneal areas concerned are described on p. 1309.

In the usual position of the parts, the floor of the lateral inguinal fossa corresponds to the deep (abdominal) inguinal ring, and into this fossa an oblique inguinal hernia descends. On the medial side of the epigastric fold are the medial inguinal and the supravesical fossæ, and through either of these a direct hernia may descend. The whole of the space between the inferior epigastric artery, the margin of the Rectus abdominis, and the inguinal ligament, is known as the inguinal triangle.

Inguinal hernia.—Inguinal hernia is that form of protrusion which makes its way through the abdominal wall in the inguinal region. There are two principal varieties: lateral or oblique, and medial or direct.

In *oblique inguinal hernia* the intestine escapes from the abdominal cavity at the deep inguinal ring, pushing before it a pouch of peritoneum which forms the hernial sac. As it enters the inguinal canal it receives an investment from the extraperitoneal tissue and passes into the internal spermatic fascia which encloses the constituents of the spermatic cord. In passing along the inguinal canal it displaces upwards the arched fibres of the Transversus and Obliquus internus, and receives a covering of Cremaster muscle and cremasteric fascia. It lies in front of the constituents of the spermatic cord and escapes from the inguinal canal at the superficial inguinal ring, becoming invested by the external spermatic fascia. Lastly it descends into the scrotum, receiving coverings from the superficial fascia and the skin.

The site of strangulation in oblique inguinal hernia is either the deep or the superficial inguinal ring; most frequently at the former situation. If it is situated at the superficial

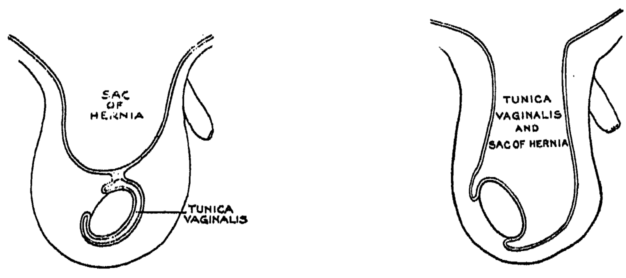
ring, the division of a few fibres at one point of the circumference is all that is necessary for the replacement of the hernia. If at the deep ring, it is necessary to divide the aponeurosis of the Obliquus externus so as to lay open the inguinal canal; in dividing the aponeurosis the incision should be directed parallel to the inguinal ligament, and the constriction at the deep ring should then be divided in an upward direction.

The great majority of varieties of oblique inguinal hernia depend upon congenital defects in the processus vaginalis, the pouch of peritoneum which precedes the descent of the testis. Normally this pouch is closed before birth, closure commencing at two points, viz. at the deep inguinal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process, variations in the relation of the hernial protrusion to the testis and tunica vaginalis are produced; these constitute distinct varieties of inguinal hernia, viz. the hernia of the funicular process and the complete congenital variety.

Where the processus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *complete* congenital (fig. 1196), the term does not imply that the hernia existed at birth, but merely that a condition is present which may allow of the descent of the hernia at any moment. As a matter of fact, congenital herniæ frequently do not appear till adult life.

Where the processus vaginalis is occluded at the lower point only, i.e. just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is pre-

FIG. 1196.—The varieties of oblique inguinal hernia.



Incomplete congenital   Complete congenital

vented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch. This is known as *hernia into the funicular process* or *incomplete congenital* hernia (fig. 1196); it differs from the former in that instead of enveloping the testis it lies above it.

In *direct inguinal hernia* the protrusion makes its way through some part of the inguinal triangle, either through (*a*) the lateral part, where only extraperitoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the Obliquus externus; or through (*b*) the conjoint tendon, which stretches across the medial two-thirds of the triangle between the artery and the median plane. In the former the hernial protrusion escapes from the abdomen on the lateral side of the conjoint tendon, pushes before it the peritoneum, extraperitoneal tissue and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the superficial ring, receiving an investment from the external spermatic fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the internal spermatic fascia so that the hernia lies between the innermost and the middle covering of the spermatic cord.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the conjoint tendon, or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the superficial ring, lying on the medial side of the cord, and receives additional coverings from the external spermatic fascia, the superficial fascia and the skin. The coverings of this form therefore differ from those of the oblique form in that the conjoint tendon is substituted for the Cremaster, and the internal spermatic fascia is replaced by a portion of the general layer of the transversalis fascia. It may be observed that in all the varieties of inguinal hernia the most superficial covering is an investment from the external spermatic fascia and is identical with the outermost covering of the spermatic cord. An oblique inguinal hernia lies within the spermatic cord and shares all its coverings, but the covering which a direct hernia acquires from the transversalis fascia is distinct from the covering which the spermatic cord receives from that layer.

Direct inguinal hernia is of much less frequent occurrence than oblique, and is found more often in men than in women. The main differences in position between it and the oblique form are: (*a*) it is placed over the os pubis and not in the course of the inguinal canal; (*b*) the inferior epigastric artery runs on the lateral or iliac side of the neck of the sac; and (*c*) the spermatic cord lies along its lateral and posterior sides, not directly behind it as in oblique inguinal hernia. A direct hernia is always of the acquired variety.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the superficial ring. In that form which perforates the conjoint tendon it may occur at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture directly upwards; by cutting in this direction the incision is made parallel to the inferior epigastric artery, and all chance of wounding the vessel is thus avoided.

Femoral hernia.—In femoral hernia the protrusion of the intestine takes place through the femoral ring. As already described (p. 785), this ring is closed by the femoral septum, a partition of modified extraperitoneal tissue; it is therefore a weak spot in the abdominal wall, and especially in the female, where the ring is larger, and where profound changes are produced in the tissues of the abdomen by pregnancy. Femoral hernia is therefore more common in women than in men.

When a portion of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum which forms the hernial sac. It receives an investment from the extraperitoneal tissue or femoral septum, and descends along the femoral canal as far as the saphenous opening (fossa ovalis); at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the latter, and its close contact with the vessels, and also the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the saphenous opening. The tumour is consequently directed forwards, pushing before it the cribriform fascia, and then curves upwards over the inguinal ligament and the lower part of the aponeurosis of the Obliquus externus, being covered by the superficial fascia and skin. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts, but when it escapes from the saphenous opening into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia is at first downwards, then forwards and upwards; in the application of taxis for the reduction of a femoral hernia, therefore, pressure should be directed in the reverse order, and the thighs should be passively flexed in order that the greatest degree of relaxation may be obtained.

The coverings of a femoral hernia from within outwards are: peritoneum, femoral septum, femoral sheath, cribriform fascia, superficial fascia and skin. Sir Astley Cooper described an investment for femoral hernia under the name of *fascia propria*, lying immediately external to the peritoneal sac but frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained extraperitoneal fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the 'fascia propria.' In many cases it resembles a fatty tumour, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The fascia propria is merely a modified femoral septum which had been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the saphenous opening the condition is known as *incomplete* femoral hernia, in contradistinction to the *complete* hernia, which has passed through the opening. The small size of the protrusion in the incomplete form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects.

The site of strangulation of a femoral hernia varies: it may be at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament (lacunar ligament); or it may be at the margin of the saphenous opening. The stricture should in every case be divided in a direction upwards and medially for a distance of about 4 mm. to 6 mm. All vessels or other structures of importance in relation to the neck of the sac will thus be avoided.

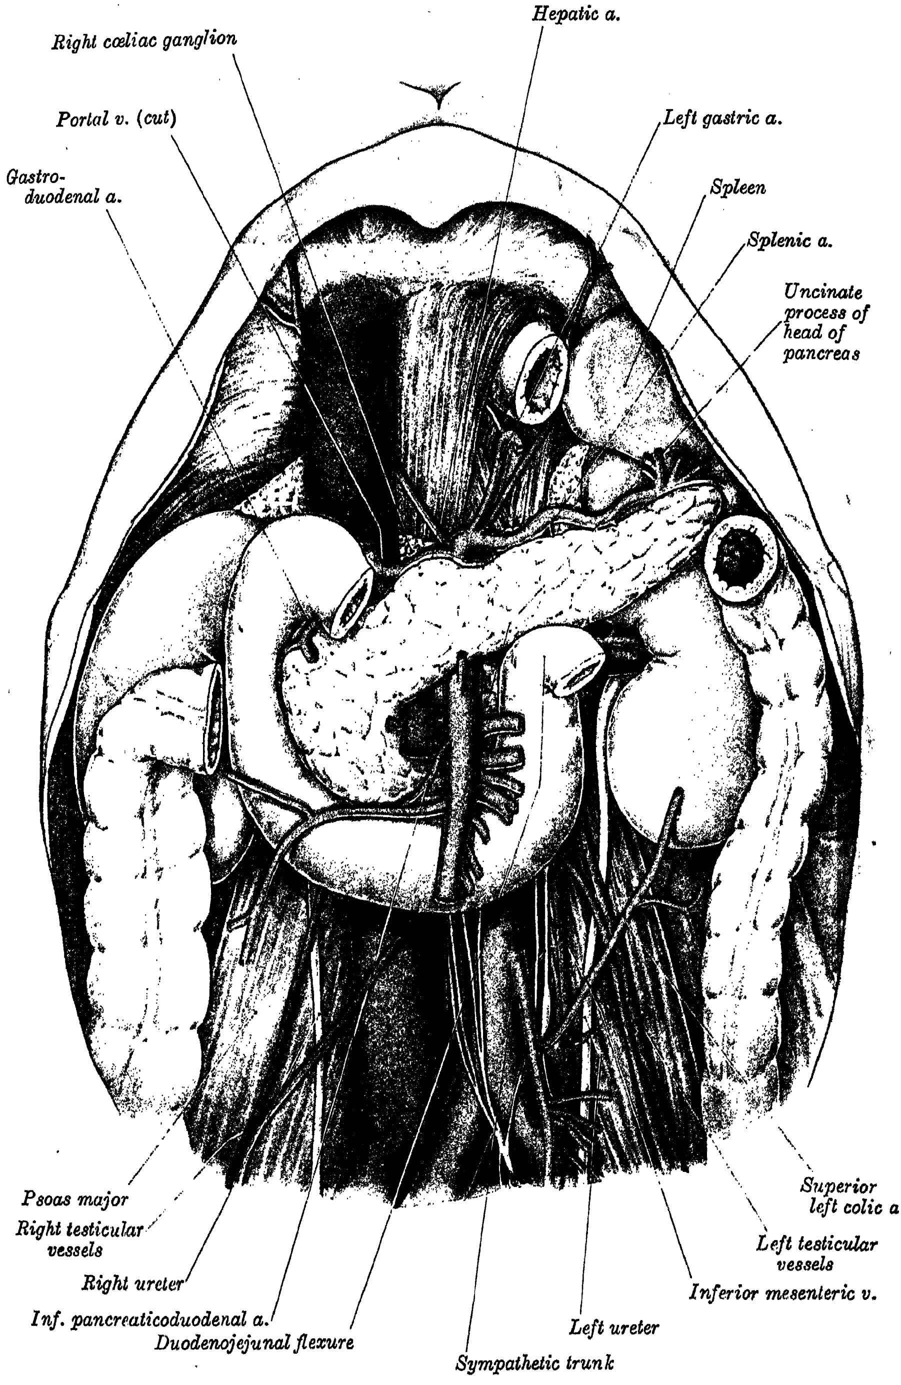
The pubic tubercle forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The neck of the inguinal protrusion is above and medial to the tubercle, while the neck of the femoral protrusion is below and lateral to it.

The Pancreas

The pancreas is a compound racemose gland, analogous in its structure to the salivary glands, but softer, and less compactly arranged. It is flattened and elongated, measuring from 12 cm. to 15 cm. long. Its broad, right extremity

is called the *head*, and is connected to the main portion, or *body*, by a slightly constricted *neck*; its narrow, left extremity forms the *tail*. It passes obliquely

FIG. 1197.—The pancreas and duodenum. Anterior aspect.



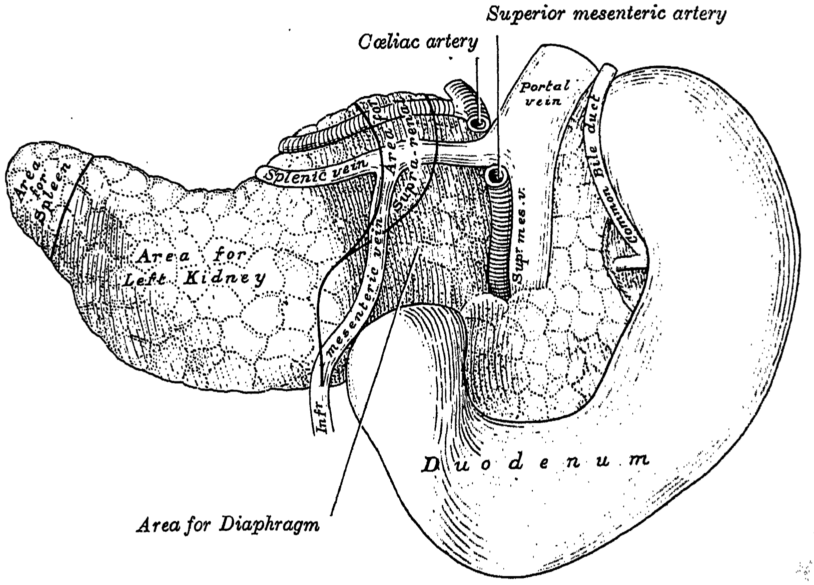
upwards and to the left, across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions.

Relations (figs. 1197 to 1199).—The **head**, flattened from before backwards,

is lodged within the curve of the duodenum. Its upper border is overlapped by the first part of the duodenum; the other borders are grooved to receive the adjacent margin of the duodenum, which they overlap in front and behind to a variable extent. At the angle of junction of the lower with the left lateral border there is a prolongation named the *uncinate process*, which projects upwards and to the left behind the superior mesenteric vessels. In or near the groove between the duodenum and the right lateral and lower borders anteriorly are the anastomosing superior and inferior pancreaticoduodenal arteries.

Anterior surface.—From the upper part of the front of the head of the pancreas, the neck juts forwards, upwards and towards the left, to be continued into the body of the pancreas. The boundary between the head and neck, on the right side, is a groove for the gastroduodenal artery; on the left side a deep notch intervenes between the head and the neck, and in it the superior mesenteric and splenic veins unite to form the portal vein. Below and to the right of

FIG. 1198.—The pancreas and duodenum. Posterior surface. (From a model by His.)



the neck the anterior surface of the head is in contact with the transverse colon, only areolar tissue intervening, while still lower the surface is covered with peritoneum continuous with the inferior layer of the transverse mesocolon (fig. 1161), and is in contact with a coil of the jejunum. The uncinate process is crossed by the superior mesenteric vessels.

Posterior surface.—The posterior surface of the head of the pancreas is in relation with the inferior vena cava, which runs upwards behind it and covers nearly the whole of this aspect. In addition, it is related to the terminal parts of the renal veins and the right crus of the Diaphragm. The uncinate process passes in front of the aorta. The bile duct lies either in a groove on the upper and lateral part of the posterior surface of the head of the pancreas or in a canal in its substance (McConnell *).

The **neck**, about 2 cm. long, is confluent below and to the right with the anterior surface of the head; it extends upwards and to the left, and merges imperceptibly into the body. Its anterior surface is covered with peritoneum and supports the pylorus, a portion of the lesser sac of the peritoneum (omental bursa) intervening; the gastroduodenal and the superior pancreaticoduodenal arteries descend in front of the gland at the right side of the junction of the neck with the head; its posterior surface is in relation with the superior mesenteric vein and the beginning of the portal vein.

* *Journal of Anatomy and Physiology*, vol. xlix.

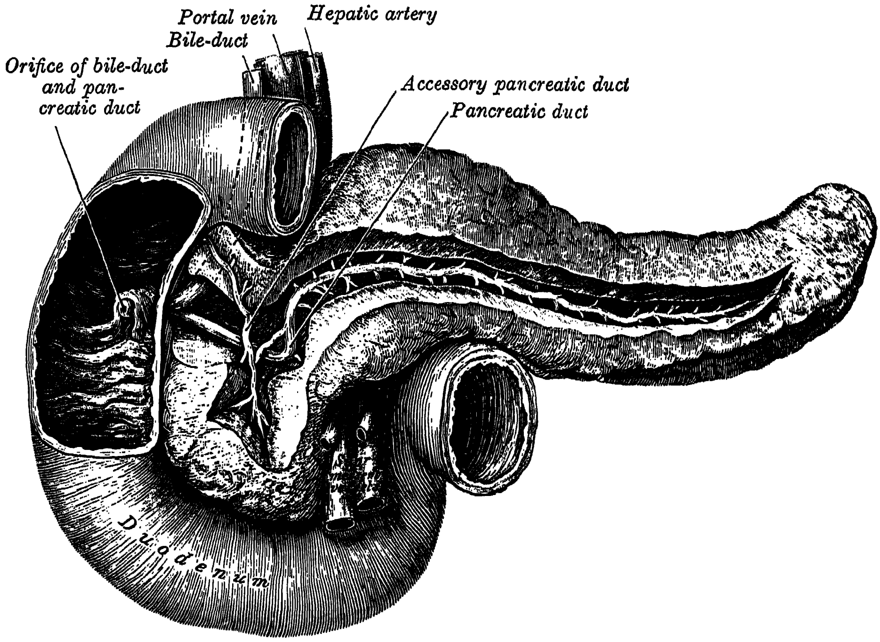
The **body** is somewhat prismoid in shape, and has three surfaces: anterior, posterior and inferior.

The *anterior surface* is concave, and is directed forwards and upwards; it is covered with peritoneum and is separated from the stomach by the lesser sac.

The *posterior surface* is devoid of peritoneum, and is in contact with the aorta and the origin of the superior mesenteric artery, the left crus of the Diaphragm, the left suprarenal gland and the left kidney and its vessels. It is intimately related to the splenic vein, which courses from left to right and separates it from the structures mentioned.

The *inferior surface* is narrow on the right but broader on the left, and is covered with peritoneum; it lies upon the duodenojejunal flexure and on some coils of the jejunum; its left extremity rests on the left colic flexure.

FIG. 1199.—The pancreatic duct.



The *superior border* is blunt and flat to the right; narrow and sharp to the left, near the tail. A process, termed the *tuber omentale*, usually projects from the right end of the superior border above the level of the lesser curvature of the stomach, and is in contact with the posterior surface of the lesser omentum. It is in relation above with the cœliac artery, from which the hepatic artery courses to the right just above the gland, while the splenic artery runs towards the left following a wavy course along this border.

The *anterior border* separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from each other: one passing upwards over the anterior surface, the other backwards over the inferior surface.

The *inferior border* separates the posterior from the inferior surface: the superior mesenteric vessels emerge under its right extremity.

The **tail** is narrow, and usually lies in contact with the inferior part of the gastric surface of the spleen. It is contained within the two layers of the lienorenal ligament and is closely related to the splenic vessels.

The pancreatic duct traverses the pancreas from left to right, lying nearer its posterior than its anterior surface (fig. 1199). It begins by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck of

the pancreas, and turning downwards, backwards, and to the right, comes into relation with the bile duct, which lies to its right side. Together the two ducts pass obliquely into the wall of the second part of the duodenum, and there unite to form a short dilated duct, named the *ampulla of the bile duct*. The constricted distal end of this ampulla opens on the summit of the duodenal papilla, which is situated within this part of the duodenum at the junction of its medial and posterior walls, from 8 cm. to 10 cm. distal to the pylorus. The pancreatic duct, near the duodenum, is about the size of an ordinary quill. Sometimes the pancreatic duct and the bile-duct open separately into the duodenum. Frequently there is an additional duct, which receives the ducts from the lower part of the head, and is known as the *accessory pancreatic duct* (fig. 1199). It runs upwards in front of the pancreatic duct, to which it is connected by a communicating duct, and opens into the duodenum about 2 cm. above and slightly ventral to the duodenal papilla.

Structure (fig. 1200).—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture.

Fig. 1200.—A section through a part of the human pancreas. Stained with hæmatoxylin and eosin. ×400.

It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, ending in a number of alveoli, which are tubular and somewhat convoluted. The minute ducts (intercalary ducts) connected with the alveoli are narrow and lined with flattened cells. In some animals spindle-shaped cells occupy the centre of the alveolus and are known as *centro-acinar cells*. The true secreting cells, which line the wall of the alveolus, are columnar in shape and present two zones; an outer, clear and faintly striated, next the basement-membrane, and an inner, which contains secretory granules. In hardened specimens the outer zone stains deeply with basic dyes, whereas the inner zone stains slightly. During activity the granular zone gradually diminishes in size; during the resting stages it gradually increases until it forms nearly three-fourths of the cell. In some of the secreting cells of the pancreas there is a spherical mass, staining more easily than the rest of the cell; this is termed the *paranucleus*, and is believed to be derived from the nucleus. Between the alveoli collections of cells are found in certain parts, which are termed *interalveolar cell-islets*, or islands of Langerhans. The cells of these stain lightly with hæmatoxylin or carmine, and are more or less polyhedral in shape, forming a network in which many capillaries ramify. There are two main types of cell in the islets, distinguished as A-cells and B-cells according to the special staining reactions of the granules they contain. The cell-islets are believed to produce insulin, the internal secretion of the pancreas which is necessary for carbohydrate metabolism.

The wall of the pancreatic duct is thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, lined with columnar epithelium, and furnished near its termination with a few scattered follicles.

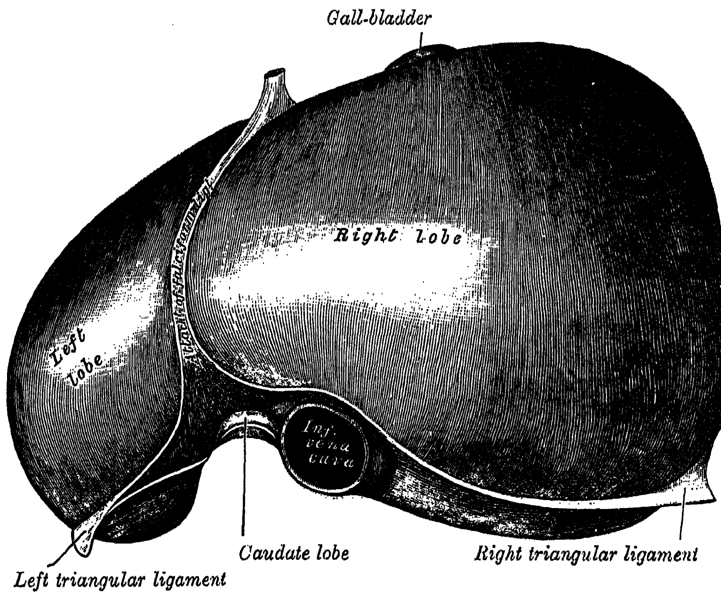
Vessels and Nerves.—The *arteries of the pancreas* are derived from the splenic artery, and from the pancreaticoduodenal branches of the hepatic and superior mesenteric arteries. Its *veins* open into the portal, splenic and superior mesenteric veins. Its *lymph vessels* are described on p. 868. Its *nerves*, derived from the vagus and splanchnic nerves, reach it through the splenic plexus.

Applied Anatomy.—Cysts of the pancreas may attain a large size, and cause symptoms by pressing on the stomach, Diaphragm or bile-duct. They generally push their way forwards between the stomach and transverse colon, and may then be felt in the upper part of the abdomen as a definite tumour in the median plane. The tumour is fixed and does not move with respiration. The pancreas is often the seat of cancer; this usually affects the head, and therefore speedily involves the bile-duct, leading to persistent jaundice; or it may press upon the portal vein, causing ascites, or involve the stomach, causing pyloric obstruction. The second part of the duodenum is occasionally encircled by the head of the pancreas, and should the latter then be the seat of malignant disease or chronic inflammation it may cause obstruction of the duodenum.

The Liver (Hepar) (figs. 1201 to 1203)

The liver, the largest gland in the body, is situated in the upper and right parts of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly extending into the left hypochondrium as far as the mammary line. In the male it weighs

Fig. 1201.—The superior, anterior, and right lateral surfaces of the liver. (From a model by His.)



from 1·4 to 1·6 kilogm., in the female from 1·2 to 1·4 kilogm. It is relatively much larger in the fœtus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body weight. Its greatest transverse measurement is from 15 cm. to 20 cm. Vertically, near its right surface, it measures from 15 cm. to 17 cm., while its greatest anteroposterior diameter is on a level with the upper end of the right kidney, and is from 12 cm. to 15 cm.; opposite the vertebral column this diameter is reduced to about 7 cm. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its colour is a dark reddish-brown.

When the liver has been hardened *in situ* it presents the appearance of a

wedge, the base of which is directed to the right and the edge to the left. Symington describes its shape as that 'of a right-angled triangular prism with the right angles rounded off.'

The liver possesses five surfaces, which will be described later, viz. superior, inferior, anterior, posterior, and right.

Borders.—The superior, anterior, and right surfaces are united by rounded borders, but a sharp margin, termed the *inferior border*, separates the right lateral and anterior surfaces from the inferior or visceral surface. Somewhat rounded where it intervenes between the right lateral and inferior surfaces, it is thin and sharp where it forms the lower margin of the anterior surface and is marked by a notch, termed the *notch of the ligamentum teres*, in or near the median plane. Lateral to the fundus of the gall bladder, which often corresponds to a second notch placed 4 to 5 cm. to the right of the median plane, this border generally corresponds with the costal margin. To the left of the fundus of the gall-bladder, it ascends less obliquely than the right costal margin and, crossing the infrasternal angle, passes behind the left costal margin in the neighbourhood of the tip of the eighth costal cartilage. Thereafter it ascends sharply and merges with the thin left margin of the left lobe. As it crosses the infrasternal angle the inferior border is closely related to the deep surface of the anterior abdominal wall and is readily accessible to examination by palpation or percussion. It should be noted that in women and children this border usually lies at a slightly lower level, i.e. it tends to project downwards for a short distance below the right costal margin.

Lobes.—The liver is divided, very imperfectly, into a large right and a much smaller left lobe. On the anterior and superior surfaces the two lobes meet along the line of attachment of a sickle-shaped fold of peritoneum which passes to the liver from the anterior abdominal wall and the under surface of the Diaphragm and is termed the falciform ligament (p. 1351). On the posterior and inferior surfaces the separation is more obvious and is effected by two fissures which meet end to end at the left extremity of the porta hepatis ; they are termed the fissure for the ligamentum venosum and the fissure for the ligamentum teres. The *fissure for the ligamentum venosum* is a deep cleft, lined with peritoneum, which descends on the posterior surface, nearer to its left than to its right limit. The *fissure for the ligamentum teres*, which is usually shallow, runs upwards and backwards on the inferior surface and extends from the inferior border of the liver to the left extremity of the porta hepatis.

The *left lobe* is thin, flattened from above downwards and only about one-sixth of the size of the whole organ. It presents anterior, superior, posterior and inferior surfaces, which are described with the surfaces of the liver (p. 1352).

The *right lobe*, which is somewhat cuboidal in form, constitutes the remaining five-sixths of the organ. It contributes to all of the surfaces of the liver, with which its surfaces will be described (p. 1352). The portion of the right lobe which adjoins the left lobe on the inferior and posterior surfaces is further subdivided into two smaller lobes, termed the quadrate and caudate lobes.

The *quadrate lobe* is placed on the inferior surface, and is somewhat rectangular in outline. It is bounded in front by the inferior border of the liver : on the left by the fissure for the ligamentum teres : behind by the porta hepatis : and on the right by a shallow fossa which lodges the gall-bladder.

The *caudate lobe* is situated on the posterior surface. It is bounded on the left by the fissure for the ligamentum venosum : below by the porta hepatis : and on the right by the deep groove which lodges the upper portion of the inferior vena cava. Above, it is continuous with the superior surface to the right of the upper end of the fissure for the ligamentum venosum. Below and to the right the caudate lobe is connected to the rest of the right lobe by a narrow tongue of liver substance, termed the *caudate process*, which lies immediately behind the porta hepatis and forms the roof of the aditus to the lesser sac (epiploic foramen). Below and to the left the caudate lobe presents a small rounded projection, which is termed the *papillary process*. In addition, owing to the depth of the fissure for the ligamentum venosum, the caudate lobe possesses a peritoneal-covered anterior surface, which forms the posterior wall of the fissure and is in contact with the hepatic part of the lesser omentum.

The relations of the quadrate and caudate lobes will be described with the surfaces of the liver (p. 1353).

Peritoneal connexions of the liver.—With the exception of an extensive, triangular area on the posterior surface of the right lobe, the liver is almost completely invested with peritoneum. It is connected to the stomach and duodenum, to the diaphragm and to the anterior abdominal wall by a number of peritoneal folds, and the lines along which they meet the organ are also necessarily devoid of a peritoneal covering. These folds include the falciform ligament, the right and left triangular ligaments, the coronary ligament and the lesser omentum.

The *falciform ligament* is a sickle-shaped fold consisting of two closely applied layers of peritoneum which connects the liver to the Diaphragm and the anterior abdominal wall. Its convex margin is fixed to the inferior surface of the Diaphragm and to the posterior surface of the anterior abdominal wall, extending downwards to the umbilicus ; as this attachment ascends from the umbilicus it passes slightly to the right of the median plane. The concave margin of the falciform ligament is attached to the notch for the ligamentum teres on the inferior border of the liver and to its anterior and superior surfaces. Its base or free edge, which extends from the umbilicus to the notch for the ligamentum teres, contains the ligamentum teres and the small para-umbilical veins, and lies in front of the pyloric portion of the stomach. At its upper end the two layers of the falciform ligament separate from each other and expose a small triangular area on the superior surface of the liver which is devoid of peritoneum. The left layer becomes continuous with the anterior layer of the left triangular ligament : the right with the upper layer of the coronary ligament.

The *coronary ligament* is formed by the reflection of the peritoneum from the Diaphragm to the superior and posterior surfaces of the right lobe. It consists of an upper and a lower layer, continuous at their right extremities with the right triangular ligament of the liver but diverging widely to the left so as to enclose a large triangular area of the right lobe which is uncovered with peritoneum and is termed the ' bare area.' The upper layer is continuous with the right layer of the falciform ligament, skirts the upper end of the groove for the inferior vena cava anteriorly and then gradually descends from the posterior part of the upper surface to the upper part of the posterior surface. There it is continuous with the anterior layer of the right triangular ligament. The lower layer is continuous with the posterior layer of the right triangular ligament and passes almost horizontally along the lower limit of the posterior surface of the right lobe. In this situation the peritoneum may be reflected on to the upper part of the anterior surface of the right kidney instead of on to the Diaphragm beyond the margin of that organ. At its left extremity the lower layer of the coronary ligament passes in front of the lower end of the groove for the inferior vena cava and becomes continuous with the line of peritoneal reflexion from the right border of the caudate lobe, i.e. the right margin of the upper recess of the lesser sac of peritoneum.

The *left triangular ligament* of the liver passes from the upper surface of the left lobe upwards and backwards to the under surface of the Diaphragm. It consists of two closely applied layers of peritoneum which become continuous with each other when traced to the left, where the ligament ends in a free margin. Traced to the right the anterior layer becomes continuous with the left layer of the falciform ligament, and the posterior layer with the anterior layer of the lesser omentum at the upper end of the fissure for the ligamentum venosum. It is placed in front of the abdominal part of the œsophagus, the upper end of the lesser omentum and part of the fundus of the stomach.

The *right triangular ligament* is a short V-shaped fold which connects the lateral part of the posterior aspect of the right lobe to the Diaphragm. The apex of the V forms a free right, or lower, margin for the ligament, around which its two layers become continuous with each other. The ligament really constitutes the right limit of the coronary ligament.

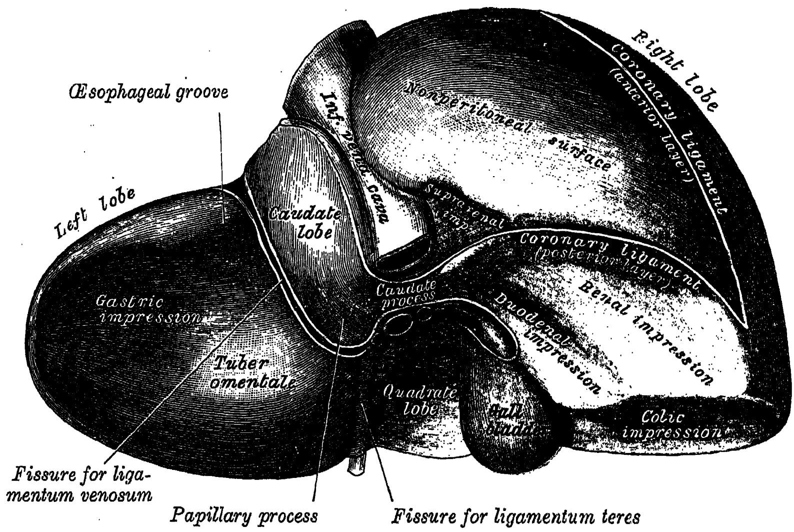
The *lesser omentum* has already been described (p. 1312) in detail. It will be sufficient to add that at the upper end of the fissure for the ligamentum venosum, its anterior layer becomes continuous with the posterior layer of the left triangular ligament, and its posterior layer with the line of reflexion of the

peritoneum from the upper end of the right border of the caudate lobe and so, indirectly, with the lower layer of the coronary ligament.

Surfaces.—The *superior surface* of the liver (fig. 1201) includes portions of the right and left lobes. It fits under the vault of the Diaphragm, and is covered with peritoneum, except over a small triangular area where the two layers of the upper part of the falciform ligament diverge. Its right and left portions are convex, but its central part presents a shallow *cardiac impression*, which corresponds with the position of the heart on the upper surface of the Diaphragm. It is related to the diaphragmatic pleura of the right side and the base of the right lung, to the pericardium and ventricular part of the heart, and, to a much smaller extent, to the diaphragmatic pleura of the left side and the base of the left lung.

The *anterior surface*, which is triangular in shape, also comprises portions of both right and left lobes, and is covered with peritoneum except at the line of attachment of the falciform ligament. A large part of this surface is in contact

FIG. 1202.—The posterior and inferior surfaces of the liver. (From a model by His.)



with the Diaphragm, which separates it, on the right side, from the pleura and the sixth to the tenth ribs and their cartilages and, on the left side, from the seventh and eighth costal cartilages. The thin anterior margin of the base of the lung is related to the upper part of this surface, but the relationship is much more extensive on the right than it is on the left side. The median part of the anterior surface of the liver lies behind the xiphoid process of the sternum and the anterior abdominal wall in the infracostal angle.

The *right surface* is convex from before backwards, and slightly so from above downwards. It is covered with peritoneum and is related to the right portion of the Diaphragm, which separates it from the right lung and pleura, and the right costal arches from the seventh to the eleventh inclusive. Over its upper third both lung and pleura intervene between the Diaphragm and the costal arches ; over its middle third only the costodiaphragmatic recess of the pleura is interposed ; over its lower third the Diaphragm is in actual contact with the costal arches.

The *posterior surface* includes portions of both right and left lobes ; it is thick and convex on the right, but thin on the left. A deep concavity marks its median portion and corresponds with the forward convexity formed by the vertebral column (fig. 1201). A large part of this surface of the right lobe is devoid of peritoneal covering and is attached to the Diaphragm by areolar tissue. This non-peritoneal surface constitutes the 'bare area' of the liver. It is triangular in outline and is limited above and below by the superior and inferior layers of the coronary ligament. Its base is formed by the deep groove for the inferior

vena cava, while its apex, directed downwards and laterally, corresponds with the right triangular ligament. The *groove for the inferior vena cava* is a deep depression, occasionally a complete tunnel, on the posterior surface of the liver and is devoid of peritoneal covering. It lodges the upper part of the vessel and its floor is pierced by the hepatic veins (p. 840). At its lower end the groove is separated from the porta hepatis in front by the caudate process. Immediately lateral to the lower end of the groove the ‘ bare area ’ presents a somewhat triangular impression on the formalin-hardened liver, which lodges the upper part of the right suprarenal gland and is therefore termed the *suprarenal impression*. On the left side of the groove for the inferior vena cava the *caudate lobe* occupies the rest of the posterior surface of the right lobe. It lies in the upper recess of the lesser sac of peritoneum (omental bursa), and is usually described as forming its anterior wall. This description is not quite accurate, because the peritoneum covering its posterior aspect is continued round its left border on to its anterior aspect, which forms the posterior wall of the fissure for the ligamentum venosum. The caudate lobe should therefore be regarded as projecting into the upper recess of the omental bursa from its right border. The posterior surface of the caudate lobe is related to the crura of the Diaphragm above the aortic opening and to the right phrenic artery, and is separated by them from the descending thoracic aorta. The *papillary process* often projects downwards in front of the origin of the cœliac artery.

The lips of the *fissure for the ligamentum venosum* separate the posterior aspect of the caudate from the posterior aspect of the left lobe. The fissure itself cuts deeply into the liver in front of the caudate lobe and contains the two layers of the lesser omentum. At its lower end it curves laterally below, or in front of, the papillary process, and reaches the left extremity of the porta hepatis. The *ligamentum venosum*, which is the fibrous remnant of the ductus venosus (p. 158), is attached below to the upper border of the left branch of the portal vein. It ascends in the floor of the fissure and passes laterally at the upper end of the caudate lobe to join the left hepatic vein near its point of entry into the inferior vena cava, or sometimes the vena cava itself.

The posterior aspect of the left lobe is marked by a shallow notch near the upper end of the fissure for the ligamentum venosum. It is occupied by the abdominal portion of the œsophagus and is termed the *œsophageal impression*. To the left of this impression the left lobe is related to a part of the fundus of the stomach.

The *inferior* or *visceral surface* is directed downwards, backwards and to the left, and, in the formalin-hardened organ, bears the imprints of the neighbouring viscera. It is invested with peritoneum except at the porta hepatis, the fissure for the ligamentum teres and the fossa for the gall-bladder. On the inferior surface of the left lobe, in direct continuity with the œsophageal impression, the *gastric impression* is moulded over the stomach. On the right of this impression there is a rounded ridge, the lower part of which is sometimes prominent and is termed the *omental tuberosity*. This ridge occupies the concavity of the lesser curvature of the stomach and is in contact with the lesser omentum. The *fissure for the ligamentum teres* is a cleft of variable depth which passes upwards and backwards from the corresponding notch on the inferior border of the liver to the left end of the porta hepatis where it meets the lower end of the fissure for the ligamentum venosum. It forms the left boundary of the quadrate lobe and may be, partially or completely, bridged over by a band of liver substance. Its floor lodges the *ligamentum teres of the liver*, which is the obliterated remains of the left umbilical vein in the fœtus (p. 687). Commencing at the umbilicus it ascends in the free margin of the falciform ligament to the inferior border of the liver, traverses the fissure and ends by joining the left branch of the portal vein at the left extremity of the porta hepatis.

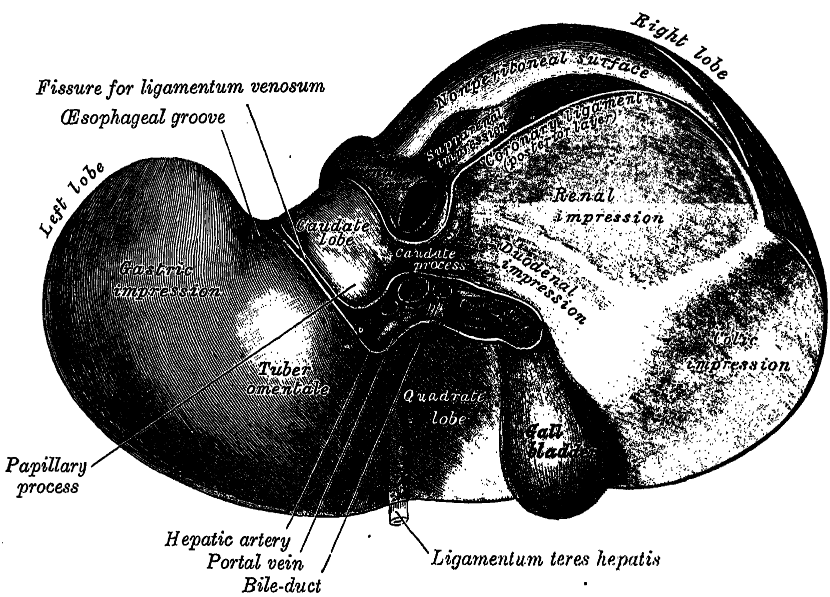
The gastric impression may be continued on to the anterior part of the *quadrate lobe*, which is hollowed out and moulded over the pyloric part of the stomach and the beginning of the duodenum, when these organs are dilated. The posterior, or upper, part of the quadrate lobe is in contact with the right free border of the lesser omentum and its contained structures. When the stomach is empty the quadrate lobe is related to the first part of the duodenum and a portion of the transverse colon.

The *porta hepatis* is placed on the inferior surface of the liver between the quadrate lobe in front and the caudate process behind. It is a deep fissure which runs transversely between the upper ends of the fissure for the ligamentum teres and the fossa for the gall-bladder. Through the porta hepatis the portal vein, the hepatic artery and the hepatic plexus of nerves enter the liver, and the right and left hepatic and the cystic ducts and some lymph vessels emerge. The hepatic ducts are situated anteriorly, the portal vein and its right and left branches posteriorly and the hepatic artery and its right and left branches are intermediate in position.

The *caudate process* connects the lower and lateral part of the caudate lobe to the remainder of the right lobe. It is placed behind the porta hepatis and in front of the inferior vena cava, and is covered with peritoneum. It forms the roof of the aditus to the lesser sac.

The *fossa for the gall-bladder* forms the right boundary of the quadrate lobe and extends from the inferior border of the liver to the right extremity of the

FIG. 1203.—The inferior surface of the liver. (From a model by His)



porta hepatis. It is usually shallow and devoid of peritoneal covering, but the breadth of this bare area is subject to individual variation.

To the right of the fossa for the gall-bladder, the inferior surface of the right lobe is marked by three impressions, viz. colic, renal and duodenal. The *colic impression* is related to the right colic flexure and is placed on the anterior part of the area, immediately adjoining the inferior border of the liver. The *renal impression* is usually well marked ; it is situated behind the colic impression and is separated from the neck and the adjoining part of the gall-bladder by the duodenal impression. It is related to the upper part of the anterior surface of the right kidney, and in its superomedial part to the lower pole of the right suprarenal gland. When the lower layer of the coronary ligament is reflected from the liver on to the right kidney, the renal impression extends for a short distance on to the lower part of the 'bare area.' The *duodenal impression* lies to the lateral side of the neck and adjoining part of the gall-bladder, and is related to the termination of the first part and the commencement of the second part of the duodenum.

The relations of the liver show considerable variation, for which posture and the movements of respiration are only partly responsible. *Those which have been enumerated refer to the body in the supine position.*

Vessels and Nerves.—The vessels connected with the liver are the portal vein, and the hepatic artery and veins.

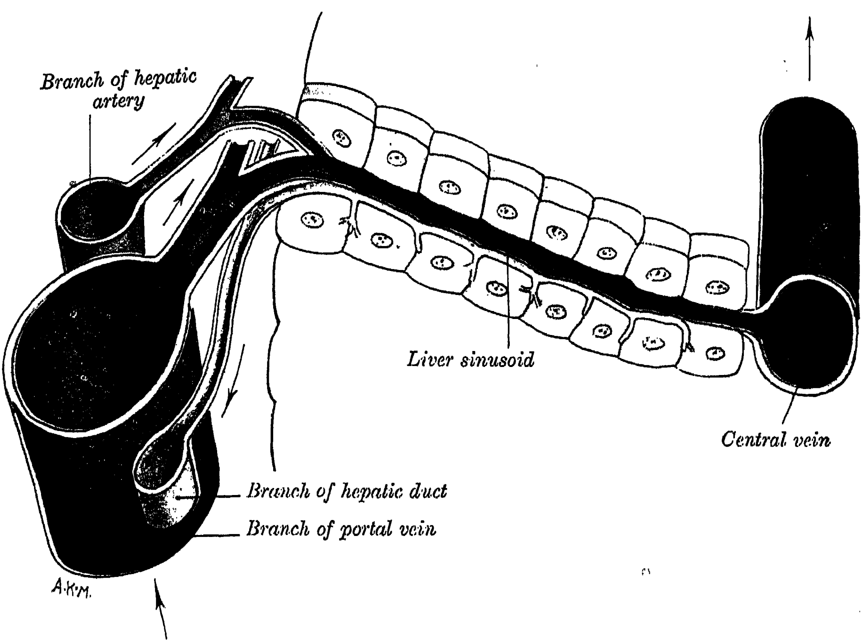
The *portal vein* and *hepatic artery,* accompanied by numerous nerves, ascend between the layers of the lesser omentum to the porta hepatis, where each divides into two branches; the *bile-duct* and lymph vessels descend from the porta hepatis between the layers of the same omentum. They are all enveloped in a loose areolar tissue, termed the *hepato-biliary capsule* (*of Glisson*), which accompanies the vessels in their course through the portal canals in the interior of the liver.

The *hepatic veins* (fig. 1204) convey the blood from the liver to the inferior vena cava, and are described on p. 840. They have very little cellular investment, but what there is binds them closely to the walls of the canals through which they run; so that, on section of the liver, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.

The *lymph vessels* of the liver are described on p. 867.

The *nerves* of the liver, derived from the left and right vagus, right phrenic, and sympathetic, enter at the porta hepatis and accompany the vessels and ducts to the

FIG. 1204.—Diagram to illustrate the circulation through a lobule of the liver.



Note that the sinusoids receive blood from both the hepatic artery and the portal vein. The central vein joins the system of hepatic veins and so drains into the inferior vena cava. The arrows indicate the direction of flow.

interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated enter the lobules and ramify between the cells.

Structure of the liver.—The greater part of the liver is invested with peritoneum, which covers a thin capsule of connective tissue. With the naked eye the liver can be seen to consist of an enormous number of polyhedral lobules, each of which is about 1 mm. in diameter. In the pig each lobule is sharply marked off from those adjoining it by connective tissue septa, but in the human liver there are no such definite boundaries.

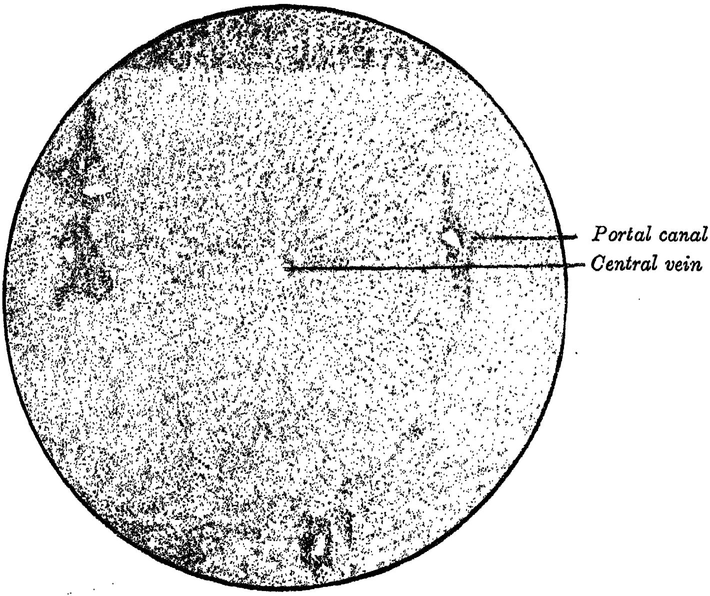
A *lobule* consists of a mass of cells, arranged in columns which radiate from a central vein (fig. 1205). Irregular blood-vessels (sinusoids) occupy the intervals between the columns.

A *liver-cell* is approximately cubical in shape, and is from 12μ to 25μ in diameter. It possesses one or two spherical nuclei, and its protoplasm usually contains granules of glycogen, and of a compound of iron. Fat droplets may also be present in the liver-cell.

Blood is conveyed to the liver by the portal vein and hepatic artery. These vessels enter the liver at the porta hepatis, and, as already stated, are enclosed together with the hepatic duct in a connective tissue sheath termed the hepato-biliary capsule. In the porta hepatis the portal vein, hepatic artery and common hepatic duct all divide into right and left

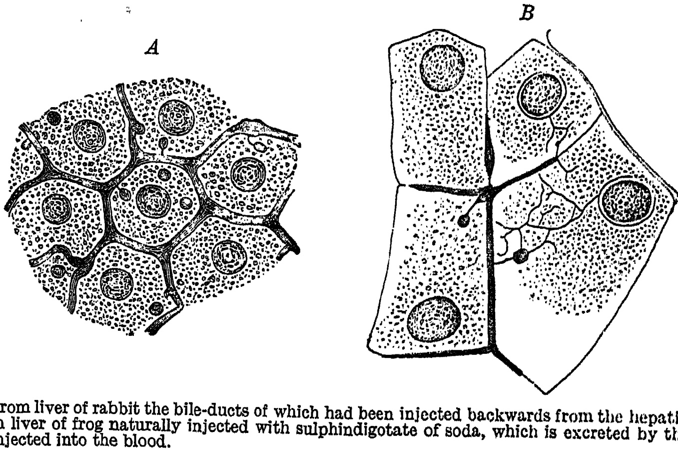
branches, and these branches subsequently ramify, in their connective tissue capsule, throughout the substance of the liver, and are accompanied by nerves and lymph vessels. The spaces occupied by these various structures are named *portal canals*. The smallest

FIG. 1205.—A section through a lobule of the human liver. Stained with hæmatoxylin and eosin. × 60.



branches of the portal vein form *interlobular plexuses* between the lobules, and from these plexuses capillary-like vessels, named sinusoids, run between the columns of liver-cells and open into the *central* veins in the centres of the lobules. The central veins join to form *sublobular veins*, and these unite to form the *hepatic veins* (fig. 1204), which drain the blood from the liver into the inferior vena cava.

FIG. 1206.—Sketches illustrating the manner in which bile passes from the hepatic cells into the intercellular bile-channels. (R. Heidenhain, after Kupffer.) (From Sharpey-Schafer's *Essentials of Histology*.)



A, from liver of rabbit the bile-ducts of which had been injected backwards from the hepatic duct; *B*, from liver of frog naturally injected with sulphindigotate of soda, which is excreted by the liver, when injected into the blood.

The *hepatic artery* conveys arterial blood to the connective tissue of the liver, to the walls of the subdivisions of the portal vein, and to the bile-ducts; its ultimate branches open into the interlobular plexuses and provide oxygenated blood for the liver cells.

The *sinusoids* are wider and more irregular than capillaries, and have an incomplete wall formed of branched cells (stellate cells of Kupffer) (p. 31). There is no lymph-space between the wall of the sinusoid and the liver-cells, and, in consequence of the gaps

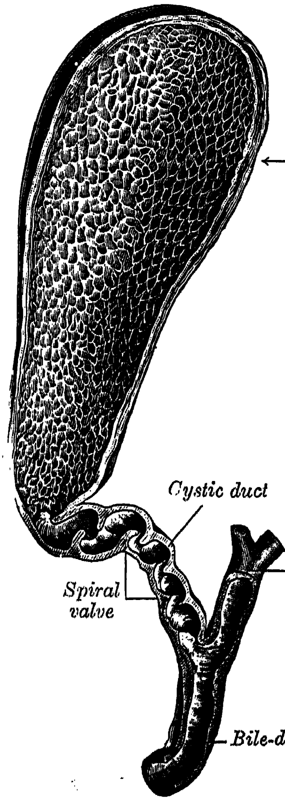
in the former, the blood comes into direct contact with the hepatic cells. Moreover, according to Herring and Simpson, minute channels penetrate the liver-cells, conveying the constituents of the blood into their substance.

The *bile ductules* do not penetrate the lobules, but receive minute canaliculi which convey the bile from the cells to the periphery of the lobules. These canaliculi, or *bile-capillaries,* are merely little channels or spaces between adjacent cells, and are always separated from the sinusoids by at least half the width of a liver-cell (fig. 1206).

Structure of the ductules.—The walls of the biliary ductules consist of a connective tissue coat, in which non-striped muscle-cells are arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells resting on a basement-membrane.

Nerve-fibrils are said to be distributed between the cells of the liver, and even to enter their substance.

Fig. 1207.—The gall-bladder and bile-ducts laid open. (Spalteholz.)



The Excretory Apparatus of the Liver

The excretory apparatus of the liver consists of (1) the *common hepatic duct,* formed by the junction of the right and left hepatic ducts, which leave the liver at the porta hepatis; (2) the *gall-bladder,* which serves as a reservoir for the bile; (3) the *cystic duct,* or duct of the gall-bladder; and (4) the *bile duct,* formed by the junction of the common hepatic and cystic ducts.

The **common hepatic duct.**—Two main ducts (right and left hepatic) issue from the liver and unite near the right end of the porta hepatis to form the common hepatic duct, which passes downwards for about 3 cm., and is joined at an acute angle by the cystic duct; by the union of the common hepatic with the cystic duct the bile duct is formed (fig. 1208). The common hepatic duct is on the right of the hepatic artery and in front of the portal vein.

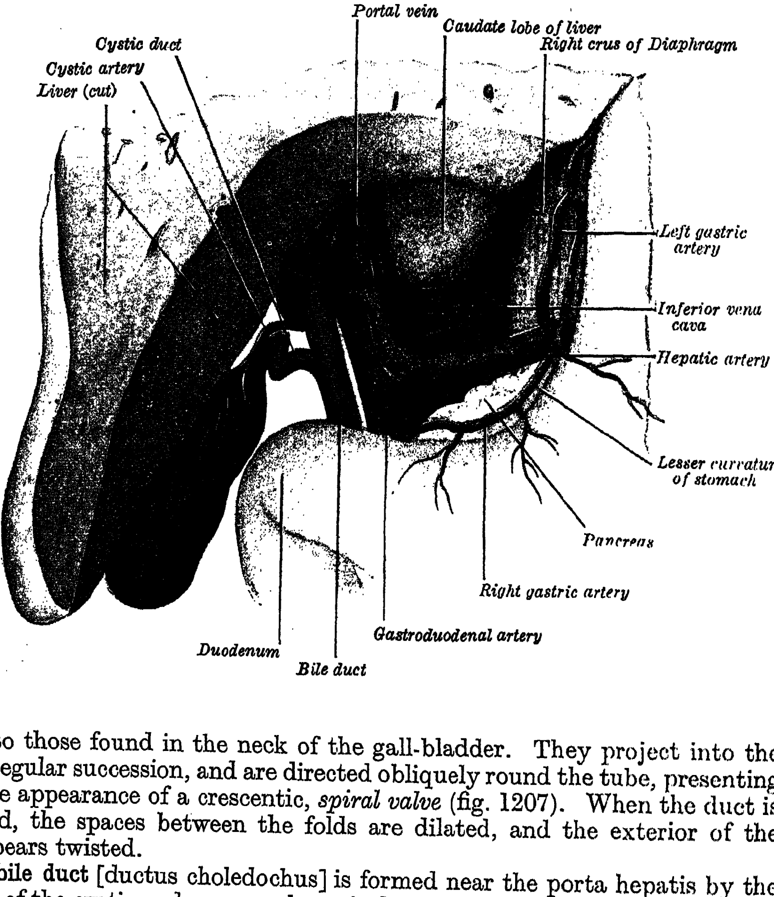
The **gall-bladder** [vesica fellea] (figs. 1203, 1207, 1208) is a conical or pear-shaped sac lodged in a fossa on the under surface of the right lobe and extending from near the right extremity of the porta hepatis to the inferior border of the liver. Its upper surface is attached to the liver by connective tissue; its under surface and sides are covered with peritoneum continued from the surface of the liver. Occasionally it is completely invested with peritoneum and may be connected to the liver by a short mesentery. It is from 7 cm. to 10 cm. long, 3 cm. broad at its widest part, and holds from 30 c.cm. to 50 c.cm. It is divided into a fundus, body and neck.

The *fundus,* or expanded end, is directed downwards, forwards and to the right. It projects beyond the inferior border of the liver, and comes into relationship with the posterior surface of the anterior abdominal wall below the ninth right costal cartilage, and behind the point where the lateral edge of the right Rectus abdominis crosses the costal margin; posteriorly the fundus is in relation with the transverse colon, near its commencement. The *body* is directed upwards, backwards and to the left; near the right end of the porta hepatis it is continuous with the neck. It is in relation by its upper surface with the liver; by its under surface, with the commencement of the transverse colon; and farther back usually with the upper end of the second part of the duodenum, but sometimes with the first part of the duodenum or pyloric end of the stomach. The *neck* is narrow; it curves upwards and forwards, and then, turning abruptly backwards and downwards, becomes continuous with the

cystic duct; at its point of continuity with the cystic duct there is a constriction. The neck is attached to the liver by areolar tissue in which the cystic artery is imbedded. The mucous membrane which lines the neck projects into its lumen in the form of oblique ridges, forming a sort of spiral valve.

The **cystic duct** (figs. 1203, 1208), from 3 cm. to 4 cm. long, passes backwards, downwards and to the left from the neck of the gall-bladder, and joins the common hepatic duct to form the bile duct; it runs parallel with and adheres to the common hepatic duct for a short distance before joining with it. The junction is usually situated immediately below the porta hepatis, but it may be at a considerably lower level. In the latter event the cystic duct lies in the right free margin of the lesser omentum. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number,

FIG. 1208.—Drawing of a dissection to show the relations of the hepatic artery, bile-duct and portal vein in the lesser omentum.



similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a crescentic, *spiral valve* (fig. 1207). When the duct is distended, the spaces between the folds are dilated, and the exterior of the duct appears twisted.

The **bile duct** [ductus choledochus] is formed near the porta hepatis by the junction of the cystic and common hepatic ducts; it is about 7 cm. long, and of the diameter of a goose-quill.

It runs at first downwards, backwards and to the left anterior to the aditus to the lesser sac (epiploic foramen); here it lies in the right border of the lesser omentum, in front of the right edge of the portal vein, and on the right of the hepatic artery (fig. 1208). It passes behind the first part of the duodenum with the gastroduodenal artery on its left, and then runs in a groove on the upper and lateral part of the posterior surface of the head of the pancreas (fig. 1198); here it is situated in front of the inferior vena cava, and is sometimes completely imbedded in the pancreatic substance. At the left side of the second part of the duodenum it comes into contact with the pancreatic duct, and accompanies it into the wall of this part of the gut, and there the two ducts unite to form

the *ampulla of the bile duct*; the distal, constricted end of this ampulla opens into the second part of the duodenum on the summit of the duodenal papilla (fig. 1199) from 8 to 10 cm. from the pylorus (p. 1325).

Structure (fig. 1209).—The gall-bladder has three coats: serous, fibromuscular and mucous.

Fig. 1209.—Section of the wall of the gall-bladder. Human. (E. Sharpey-Schafer.) ×355. Photograph. Preparation by C. F. W. Illingworth. (From Sharpey-Schafer's *Essentials of Histology*.)

The *external* or *serous coat* is derived from the peritoneum; it completely invests the fundus, but covers only the under surfaces and sides of the body and neck.

The *fibromuscular coat*, a thin but strong layer, consists of dense, fibrous tissue, mixed with plain muscular fibres, which are disposed chiefly in a longitudinal direction, a few running transversely.

The *internal* or *mucous coat* is loosely connected with the fibrous layer. It is generally of a yellowish-brown colour, and is elevated into minute rugæ (fig. 1207). It is continuous through the common hepatic duct with that of the ducts of the liver, and through the bile-duct with that of the duodenum. Its epithelium is columnar, and actively absorbs fluid from the bile, rendering it more concentrated. It also secretes cholesterol.

The coats of the large biliary ducts are an external or fibrous, and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue, arranged, for the most part, in a circular manner around the ducts. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts.

Applied Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the other abdominal viscera. The rupture may vary from a slight scratch to an extensive and complete laceration of its substance, dividing it into two parts. Sometimes an internal rupture, without laceration of the peritoneal covering, takes place, and such injuries are most susceptible to repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and moreover are unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm.

Abscess of the liver is of not infrequent occurrence and may enlarge in many different directions. Thus it has been known to burst into the lungs, when the pus is coughed up; or into the stomach, when the pus is vomited; it may burst into the colon, or duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. It often makes its way forwards, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardial cavities.

Hydatid cysts are more often found in the liver than in any of the other viscera. The reason for this is not far to seek. The embryo of the egg of the Tænia echinococcus, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid.

The gall-bladder may become distended in cases of obstruction of the cystic duct or of the bile duct, or from a collection of gall-stones in its interior, thus forming a large tumour. The swelling is pear-shaped, and projects downwards and forwards towards the umbilicus. It moves with respiration, since it is attached to the liver.

Obstruction of the bile duct, apart from stone, is often due to occlusion of this canal by pressure of malignant growths, especially those commencing in the pylorus or pancreas. It is also seen following ulceration of the duct, cicatricial contraction of the scar tissue taking place. Enormous distension, both of the bile duct itself and of its radicles in the liver substance, may occur at times.

THE UROGENITAL SYSTEM

The urogenital apparatus consists of (*a*) the urinary organs for the secretion and discharge of the urine, and (*b*) the genital organs, which are concerned with the process of reproduction. The two groups are included in one system because, in the male, they are not entirely independent of one another, since one passage (viz. the urethra) serves to convey both the urine and the seminal fluid.

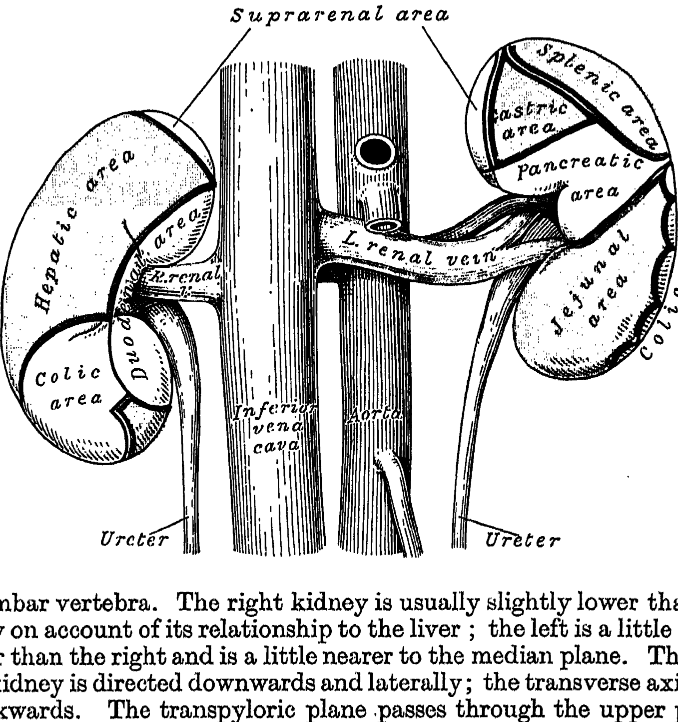
THE URINARY ORGANS

The urinary organs comprise (1) the *kidneys*, which secrete the urine ; (2) the *ureters*, which convey it to (3) the *urinary bladder*, where it is stored temporarily ; and (4) the *urethra*, through which it is discharged from the urinary bladder.

The Kidneys [Renes]

The **kidneys** are situated in the posterior part of the abdomen, one on each side of the vertebral column, behind the peritoneum ; they are surrounded by a mass of fat and some loose areolar tissue. Their upper ends are on a level with the upper border of the twelfth thoracic vertebra, their lower, with the

Fig. 1210.—The anterior surfaces of the kidneys, showing the areas of contact of the neighbouring viscera.



third lumbar vertebra. The right kidney is usually slightly lower than the left, probably on account of its relationship to the liver ; the left is a little longer and narrower than the right and is a little nearer to the median plane. The long axis of each kidney is directed downwards and laterally; the transverse axis, laterally and backwards. The transpyloric plane passes through the upper part of the hilum of the right kidney, and through the lower part of the hilum of the left.

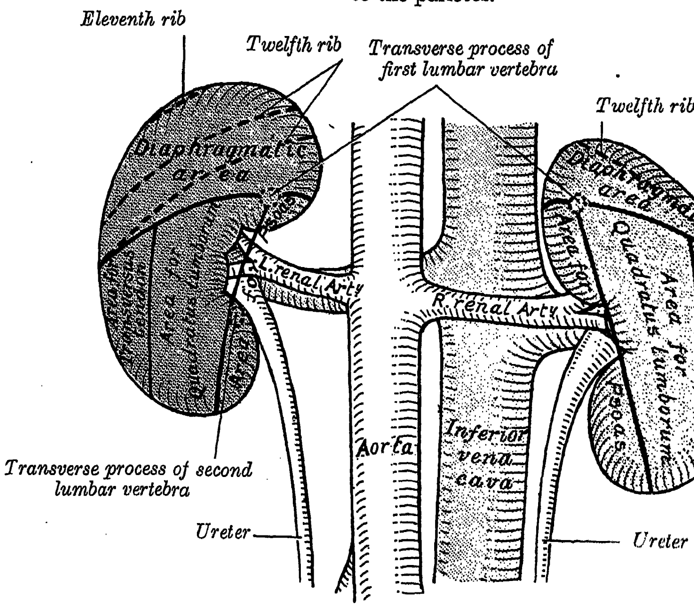
Each kidney is about 11 cm. in length, 6 cm. in breadth, and about 3 cm. in thickness. In the adult male the weight of the kidney varies from 125 gm. to 170 gm. ; in the adult female from 115 gm. to 155 gm.

The kidney has a characteristic form, and presents for examination two surfaces, two borders, and an upper and a lower end.

Relations.—The *anterior surface* (figs. 1197, 1210) of each kidney is convex, and looks forwards and laterally. Its relations to adjacent viscera differ on the two sides of the body.

(*a*) *Anterior surface of right kidney.*—A narrow portion at the upper extremity is in contact with the right suprarenal gland. The gland may overlap the upper pole, or the upper part of the medial border, or it may occupy a position midway between the two. A large area just below this and involving about three-fourths of the surface, lies in the renal impression on the inferior surface of the right lobe of the liver, and a narrow but somewhat variable area near the medial border is in contact with the second part of the duodenum. The lower part of the anterior surface is in contact laterally with the right colic flexure, and medially, as a rule, with a part of the small intestine. The area in relation with small intestine and almost the whole of the area in contact with the liver are covered with peritoneum; the suprarenal, duodenal and colic areas are devoid of peritoneum.

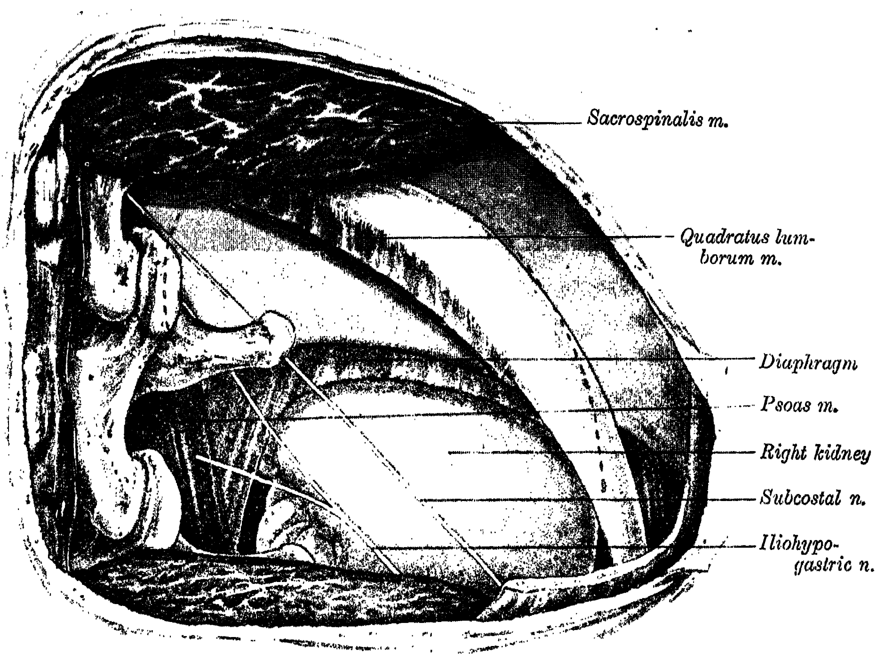
FIG. 1211.—The posterior surfaces of the kidneys, showing the areas of relation to the parietes.



(*b*) *Anterior surface of left kidney.*—A small area along the upper part of the medial border is in relation with the left suprarenal gland, and the upper two-thirds or less of the lateral half of the anterior surface are in contact with the renal impression on the spleen. A somewhat quadrilateral field, about the middle of the anterior surface, is in contact with the body of the pancreas and the splenic vessels behind it. Above this there is a small triangular portion, between the suprarenal and splenic areas, which is in contact with the stomach. The size of the gastric area is very variable. It is diminished, or may even be absent, when the left kidney lies at an abnormally low level, or when the obliquity of the body of the pancreas is accentuated. Below the pancreatic and splenic areas the lateral part is in relation with the left colic flexure and the commencement of the descending colon, the medial with the first coils of the jejunum. The jejunal area is always extensive but, as the descending colon is normally in a condition of contraction, the colic area forms an irregular, narrow strip immediately adjoining the lateral border of the kidney. The area in contact with the stomach is covered with the peritoneum of the lesser sac, while those in relation to the spleen and the jejunum are covered with the peritoneum of the greater sac; behind the peritoneum of the jejunal area some branches of the superior left colic vessels are related to the kidney. The suprarenal, pancreatic, and colic areas are devoid of peritoneum.

The *posterior surface* (figs. 1211 to 1214) of each kidney is directed backwards and medially. It is imbedded in areolar and fatty tissue, and is devoid of peritoneal covering. It lies upon the Diaphragm, the medial and lateral arcuate ligaments (lumbocostal arches), the Psoas major, the Quadratus lumborum, and the tendon of origin of the Transversus abdominis, the subcostal vessels, and the last thoracic, iliohypogastric and ilioinguinal nerves. The right kidney rests upon the twelfth rib, the left usually on the eleventh and twelfth. The Diaphragm separates the kidney from the pleura, which dips down to form the costodiaphragmatic recess (fig. 1212), but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the lateral arcuate ligament, and when this is so the perinephric areolar tissue is in contact with the diaphragmatic pleura.

FIG. 1212.—The right kidney, exposed from behind.



The *blue* area represents the pleura, the broken *red* line the upper part of the kidney.

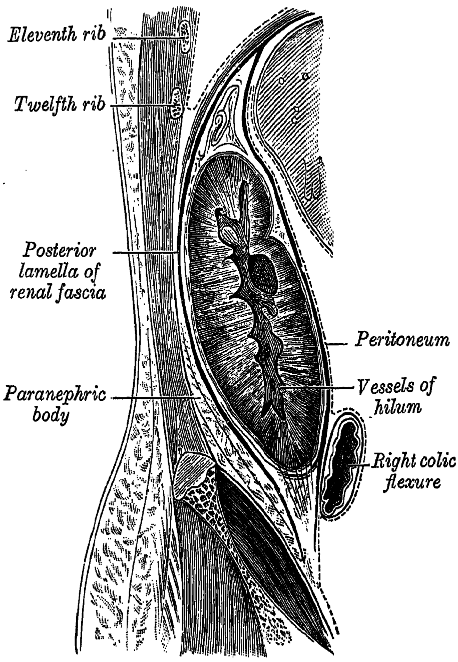
The *upper end* of the kidney is thick and round, and is nearer the median plane than the lower; it is surmounted by the suprarenal gland, which covers also a small portion of the anterior surface. The *lower end*, smaller and thinner than the superior, extends to within 5 cm. of the iliac crest.

The *lateral border* is convex; that of the left kidney is in contact, at its upper part, with the spleen and, at its lower part, with the descending colon; that of the right with the right lobe of the liver.

The *medial border* is concave in the centre and convex at each end; it is directed a little downwards and forwards. In its central part there is a deep vertical fissure, termed the ***hilum***, which is bounded by an anterior and a posterior lip, and transmits the renal vessels and nerves and the funnel-shaped upper end (*pelvis*) of the ureter. The relative positions of the main structures in the hilum are as follows: the renal vein is in front, the renal artery in the middle and the pelvis of the ureter behind. As a rule one of the branches of the renal artery enters the hilum behind the ureteral pelvis, and it is not uncommon to find one of the tributaries of the renal vein issuing from the hilum in the same plane. Above the hilum the medial border is in relation with the suprarenal gland, below with the commencement of the ureter.

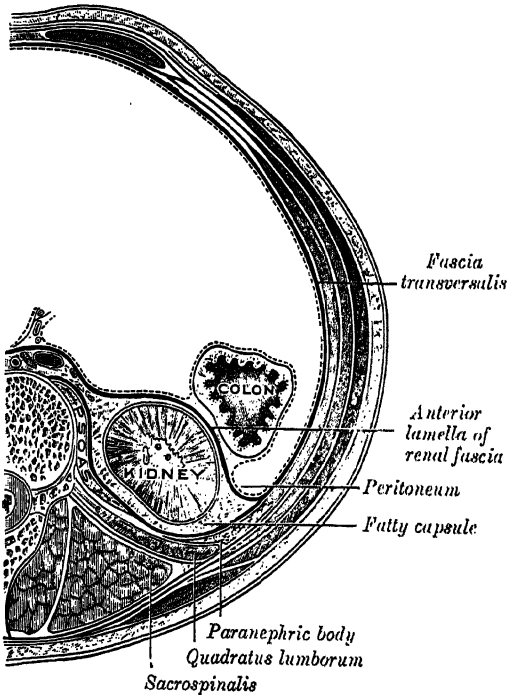
The hilum leads into a central recess or cavity named the *renal sinus,* which is lined by a continuation of the capsule of the kidney and is almost entirely filled by the ureteral pelvis and renal vessels; numerous nipple-like elevations, termed the *renal papillæ,* mark the wall of the sinus. Within the sinus the pelvis of the ureter divides into two, sometimes three, large branches which are named the *calyces majores,* and each of these divides again into several short branches named the *calyces minores* (fig. 1216). In all, there are usually from seven to thirteen of these lesser calyces; each expands as it approaches the wall of the renal sinus, and the expanded end is indented and moulded round from one to three renal papillæ (Pl. II, fig. 2). The wall of the expanded end of the calyx is firmly adherent to the capsule lining the renal sinus; it is perforated by the collecting tubules which open on the summits of the renal papillæ.

FIG. 1213.—A sagittal section through the posterior abdominal wall showing the relations of the renal fascia. (After Gerota.)



The kidney and its vessels are imbedded in a mass of fatty tissue, termed the *renal fat,* which is thickest at the borders of the kidney and is prolonged through the hilum into the renal sinus. The fibro-areolar tissue surrounding the kidney and the renal fat is condensed to form a sheath and is termed the *renal fascia.*

FIG. 1214.—A transverse section, showing the relations of the renal fascia. (After Gerota.)

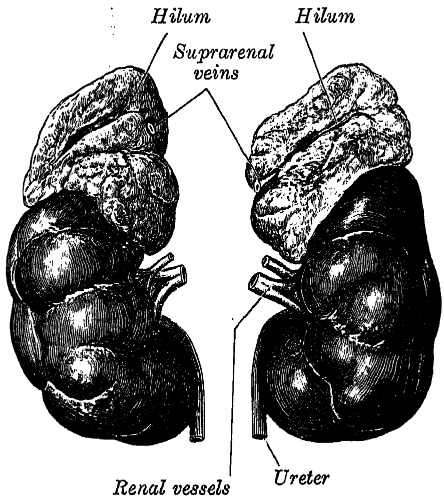


At the lateral border of the kidney the two layers of the sheath are fused. The anterior layer is carried medially in front of the kidney and its vessels, and at the level of the latter is continuous over the aorta with the corresponding layer of the opposite side.* The posterior layer extends medially behind the kidney and in front of the fascia on the Quadratus lumborum and Psoas major, and is attached to the vertebræ and intervertebral discs. Above the suprarenal gland the two layers of the renal fascia fuse, and are connected with the fascia of

* A. H. Southam (*Quarterly Journal of Medicine,* Number 64, July 1923, p. 283) maintains that the anterior layer of the renal fascia is not continued across the median plane. He says it "can be traced as far as the pancreas and to the root of the mesentery, and there becomes lost in the connective tissue elements present in this situation."

the Diaphragm; below the kidney they remain separate, and are gradually lost in the extraperitoneal tissue of the iliac fossa. The renal fascia is connected to the fibrous capsule of the kidney by numerous trabeculæ, which traverse the fatty capsule, and are strongest near the lower end of the organ. Behind the renal fascia there is a considerable quantity of fat, which is sometimes termed the *paranephric body*. The kidney is held in position partly through the attachments of the renal fascia but principally by the apposition of the neighbouring viscera.

FIG. 1215.—The kidneys and suprarenal glands of a new-born child. Anterior aspect.



In the fœtus the kidney consists of about twelve distinct lobules (fig. 1215), but in the adult these are fused and the kidney presents a uniformly smooth surface.

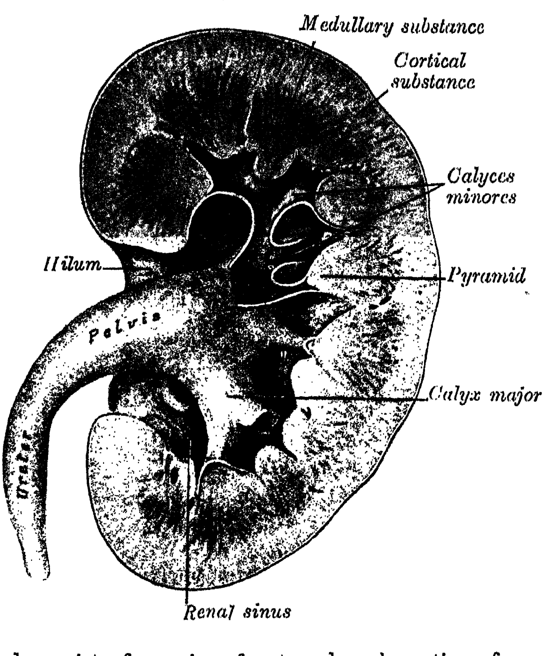
General structure of the Kidney. The kidney is invested by a fibrous capsule which is easily stripped off; an incomplete layer of smooth muscular fibres lies beneath the fibrous capsule.

If a vertical section be made from its lateral to its medial border, and the loose tissue and fat removed from around the vessels and the excretory duct, the *renal sinus* will be seen surrounded at all parts but one by the proper kidney-substance (fig. 1216). The fibrous capsule is prolonged into the sinus round the lips of the hilum, to become continuous with the outer coat of the pelvis of the ureter.

The kidney is composed of an internal, medullary and an external, cortical substance.

The *medullary substance* consists of a series of pale, striated, conical masses, termed the *renal pyramids*, the bases of which are directed towards the circumference of the kidney, while their apices converge towards the renal sinus, where they form prominent papillæ projecting into the interior of the calyces, each calyx minor receiving from one to three papillæ.

FIG. 1216.—A vertical section through a kidney, to show the pelvis of the ureter and calyces, and the cortical and medullary substance.



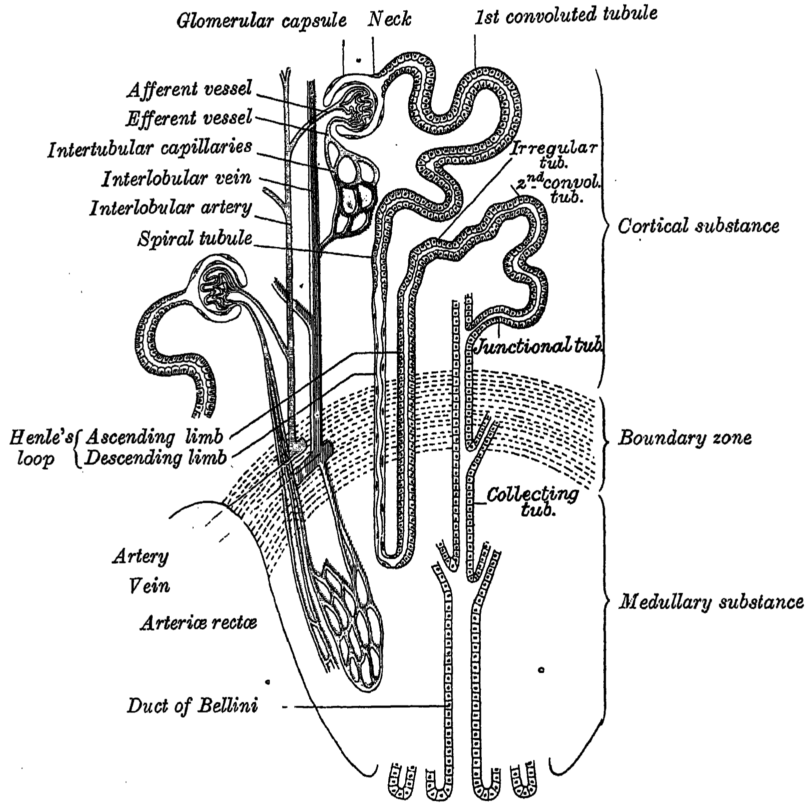
The *cortical substance* is reddish-brown in colour, and soft and granular in consistence. It lies immediately beneath the fibrous capsule, arches over the bases of the pyramids, and dips in between adjacent pyramids towards the renal sinus. The parts dipping in between the pyramids are named the *renal columns*, while the portions which connect the renal columns with each other and intervene between the bases of the pyramids and the fibrous capsule are called the *cortical arches*. If the cortex be examined with a lens, it will be seen to consist of a series of lighter-coloured, conical areas, termed *medullary rays* (fig. 1220), and a darker-coloured intervening substance, which from the complexity of its structure is named the *convoluted part*. The rays gradually taper towards the circumference of the kidney, and consist of a series of outward prolongations from the base of each renal pyramid.

The cortical and medullary substances are made up of renal tubules and blood-vessels, united and bound together by a connecting stroma.

Minute Anatomy.—The *renal tubules* (fig. 1217) commence in the cortical substance, and after pursuing a very tortuous route through the cortical and medullary substances finally

end at the apices of the renal pyramids by open mouths. If the surface of one of the papillæ be examined with a lens, it will be seen to be studded over with minute openings, the orifices

FIG. 1217.—A scheme of a renal tubule and its vascular supply.



of the renal tubules, from sixteen to twenty in number, and if pressure be made on a fresh kidney, urine will be seen to exude from these orifices. The tubules commence in the convoluted part and renal columns as the *renal* (*Malpighian*) *corpuscles*, which are small rounded masses of a deep red colour, averaging about 0·2 mm. in diameter. Each of these bodies is

FIG. 1218.—The distribution of the blood-vessels in the cortex of kidney.

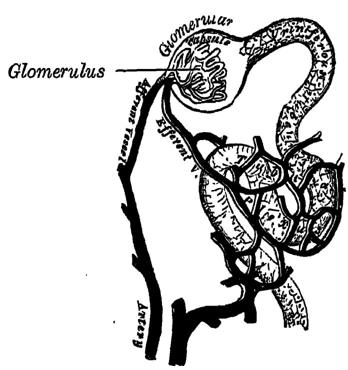


FIG. 1219.—A glomerulus.

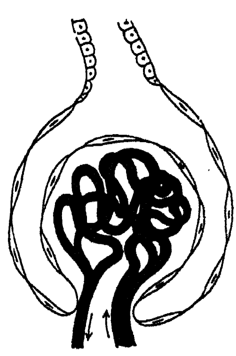


composed of two parts: a central *glomerulus* of vessels, and a membranous envelope, termed the *glomerular capsule*, which is the small pouch-like commencement of a renal tubule.

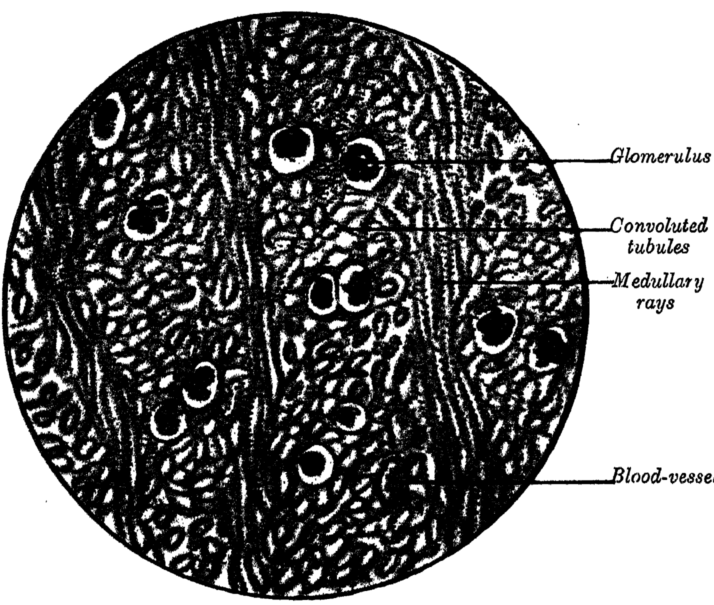
The *glomerulus* is a lobulated tuft of convoluted, capillary blood-vessels, held together by scanty connective tissue. This capillary network is derived from a small arterial twig (the *afferent vessel*), which enters the capsule, generally at a point opposite to that at which

the latter is connected with the tubule; the *efferent vessel* emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (figs. 1218, 1219).

The *glomerular capsule* is the blind, expanded end of the renal tubule, indented for the reception of the glomerulus. It consists of a basement-membrane, lined by a single layer of flattened epithelial cells. Thus between the glomerulus and the outer layer of the capsule there is a space lined by a continuous layer of flattened cells; this cavity varies in size according to the state of secretion and the amount of fluid present in it. In the fœtus and young subject the lining epithelial cells are polyhedral or columnar.

Each *renal tubule* consists of the following parts: (1) the *glomerular capsule*, already described, (2) a constricted portion or *neck*, (3) the *first convoluted tubule*, (4) the *spiral tubule*, which takes a course towards the medulla, (5) the *descending limb of Henle's loop*, narrower than the preceding, and running into the medullary substance, where it turns to form (6) the *loop of Henle*, (7) the *ascending limb of Henle's loop*, broader than the descending limb, which re-enters the cortical substance, (8) an angular segment, termed the *irregular* or *zig-zag tubule*, (9) the *second convoluted tubule*, (10) the *junctional tubule*, which opens into (11), the *collecting tubule* (fig. 1217).

FIG. 1220.—A radial section through the cortex of a human kidney. Stained with hæmatoxylin and eosin. ×100.



The *straight* or *collecting tubules* commence in the medullary rays of the cortex; they unite at short intervals with one another; the terminal tubes present a considerable increase in calibre, and are known as the *ducts of Bellini*; they open finally on the summit of a papilla.

Structure of the renal tubules.—The renal tubules consist of a basement-membrane lined with epithelium. In the neck the epithelium is continuous with that lining the glomerular capsule, and like it consists of flattened cells each containing an oval nucleus (fig. 1219). The two convoluted tubules, the spiral and zig-zag tubules, and the ascending limb of Henle's loop are lined with a type of epithelium which is histologically similar in all. The cells are somewhat columnar in shape and dovetail into one another on their lateral aspects. Each has a striated border next the lumen of the tube; its substance is granular, the granules in the outer portion being arranged in vertical rows. The nucleus is spherical and situated about the centre of the cell. In the descending limb of Henle's loop the epithelium resembles that found in the glomerular capsule and the commencement of the tube, consisting of flat, clear, epithelial plates, each with an oval nucleus. The nuclei alternate on opposite surfaces of the tubule so that the lumen remains fairly constant.

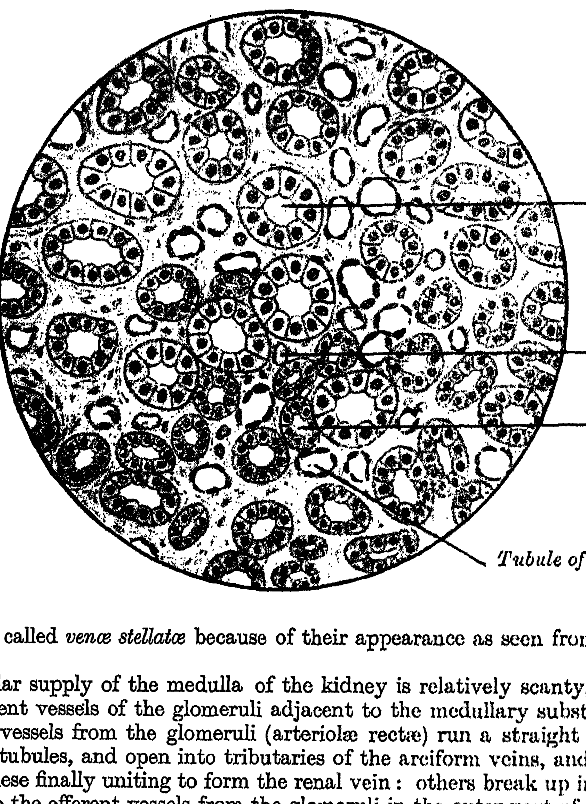
In the collecting tubule the epithelium is clear and cubical: in its papillary portion the cells are columnar and transparent (fig. 1221).

The renal blood-vessels.—Before entering the kidney, each artery divides into four or five branches which at the hilum lie mainly between the renal vein and pelvis of the ureter, the vein being in front, the pelvis behind; one branch usually lies behind the pelvis. Each vessel gives off some small branches to the suprarenal glands, to the ureter, and to the surrounding cellular tissue and muscles. One or two *accessory renal arteries* may arise from the abdominal aorta, either above or below the renal artery. Such vessels do not enter the hilum, but pierce the upper or lower parts of the kidney. The branches of the renal artery,

while in the sinus, give off a few twigs for the nutrition of the surrounding tissues, and divide into *lobar arteries*, one for each renal papilla. Before entering the kidney substance each lobar artery divides into two (sometimes three) *interlobar arteries* which run towards the cortex on each side of the pyramid. At the junction between the cortex and the medulla each interlobar artery divides dichotomously into branches which run at right angles to the parent stem. These are termed the *arciform arteries*, and it is to be noted that the interlobar and arciform arteries to each lobe do not anastomose with the corresponding arteries of neighbouring lobes. The arciform arteries give off a large number of straight arteries [*interlobular*], arranged vertically to the surface, each of which gives off a number of lateral branches, afferent vessels of the glomeruli, or *glomerular arteries*. Each interlobular artery with its branches and associated glomeruli resembles a string of red currants.

From the capillaries of each glomerulus an efferent vessel, smaller than the afferent vessel, arises and divides to form a second set of capillaries which run between the tubules and are called *intertubular capillaries*. These unite to form *interlobular veins*, which discharge into the tributaries of the *interlobar veins* running with the interlobar arteries. Each interlobular vein begins beneath the fibrous capsule of the kidney by the convergence of

FIG. 1221.—A transverse section through a pyramid of a human kidney. Stained with hæmatoxylin and eosin. ×400.



smaller veins, called *venæ stellatæ* because of their appearance as seen from the surface of the organ.

The vascular supply of the medulla of the kidney is relatively scanty, and is derived from the efferent vessels of the glomeruli adjacent to the medullary substance. Many of these efferent vessels from the glomeruli (arteriolæ rectæ) run a straight course between the collecting tubules, and open into tributaries of the arciform veins, and so reach interlobar veins, these finally uniting to form the renal vein: others break up into intertubular capillaries, like the efferent vessels from the glomeruli in the outer part of the cortex.

The circulation through the kidney is primarily a glomerular circulation, and all the branches which arise from the arciform and interlobular arteries terminate in glomeruli.*

In the living subject a pale streak, known as Brödel's line, marks the dorsal part of the lateral convex border of the kidney and indicates on the surface of the organ the boundary zone between the areas of distribution of the anterior and the posterior branches of the renal artery.

Nerves of the kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the cœliac plexus, the lower and lateral part of the cœliac ganglion and aortic plexus, and from the lesser and lowest splanchnic nerves. The nerves which supply the kidney are derived from the tenth, eleventh and twelfth thoracic segments of the spinal cord. The nerves communicate with the testicular plexus, a circumstance which may explain the occurrence of pain in the testis in affections of the kidney.

* D. B. MacCallum, *American Journal of Anatomy*, vol. xxxviii. 1926. R. A. Moore, *Anatomical Record*, vol. xl. 1928.

They accompany the renal artery and its branches, and are distributed to the blood-vessels and to the cells of the urinary tubules.

The *lymph vessels* of the kidney are described on p. 871.

Connective tissue, or *intertubular stroma*.—Although the tubules and vessels are closely packed, a small amount of connective tissue, continuous with the fibrous capsule, binds them firmly together and supports the blood-vessels, lymph vessels and nerves.

Applied Anatomy.—In badly nourished people or in those who have become emaciated the renal fat is deficient and the kidney may become displaced; this condition, which occurs more frequently in women than in men, on account of the greater laxity of the abdominal walls, is termed movable kidney.

Injuries of the kidney are generally due to some severe crushing force, as from being run over by a heavy waggon or cart, or from the abdomen being compressed between the buffers of two railway carriages. When a laceration occurs on the posterior surface of the organ, infiltration of blood and urine takes place into the retroperitoneal tissue; when the laceration is in front, the peritoneum may be torn and extravasation of blood and urine may take place into the peritoneal cavity.

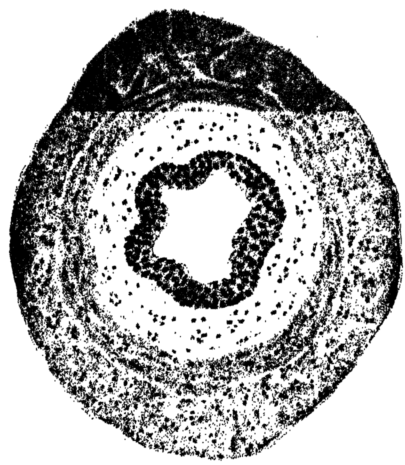
Incisions into the kidney for the purpose of displaying the interior of the renal pelvis are made along Brödel's line. The plane of the incision passes through the relatively avascular area (p. 1368) and undue hæmorrhage is thus avoided.

The early pelvic position of the kidney (p. 186) may persist, and in these cases the organ usually derives its blood-supply from the common iliac artery. The development of the kidney is partly arrested and the hilum lies on its anterior aspect.

The Ureters

The ureters are the two tubes which convey the urine from the kidneys to the urinary bladder. Each measures from 25 cm. to 30 cm. in length, and is a thick-walled, narrow, cylindrical tube which commences within the renal sinus as a funnel-shaped dilatation, termed the *pelvis of the ureter* (fig. 1216). It runs downwards and medially in front of the Psoas major, passes into the pelvic cavity, and opens into the base of the urinary bladder.

Fig. 1222.—A transverse section through the ureter. Stained with hæmatoxylin and eosin.



The *pelvis of the ureter* has already been described (p. 1364).

The *abdominal part* of the ureter lies behind the peritoneum on the medial portion of the Psoas major, which intervenes between it and the tips of the transverse processes of the lumbar vertebræ (Pl. II, fig. 2). It is crossed obliquely by the testicular (or ovarian) vessels. It enters the pelvic cavity by crossing either the end of the common, or the beginning of the external, iliac vessels.

At its origin the *right* ureter is usually covered by the second part of the duodenum; in its course downwards it lies to the right of the inferior vena cava, and is crossed by the right colic and the ileocolic vessels, while near the inlet of the pelvis it passes behind the lower part of the mesentery and the terminal part of the ileum. The *left ureter* is crossed by the left colic vessels, and near the inlet of the pelvis passes behind the pelvic colon and its mesentery, lying in the posterior wall of the recess of the pelvic mesocolon (intersigmoid recess).

The *pelvic part* of the ureter runs at first downwards on the lateral wall of the pelvic cavity, under cover of the peritoneum, and along the anterior border of the greater sciatic notch. It lies in front of the internal iliac (hypogastric) artery, and medial to the obturator nerve and the umbilical, obturator, inferior vesical, and middle rectal (hæmorrhoidal) arteries. Opposite the lower part of the greater sciatic foramen it runs medially and forwards, and reaches the lateral angle of the urinary bladder, where it is situated in front of the upper end of the seminal vesicle (and at a distance of about 5 cm. from the opposite ureter);

here the vas deferens crosses in front of it to gain its medial side, and the vesical veins surround it (fig. 1224). Finally, the ureters run obliquely through the wall of the bladder and open by slit-like apertures into the cavity of that viscus at the lateral angles of the trigone (fig. 1228). When the bladder is distended the openings of the ureters may be about 5 cm. apart, but when it is empty and contracted the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, the upper and lower walls of the terminal portions of the ureters become closely applied to each other when the bladder is distended, and, acting as valves, prevent regurgitation of urine. It should be noted that the peritoneum is closely applied to the medial side of the pelvic part of the ureter, except at its termination, where the vas deferens and, sometimes, one or two small vessels intervene (fig. 1223).

In the *female*, the pelvic part of the ureter forms the posterior boundary of a shallow depression named the *ovarian fossa*, in which the ovary is situated. It runs medially and forwards below the lower part of the broad ligament of the uterus, and passes lateral to the cervix uteri and the upper part of the vagina. It then lies for a short distance in front of the vagina, and finally pierces the wall of the bladder obliquely. In this part of its course it is accompanied for about 2·5 cm. by the uterine artery, which then crosses in front of the ureter and ascends between the two layers of the broad ligament. The ureter is distant about 2 cm. from the side of the cervix of the uterus.*

The ureter is sometimes duplicated on one or both sides, and the two tubes may remain distinct as far as the base of the urinary bladder ; they rarely open separately into the bladder cavity. The normal constrictions of the ureter have already been described (p. 186).

Structure (fig. 1222).—The ureter is composed of three coats: fibrous, muscular and mucous.

The *fibrous coat* is continuous at one end with the fibrous capsule of the kidney in the floor of the renal sinus ; while at the other it is lost on the wall of the bladder.

In the pelvis of the ureter the *muscular coat* consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calyces ; the circular fibres surround the medullary substance in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers: an external longitudinal, a middle circular, and an internal, less distinct than the other two, but having a general longitudinal direction.

The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillæ of the kidney above. It consists of fibrous tissue containing many elastic fibres, and covered with transitional epithelium. The continuation of the epithelium over the renal papillæ is columnar in type.

The *arteries* supplying the ureter are branches from the renal, testicular (or ovarian), internal iliac and inferior vesical arteries.

The *lymph vessels* of the ureter are described on p. 872.

The *nerves* are derived from the inferior mesenteric, spermatic (or ovarian), and pelvic plexuses ; through these plexuses fibres are derived from the lower three thoracic and first lumbar segments of the spinal cord. Small ganglia and isolated ganglion-cells are found in the fibrous and muscular coats.

Applied Anatomy.—Stones may become impacted in any part of the ureter, but this occurs most commonly at the points where the tube is normally constricted (p. 186). When a stone is impacted in the ureter, it gives rise to attacks of *renal colic*, probably due to spasmodic attempts on the part of the ureteral musculature to dislodge it. The pain is experienced in the cutaneous areas innervated from those segments of the spinal cord which also supply the ureter. It commences in the loin in the area supplied by the tenth thoracic nerve and shoots downwards and forwards to the groin, affecting in succession areas

* J. C. Brash (*British Medical Journal*, Oct. 28, 1922) says:

" The relation of the last portion of the ureter to the vagina is variable. There is usually a portion of the ureter in front of the vagina, lying for a short distance in the connective tissue between the vagina and bladder, and then in the wall of the bladder itself.

" With the vagina and bladder symmetrically related to each other this portion of the ureter is equal on the two sides ; but deviation from the symmetrical position is the rule. The result is an increase of this portion of the ureter on one side and a corresponding decrease on the other. There is frequently no ureter in front of the vagina on one side, and therefore a much longer portion than usual on the other side.

" In the majority of specimens examined, it is the left ureter that has the greatest relation to the vagina, and it is occasionally found crossing the middle line of the vagina. . . . It must not be forgotten, however, that occasionally the position may be reversed."

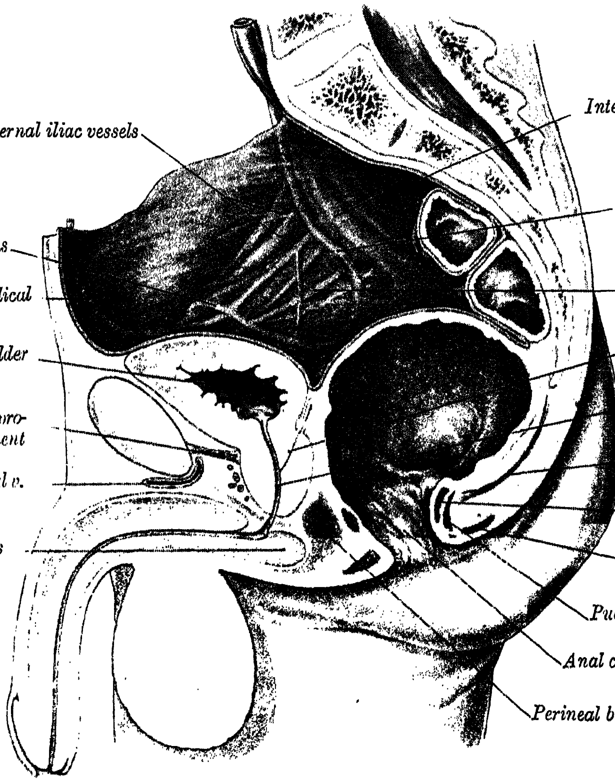
supplied by the eleventh and twelfth thoracic and the first lumbar nerves. Finally, it shoots into the testis of the same side.

The Urinary Bladder [Vesica Urinaria]

The urinary bladder (fig. 1223) is a sac which acts as a reservoir for the urine ; its size and position vary with the amount of fluid that it contains, and also with the state of distension of the neighbouring viscera. "The mean capacity of the living urinary bladder in the male adult is 220 c.c., varying from 120 c.c. to 320 c.c." *

When the empty bladder is firmly contracted, it presents the form of a

Fig. 1223.—A median sagittal section through the male pelvis.



flattened tetrahedron. It has a base or fundus, an apex, a superior and two inferolateral surfaces and a neck. The *base* is triangular in shape, and is directed downwards and backwards towards the rectum, from which it is separated by the rectovesical fascia, the vesiculæ seminales, and the terminal portions of the vasa deferentia. The *apex* is directed forwards towards the upper part of the symphysis pubis, and from it the median umbilical ligament (urachus) is continued upwards on the back of the abdominal wall to the umbilicus ; the peritoneum folded over this ligament forms the median umbilical fold. The *superior surface* is triangular, covered by peritoneum, and is in relation with the pelvic colon and the terminal coils of the ileum. It is bounded on each side by a lateral border which separates it from the inferolateral surface, and behind by a posterior border, represented by a line joining the two ureters, which intervenes between it and the basal aspect. The lateral borders run from the ureters to the apex, and from these borders the peritoneum extends to the walls of the pelvis. On each side of the bladder there is a peritoneal depression named the *paravesical fossa* (fig. 1157). The *inferolateral surfaces* are directed downwards and laterally, and are uncovered by peritoneum. They are separated in front from

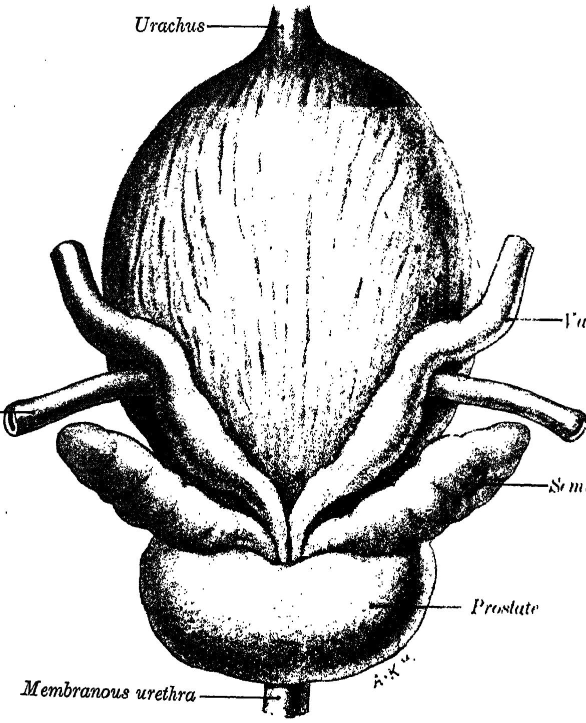
* A. Ralph Thompson, *Journal of Anatomy*, vol. liii.

the symphysis pubis by a mass of fatty tissue named the *retropubic pad* ; behind, they are in contact, on each side, with the fasciæ covering the Levator ani and Obturator internus. The neck of the bladder rests upon and is in direct continuity with the base of the prostate ; it is pierced by the internal urethral orifice. It is subject to but little alteration in position with varying conditions of the bladder and rectum, and lies a little above the plane of the pelvic outlet.

When the bladder is empty it is placed entirely within the pelvis, below the level of the obliterated umbilical arteries, and of the portions of the vasa deferentia which are in contact with the lateral wall of the pelvis.

As the bladder fills, its superior surface gradually rises into the abdominal cavity, carrying with it its peritoneal covering, and at the same time rounding off and finally obliterating the posterior and lateral borders. When the bladder is distended it assumes an ovoid form, the long diameter being directed up-

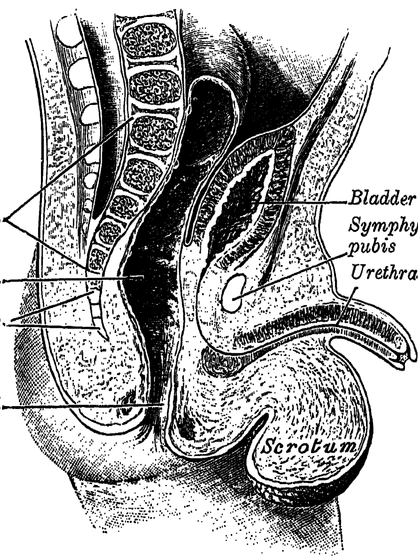
FIG. 1224.—The urinary bladder and prostate, viewed from above and behind.



wards and forwards. In this condition it presents a posterosuperior, an antero-inferior and two lateral surfaces, a base, and a summit ; owing to the obliteration of the posterior and lateral borders the four surfaces are not sharply marked off from one another. The posterosuperior surface is directed upwards and backwards, and is covered with peritoneum ; its posterior part is separated from the rectum by the rectovesical pouch, while its anterior part is in contact with coils of the small intestine. The antero-inferior surface is devoid of peritoneum, and rests against the pubic bones and the posterior surface of the anterior abdominal wall. The lower parts of the lateral surfaces are destitute of peritoneum, and are in contact with the lateral walls of the pelvis. The line of peritoneal reflection from the lateral surfaces is raised to the level of the obliterated umbilical arteries. The base, being more or less fixed, is only slightly lowered. It exhibits, however, a narrow triangular area, which is separated from the rectum merely by the rectovesical fascia. This area is bounded below by the prostate, above by the rectovesical fold of peritoneum, and laterally by the vasa deferentia. The vasa deferentia frequently come in contact with each other above the prostate, and when this occurs the lower part of the triangular area is obliterated. The line of reflection of the peritoneum

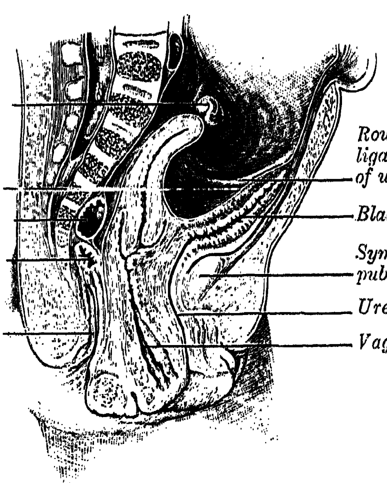
from the rectum to the bladder undergoes little or no change when the latter is distended; it is situated about 10 cm. from the anus. The summit of the bladder is directed upwards and forwards above the point of attachment of the median umbilical ligament, and hence the peritoneum, which follows the ligament, forms a pouch of varying depth between the summit and the anterior abdominal wall.

FIG. 1225.—A sagittal section through the pelvis of a new-born male child.



In the new-born child (figs. 1225, 1226) the internal urethral orifice is at the level of the upper border of the symphysis pubis; the bladder therefore lies relatively at a much higher level in the infant than in the adult. Its anterior surface "is in contact with about the lower two-thirds of that part of the abdominal wall which lies between the symphysis pubis and the umbilicus" (Symington *). Its fundus is clothed with peritoneum as far as the level of the internal orifice of the urethra. Although the bladder of the infant is usually described as an abdominal organ, Symington pointed out that only about one-half of it lies above the plane of the inlet of the pelvis. Disse maintains that the internal urethral orifice sinks rapidly during the first three years of life, and then more slowly until the ninth year, after which it remains stationary until puberty, when it again slowly descends and reaches its adult position.

FIG. 1226.—A sagittal section through the pelvis of a new-born female child. Some coils of the small intestine separated the uterus from the bladder.



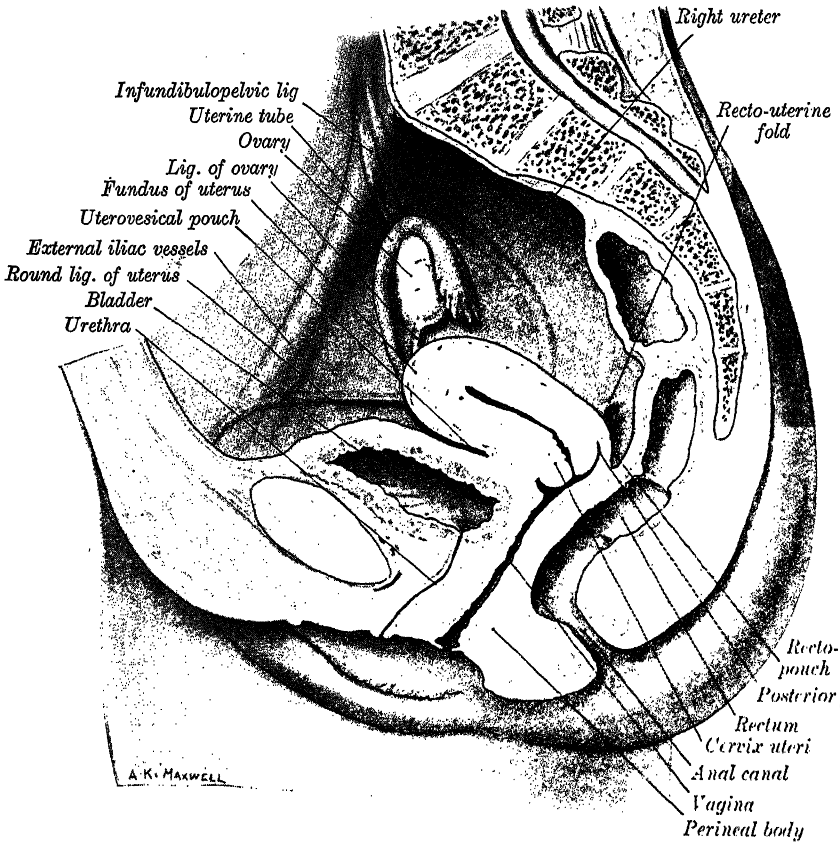
In the female, the bladder is in relation behind with the uterus and the upper part of the vagina (fig. 1227). It is separated from the anterior surface of the body of the uterus by the utero-vesical pouch, but below the level of this pouch it is connected to the front of the cervix uteri and the upper part of the anterior wall of the vagina by fibro-areolar tissue. When the bladder is empty the uterus rests upon its superior surface.

Ligaments.—Each side of the bladder is connected to the tendinous arch of the pelvic fascia (p. 574) by a condensation of fibro-areolar tissue which is often termed the *lateral true ligament* of the bladder. Anteriorly the same tissue forms two thickened bands, on each side of the median plane, termed the lateral and medial puboprostatic ligaments. The *lateral puboprostatic ligament* extends from the anterior end

* *The Anatomy of the Child.*

of the tendinous arch of the pelvic fascia downwards and medially to blend with the upper part of the sheath of the prostate; the *medial puboprostatic ligament* is attached to the back of the pubic bone near the middle of the symphysis and passes downwards and backwards to the sheath of the prostate, forming the floor of the retropubic space. The *apex* of the bladder is joined to the umbilicus by the remains of the urachus, which forms the *median umbilical ligament*. The lumen of the urachus persists throughout life and is lined by modified, transitional epithelium. It frequently communicates with the cavity of the bladder.* As the veins of the prostatic venous plexus (pudendal plexus) stream backwards from the lateral borders of the base of the bladder to join the internal iliac veins, they are enveloped in fibro-areolar tissue, which is sometimes termed the *posterior ligaments* of the bladder.

Fig. 1227.—A medial sagittal section through the female pelvis.



From the superior surface of the bladder the peritoneum is carried off in a series of folds which are sometimes termed the false ligaments of the bladder. Anteriorly there are three folds: the *median umbilical fold* on the median umbilical ligament, and two *lateral umbilical folds* on the obliterated umbilical arteries (fig. 1157). The reflections of the peritoneum from the bladder to the side walls of the pelvis form the lateral false ligaments while the sacrogenital folds (p. 1308) constitute the posterior false ligaments.

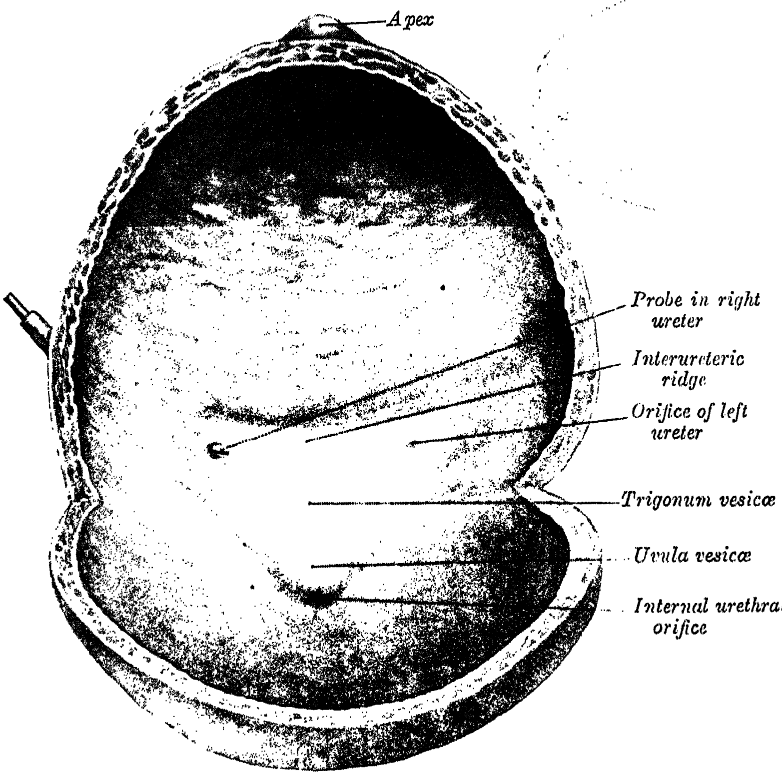
The interior of the bladder (fig. 1228).—The mucous membrane which lines the bladder is, over the greater part of the viscus, loosely attached to the muscular coat, and appears folded when the bladder is contracted: the folds are effaced when the bladder is distended. Over a small triangular area, named the *trigone of the bladder* [*trigonum vesicæ*], immediately above and behind the internal orifice of the urethra, the mucous membrane is firmly bound to the

* R. C. Begg, *Journal of Anatomy*, vol. lxiv. 1930.

muscular coat, and is always smooth. The anterior angle of the trigone is formed by the internal orifice of the urethra : its posterolateral angles by the orifices of the ureters. The base of the trigone is formed by a slightly curved ridge, termed the *interureteric ridge*, which connects the two ureteral orifices and is produced by the continuation into the bladder wall of the inner longitudinal coats of the ureters. The lateral parts of this ridge extend beyond the openings of the ureters ; they are named the *ureteric folds* and are produced by the terminal portions of the ureters as they run obliquely through the bladder-wall. When the living bladder is examined with a cystoscope the interureteric ridge appears as a pale band, and forms an important guide during the operation of introducing a catheter into the ureter.

The *orifices of the ureters* are placed at the posterolateral angles of the trigone of the bladder, and are usually slit-like in form. In the contracted bladder they are about 2·5 cm. apart and about the same distance from the

FIG. 1228.—The interior of the bladder. Viewed from in front.



internal urethral orifice ; in the distended bladder these measurements may be increased to about 5 cm.

The *internal urethral orifice* is placed at the apex of the trigone, in the most dependent part of the bladder, and is usually somewhat crescentic in form ; the mucous membrane immediately behind it exhibits a slight elevation, caused by the median lobe of the prostate and termed the *uvula vesicæ*.

Structure (fig. 1229).—The bladder is composed of four coats : serous, muscular, submucous and mucous.

The *serous coat* is a partial one, and is derived from the peritoneum. It invests the superior surface and the upper parts of the lateral surfaces, and is reflected from these on to the abdominal and pelvic walls.

The *muscular coat* consists of three layers of unstriped muscular fibres : an external and an internal of longitudinal fibres, and a middle of circular fibres.

The fibres of the *external longitudinal layer* pass in a more or less longitudinal manner, up the inferolateral surfaces of the bladder, over its apex, and then descend along its base to become attached to the prostate and its capsule in the male, and to the front of the vagina in the female. Some of the longitudinal fibres are carried on to the front of the rectum, and

are named the *Musculus rectovesicalis*. Others traverse the medial puboprostatic ligaments and are attached to the lower part of the pelvic surface of the pubis on each side. They are sometimes termed the *musculi pubovesicales*. At the sides of the bladder the fibres are arranged obliquely and intersect one another.

The fibres of the *middle circular layer* are very thinly and irregularly scattered on the body of the organ, and, although to some extent placed transverse to its long axis, are for the most part arranged obliquely. Towards the lower part of the bladder, round the internal urethral orifice, they are disposed in a thick circular layer, forming the *Sphincter vesicæ*, which is continuous with the muscular fibres of the prostate.

The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate, and are inserted by means of a fibrous process into the median

FIG. 1229.—A vertical section through the wall of the bladder (human).

lobe of the organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue, connecting together the muscular and mucous coats, and intimately united with the latter.

The *mucous coat* is thin, smooth, and of a pale rose colour. It is continuous above with that of the ureters, and below with that of the urethra; the epithelium covering it is of the transitional variety. The loose texture of the submucous layer allows the mucous coat to be thrown into folds or *rugæ* when the bladder is empty. Over the trigonum vesicæ the mucous membrane is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Vessels and Nerves.—The principal *arteries* of supply to the bladder are the superior and inferior vesical, derived from the anterior trunk of the internal iliac (hypogastric) artery. The obturator and inferior gluteal arteries also send small branches to it, and in the female additional branches are derived from the uterine and vaginal arteries.

The *veins* form a complicated plexus on the inferolateral surfaces near the prostate, and pass backwards in the posterior ligaments of the bladder to end in the internal iliac veins.

The *lymph vessels* are described on p. 873.

The *nerves* of the bladder are (1) fine medullated fibres from the second, third, and fourth sacral nerves (parasympathetic), and (2) non-medullated fibres from the hypogastric

plexus (sympathetic). They are connected with ganglia in the outer and submucous coats, and are finally distributed, all as non-medullated fibres, to the muscular layer and epithelial lining of the viscus.

Applied Anatomy.—When the bladder is distended, it may be ruptured by violence applied to the abdominal wall, without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal: that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder.* Between these muscular bundles the mucous membrane may bulge out, forming sacculi, constituting *diverticula of the bladder,* and in these little pouches phosphatic concretions may collect, forming *encysted calculi.*

Various forms of tumour have been found springing from the wall of the bladder, and in doubtful cases the cystoscope proves a valuable aid in diagnosis. This instrument consists of a tube in which is fixed a small electric light, the wires of which run through the shaft of the instrument. When it is introduced down the urethra, the bladder can be examined with the eye, and a villous growth or other tumour, a calculus, or an ulcer can be detected; or the orifices of the ureters can be examined, and renal hæmaturia diagnosed, and it can be definitely settled from which kidney the blood comes. The cystoscope can be used to catheterise the ureter, for the purpose of obtaining a specimen of urine from either kidney, or to ascertain the condition of both kidneys when it is proposed to remove one. Ureteric bougies opaque to x-rays can be passed and photographed. The pelvis of the kidney can be distended with 25 per cent. sodium bromide through the ureter and its shape photographed. More satisfactory results are now obtained from X-ray photographs taken after the intravenous injection of uroselectan.

Puncture of the distended bladder may be performed above the symphysis pubis without wounding the peritoneum.

Access to the bladder, for the purpose of removing calculi or an enlarged prostate, is almost always effected by the suprapubic route, the perineal operation being rarely resorted to. In the female, owing to the shortness of the urethra and its ready dilatability, calculi and foreign bodies and new growths, when of small size, may be removed by the urethral route. Over-dilatation of the female urethra may cause incontinence of urine.

The Male Urethra (figs. 1223, 1230)

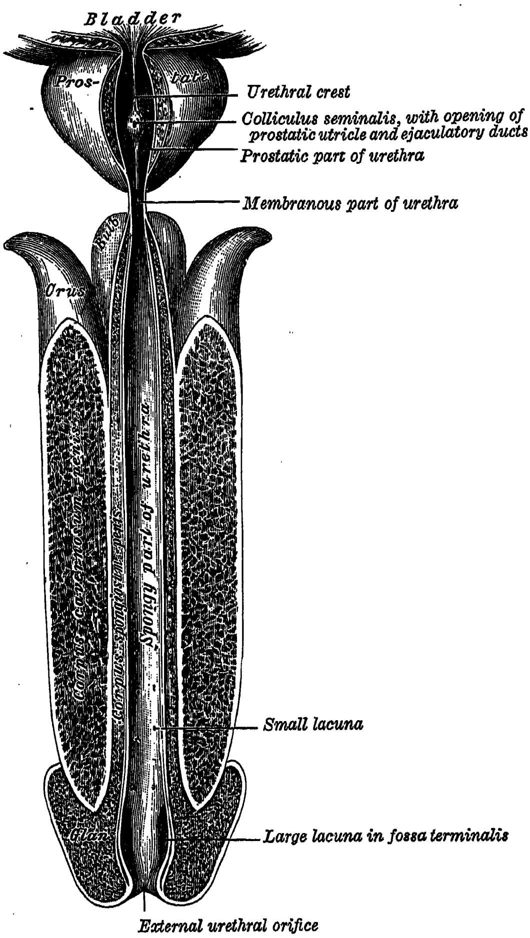
The **male urethra**, from 18 cm. to 20 cm. long, extends from the internal urethral orifice in the urinary bladder to the external urethral orifice at the end of the penis. It is divided into three portions, viz. *prostatic, membranous,* and *spongy* (cavernous), and presents a double curve in the ordinary flaccid state of the penis (fig. 1223). Except during the passage of fluid along it, the urethral canal is a mere slit or cleft; in the prostatic portion the slit is transversely arched; in the membranous portion, irregular or stellate; in the spongy portion, transverse; while at the external orifice it is sagittal.

The **prostatic portion**, which is the widest and most dilatable part of the urethra, is about 3 cm. long, and runs almost vertically through the prostate from its base to its apex; it lies nearer the anterior than the posterior surface of the prostate. It is widest in the middle, and is narrowest below, where it joins the membranous portion: on transverse section it is horseshoe-shaped with the convexity directed forwards.

Upon the posterior wall or floor a narrow median longitudinal ridge is formed by an elevation of the mucous membrane and its subjacent tissue and is termed the *urethral crest* (fig. 1236). On each side of the crest there is a shallow depression, termed the *prostatic sinus,* the floor of which is perforated by the *orifices of the prostatic ducts.* Near the middle of the urethral crest the *colliculus seminalis* forms an elevation on which the slit-like orifice of the prostatic utricle is situated; on each side of this orifice there is the small opening of the ejaculatory duct. The *prostatic utricle* is a cul-de-sac about 6 mm. long, which runs upwards and backwards in the substance of the prostate behind the median lobe. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane; the latter presents the openings of numerous small glands. It is developed from the united lower ends of the paramesonephric (Mullerian) ducts, and is therefore homologous with the vagina of the female (p. 190). The ejaculatory ducts are described on p. 1386.

The **membranous portion** is the shortest, least dilatable, and, with the exception of the external orifice, the narrowest part of the urethra. It runs downwards and forwards, with a slight concavity, from the prostate to the bulb of the penis (fig. 1223), perforating the perineal membrane about 2·5 cm. below and behind the pubic symphysis. The hinder part of the bulb of the penis lies in close apposition with the perineal membrane (inferior fascia of the urogenital diaphragm), but its upper portion diverges somewhat from this fascia; the anterior wall of the membranous urethra is thus prolonged for a short distance below the perineal membrane before it reaches the penile bulb; it measures about 2 cm. in length, while the posterior wall is only 1·25 cm. long.

FIG. 1230.—The male urethra laid open on its anterior (upper) surface.



The membranous portion of the urethra is surrounded by the fibres of the Sphincter urethræ (p. 580). In front of it the deep dorsal vein of the penis enters the pelvis between the transverse perineal ligament and the inferior (arcuate) pubic ligament; near its termination the bulbo-urethral glands are placed one on each side.

The **spongy (cavernous) portion** is contained in the corpus spongiosum penis (corpus cavernosum urethræ). It is about 15 cm. long, and extends from the end of the membranous portion to the external urethral orifice on the glans penis. Commencing below the perineal membrane it passes forwards to the front of the lower part of the symphysis pubis; and then, in the flaccid condition of the penis, it bends downwards and forwards. It is narrow, with a uniform diameter of about 6 mm. in the body of the penis; it is dilated at its commencement to form the *intrabulbar fossa*, and again within the glans penis, where it forms the *fossa terminalis* (fossa navicularis). The enlargement of the intrabulbar fossa affects the floor and sidewalls but not the roof of the urethra. The bulbo-urethral glands open into the spongy portion of the urethra about 2·5 cm. below the perineal membrane.

The *external urethral orifice* is the narrowest part of the urethra: it is a sagittal slit, about 6 mm. long, bounded on each side by a small labium.

The lining membrane of the urethra, except in the most anterior part of the tube, presents the orifices of numerous small mucous glands and follicles situated in the submucous tissue, and named the *urethral glands*. Besides these there are a number of small pit-like recesses, or *lacunæ*, of varying sizes; the orifices of these are directed forwards, and may intercept the point of a catheter in its passage along the canal. One lacuna, larger than the rest, is situated on the upper wall of the fossa terminalis; it is called *lacuna magna*.

Structure.—The urethra is composed of mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The *mucous membrane* of the urethra is continuous internally with that of the bladder, and externally with the skin covering the glans penis; it is prolonged into the ducts of the urethral, bulbo-urethral and prostatic glands; and into the vasa deferentia and vesiculæ seminales, through the ejaculatory ducts. In the spongy and membranous portions of the urethra it is aranged in longitudinal folds when the tube is empty. Small papillæ are found upon it, near the external urethral orifice; its epithelial lining is of the transitional variety as far as the orifice of the ejaculatory duct; thereafter it is of the columnar variety, usually two or three layers deep, except near the external urethral orifice, where it is squamous and stratified.

The *submucous tissue* consists of a vascular erectile layer; outside this there is a layer of unstriped muscular fibres, arranged into an inner longitudinal and an outer circular layer and best marked in the prostatic and membranous portions.

The lymph vessels of the urethra are described on p. 873.

Applied Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will point to the nature of the injury. Rupture of the urethra is due in other cases to the perforation of a peri-urethral abscess. Extravasation of urine most frequently takes place into the perineum superficial to the perineal membrane, but deep to the membranous layer of the superficial fascia. Both these layers of fascia are attached firmly to the ischiopubic rami. It is clear, therefore, that when extravasation of fluid takes place between them, it cannot pass backwards, because the two layers are continuous with each other around the Transversi perinæi superficiales; it cannot extend laterally, on account of the connexion of these layers with the rami of the pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the perineal membrane, and, therefore, so long as this layer remains intact, the only direction in which the fluid can make its way is forwards into the areolar tissue of the scrotum and the penis, and thence on to the anterior wall of the abdomen. When the pelvis is crushed the urethra may be ruptured above the perineal membrane; the extravasation of urine then takes place into the extra-peritoneal tissue of the pelvis.

The anatomy of the urethra is of considerable importance in connexion with the passage of instruments into the bladder. The urethra is capable of great dilation, so that, excepting through the external urethral orifice, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The external orifice of the urethra is not so dilatable, and therefore may require slitting. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal after the fossa terminalis has been traversed, as otherwise it is very liable to enter one of the lacunæ.

THE FEMALE URETHRA (fig. 1227)

The female urethra is about 4 cm. long and 6 mm. in diameter. It begins at the internal urethral orifice of the bladder, and runs downwards and forwards behind the symphysis pubis, imbedded in the anterior wall of the vagina. It perforates the perineal membrane and ends at the external urethral orifice, an anteroposterior slit with rather prominent margins, which is situated directly in front of the opening of the vagina and about 2·5 cm. behind the glans clitoridis. Except during the passage of fluid the anterior and posterior walls of the urethra are in apposition, and the lining membrane is thrown into longitudinal folds, one of which, placed on the posterior wall of the canal, is termed the *urethral crest*. Many small *urethral glands* and minute pit-like recesses or *lacunæ* open into the urethra. Near the lower end of the urethra there are some small glands, which are considered to be the homologues of the prostatic glands of the male; on each side they are grouped together and open into a duct, named the *ductus paraurethralis*, which runs down in the submucous tissue, and ends in a small aperture on the lateral margin of the external urethral orifice.

Structure.—The urethra consists of three coats: muscular, erectile and mucous.

The *muscular coat* is continuous with that of the bladder; it extends the whole length of the tube, and consists of inner longitudinal and outer circular fibres. In addition to this, above the perineal membrane, the female urethra is surrounded by the Sphincter urethræ, as in the male.

A thin layer of *spongy erectile tissue*, containing a plexus of large veins, intermixed with bundles of unstriped muscular fibres, lies immediately beneath the mucous coat.

The *mucous coat* is pale; it is continuous externally with that of the vulva, and internally with that of the bladder. It is lined by stratified squamous epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

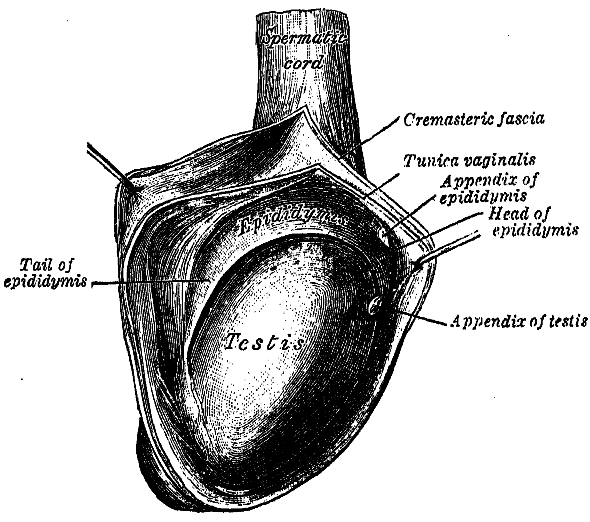
THE MALE GENITAL ORGANS

The male genital organs include the *testes* and *epididymides*, the *vasa deferentia*, the *vesiculæ seminales*, the *ejaculatory ducts* and the *penis*, together with the following accessory structures, viz. the *prostate* and the *bulbo-urethral glands*.

The Testes

The **testes**, the reproductive glands in the male, are suspended in the scrotum by the spermatic cords, the left testis hanging somewhat lower than its fellow. The average dimensions of the testis are from 4 cm. to 5 cm. in length, 2·5 cm. in breadth, and 3 cm. in the anteroposterior diameter; its weight varies from 10·5 gm. to 14 gm. Each testis is of an oval form (fig. 1231), compressed

Fig. 1231.—The right testis. Exposed by laying open the tunica vaginalis.



laterally, and has an oblique position in the scrotum; the upper extremity is directed forwards and a little laterally; the lower, backwards and a little medially. The anterior border is convex, and looks forwards and downwards; the posterior border, nearly straight, looks backwards and upwards; to it the spermatic cord is attached.

The anterior border, the medial and lateral surfaces, and the extremities of the testis, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis (p. 1381). The posterior border receives only a partial investment from that membrane. The epididymis lies along the lateral part of the posterior border.

The **epididymis** consists essentially of a tortuous canal which forms the first part of the efferent duct of the testis. This canal is folded on itself and tightly packed into the form of a long, narrow, flattened body attached to the lateral part of the posterior border of the testis. It consists of a central portion, or *body*; an upper enlarged end, or *head*; and a lower pointed end, or *tail*. The head is intimately connected with the upper end of the testis by means of the efferent ductules of the gland; the tail is connected with the lower end by cellular tissue and a reflection of the tunica vaginalis. The lateral surfaces of the head and tail of the epididymis are free and covered by the tunica vaginalis;

the body is also invested by it, except at its posterior border. A recess of the tunica vaginalis, named the *sinus of the epididymis*, lies between the body of the epididymis and the lateral surface of the testis.

The *appendages of the testis and epididymis*.—On the upper extremity of the testis, just beneath the head of the epididymis, there is a minute, oval, sessile body, termed the *appendix of the testis*; it is the remnant of the upper end of the paramesonephric duct. On the head of the epididymis there is a small, stalked appendage (sometimes duplicated); it is named the *appendix of the epididymis*, and is usually considered to be a derivative of the mesonephros.

The testis is invested by three tunics: the tunica vaginalis, tunica albuginea and tunica vasculosa.

The **tunica vaginalis** is the lower portion of the processus vaginalis of the peritoneum, which, in the fœtus, preceded the descent of the testis from the abdomen into the scrotum (p. 192). After the testis has reached the scrotum the upper part of the processus vaginalis, viz. from the deep inguinal ring to within a short distance of the testis, contracts and undergoes obliteration. The lower portion remains as a closed sac, which invests the surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and a parietal layer.

The *visceral layer* covers the lateral and medial surfaces and the anterior border of the testis, but leaves the posterior border uncovered. At the medial side of the posterior border it is reflected forwards to become continuous with the parietal layer (fig. 1237). At the lateral side of the posterior border it is reflected on to the medial aspect of the epididymis, lining the sinus of the epididymis, and then over its lateral aspect as far as its posterior border (fig. 1237), where it is reflected forwards to become continuous with the parietal layer. The continuity between the visceral and parietal layers is established also at the upper and lower poles of the testis, but at the upper pole the visceral layer covers the upper surface of the head of the epididymis before being reflected.

The *parietal layer* is more extensive than the visceral; it reaches below the testis and extends upwards for some distance in front and on the medial side of the spermatic cord. The inner surface of the tunica vaginalis is smooth, and covered with a layer of endothelial cells. The potential space between the visceral and parietal layers constitutes the cavity of the tunica vaginalis.

The obliterated portion of the processus vaginalis may frequently be seen as a fibrous thread in the anterior part of the spermatic cord; sometimes this thread may be traced from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it is lost in the spermatic cord. In some instances the upper part of the processus vaginalis is not obliterated, and the peritoneal cavity then communicates with the tunica vaginalis; in others the upper part of the processus vaginalis may persist but its lower end is shut off from the tunica vaginalis.

The **tunica albuginea** forms a fibrous covering for the testis. It is a dense membrane, of a bluish-white colour, composed of interlacing bundles of white fibrous tissue. It is covered with the visceral layer of the tunica vaginalis, except at the head and tail of the epididymis, and along the posterior border of the testis, where the testicular vessels and nerves enter the gland. It is applied to the tunica vasculosa, and, at the posterior border of the testis, is projected into the interior of the gland, forming an incomplete, vertical septum, called the *mediastinum testis*.

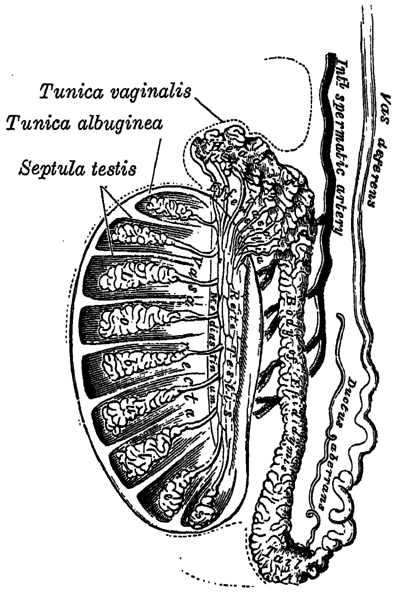
The *mediastinum testis* extends from the upper to near the lower end of the gland, and is wider above than below. From its front and sides numerous imperfect septa [*septa testis*] are given off and radiate towards the surface of the testis, where they are attached to the deep aspect of the tunica albuginea. They divide the testis incompletely into a number of cone-shaped lobes.

The bases of the lobes are at the surface of the testis, and their apices converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The **tunica vasculosa** is the vascular layer of the testis, consisting of a plexus of blood-vessels held together by delicate areolar tissue. It lines the tunica albuginea and clothes the septa, and therefore forms an investment to all the lobes of the testis.

Structure.—The serous covering of the testis consists of a layer of flattened endothelial cells similar to those which line the peritoneal cavity. The glandular structure of the testis consists of the lobes of the testis (fig. 1232). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the testis being larger and longer. Each lobe consists of from one to three, or more, minute convoluted tubes, termed the convoluted seminiferous tubules [*tubuli seminiferi convoluti*]. When the tubules have been unravelled by careful dissection under water, they are seen to commence either by free blind ends or by anastomotic loops. They are supported by loose connective tissue which contains here and there groups of *interstitial cells* (fig. 1233) containing yellow pigment granules. The total number of tubules is estimated by Lauth at 840, and the average length of each is 70 cm. to 80 cm. Their diameter varies from 0·12 mm. to 0·3 mm. The tubules are pale in colour in early life, but in old age they contain much fatty matter and acquire a deep yellow tinge. Each tubule (fig. 1233) consists of a basement-layer formed of laminated connective tissue containing numerous elastic fibres, with flattened cells between the layers, and covered externally with a layer of flattened epithelioid cells. Within the basement-membrane epithelial cells are arranged in three irregular layers. 1. An outer layer of cubical cells, with small nuclei; some of these enlarge to become *spermatogonia*. The nuclei of some of the spermatogonia may be seen to be in process of indirect division (see p. 2), and in consequence of this, daughter cells are formed which constitute the second zone. 2. Larger polyhedral cells, with clear nuclei, arranged in two or three layers; these are the *intermediate cells* or *spermatocytes*. Most of these cells are in a condition of indirect division, and the cells which result from this division form those of the next layer. 3. The third layer of cells consists of the *spermatids*, each of which becomes a *spermatozoon*. The spermatids are small polyhedral cells, the nucleus of each containing half the usual number of chromosomes. The changes which occur during the conversion of the spermatids into spermatozoa are described and illustrated on p. 49. In addition to these three layers of cells, others, termed the *supporting cells*, or *cells of Sertoli*, are seen. They are elongated and columnar, and project inwards from the basement-membrane towards the lumen of the tube. As development of the spermatozoa proceeds, the latter group themselves upon the inner extremities of the supporting cells. Ultimately the spermatozoa are liberated and set free. The structure of the spermatozoa is described on p. 48.

FIG. 1232.—A vertical section through the testis, to show the arrangement of the ducts. Diagrammatic.



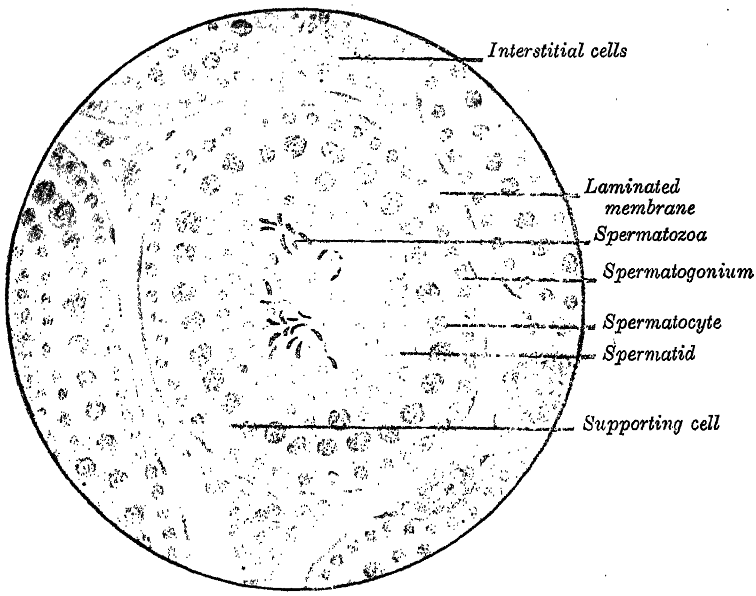
In the apices of the lobes, the tubules become less convoluted, assume a nearly straight course, and unite at acute angles to form from twenty to thirty larger straight ducts, of about 0·5 mm. in diameter, called tubuli seminiferi recti (fig. 1232).

The straight seminiferous tubules [*tubuli seminiferi recti*] enter the fibrous tissue of the mediastinum, and pass upwards and backwards, forming, in their ascent, a close network of anastomosing tubes which are merely channels in the fibrous stroma, lined by flattened epithelium, and having no proper walls; this network is named the *rete testis*. At the upper end of the mediastinum these channels terminate in from twelve to twenty ducts, termed the *efferent ductules*; they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; then they become enlarged and exceedingly convoluted, and form a series of conical masses, known as the *lobules of the epididymis*, which together constitute the head of the epididymis. Each lobule consists of a single convoluted duct, from 15 cm. to 20 cm. in length. Opposite the bases of the lobules the ducts open into a single canal, which constitutes, by its complex convolutions, the body and tail of the epididymis. When the convolutions are unravelled, this tube measures upwards of 6 metres in length; it increases in diameter and thickness as it approaches the tail of the epididymis where it becomes the vas deferens. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue.

The efferent ductules and the canal of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by ciliated columnar epithelium (fig. 1234).

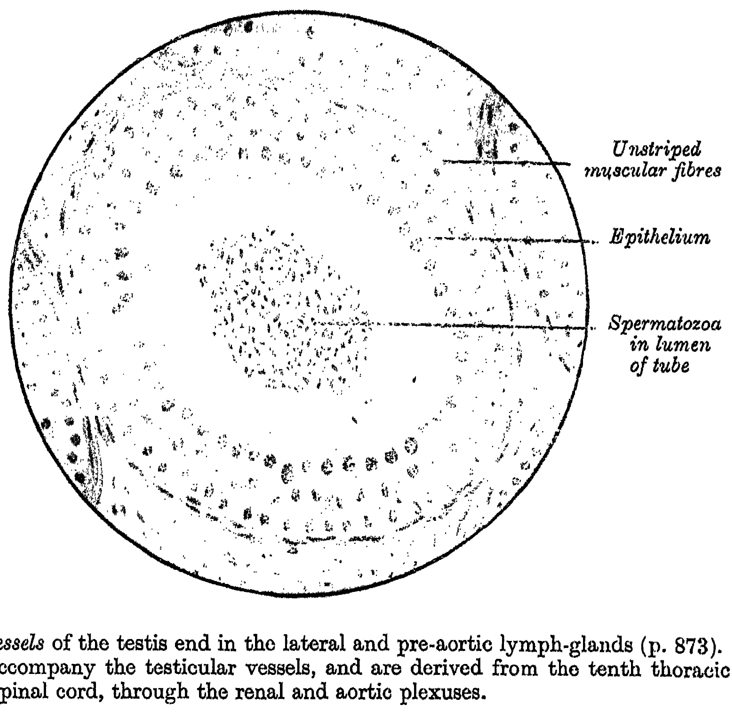
Vessels and Nerves.—The *testicular artery* is a branch of the abdominal aorta. It divides into several branches, some of which ramify in the tunica vasculosa, while others traverse the mediastinum testis and, after dividing on the septa testis, supply the semini-

FIG. 1233.—A transverse section through a part of a human testis. Stained with hæmatoxylin and eosin. ×350.



ferous tubules. Twigs are also given to the epididymis, and anastomose with the artery of the vas deferens. The *veins* emerge from the back of the testis and, after receiving tributaries from the epididymis, unite to form the pampiniform plexus (p. 839).

FIG. 1234.—A transverse section through the tube of the adult human epididymis. Stained with hæmatoxylin and eosin. ×350.



The *lymph vessels* of the testis end in the lateral and pre-aortic lymph-glands (p. 873).

The *nerves* accompany the testicular vessels, and are derived from the tenth thoracic segment of the spinal cord, through the renal and aortic plexuses.

Applied Anatomy.—At an early period of fœtal life the testes are placed in the posterior part of the abdominal cavity. Their descent into the scrotum is described on p. 192. The descent of the testis may be arrested. It may be retained in the abdomen; or it may be arrested at the deep inguinal ring, or in the inguinal canal; or it may just pass out of the superficial inguinal ring without finding its way to the bottom of the scrotum. When retained in the abdomen it gives rise to no signs or symptoms, other than the absence of the testis from the scrotum. When it is retained in the inguinal canal it is subjected to pressure and may become inflamed and painful. The retained testis is probably useless sexually; so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testis is termed *monorchism*. When a testis is retained in the inguinal canal it is often complicated with a congenital hernia, the processus vaginalis of the peritoneum not being obliterated. The testis may descend through the inguinal canal, but may miss the scrotum and assume some abnormal position (p. 192).

The testis may be inverted within the scrotum so that its posterior or attached border is directed forwards and the tunica vaginalis is situated behind. Should a hydrocele occur, and tapping be resorted to, the trocar may be thrust into the testis, unless care be taken beforehand to ascertain the position of the gland.

A number of instances of torsion of the spermatic cord, resulting in acute strangulation of the testis, have been recorded. In some it has been attributed to a strain or twist, and in several patients the condition has been associated with a late descent of the organ. In consequence of the torsion the circulation is partly arrested and the organ swells and becomes acutely painful, and the condition may be accompanied with shock and vomiting.

Fluid collections of a serous character are frequently found in the scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis. In another form, the congenital hydrocele, the fluid is in the sac of the tunica vaginalis, but this sac communicates with the general peritoneal cavity owing to the non-obliteration of the upper part of the processus vaginalis. A third variety, known as an *infantile hydrocele*, occurs in those cases where the processus vaginalis is obliterated only at or near the deep inguinal ring. It resembles the vaginal hydrocele, except as regards its shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the processus vaginalis may be obliterated both at the deep inguinal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as *encysted hydrocele of the cord*.

Encysted hydrocele of the epididymis, or *spermatocele*, is the name given to a cyst found in connexion with the head of the epididymis. Among its contents are found a varying number of spermatozoa, and it is probably a retention cyst of one of the tubules.

The Vas Deferens

The **vas deferens** (ductus deferens) is the continuation of the canal of the epididymis (fig. 1232). Commencing at the lower part of the tail of the epididymis, it is at first very tortuous, but gradually becoming straighter it ascends along the posterior border of the testis and the medial side of the epididymis. From the upper pole of the testis it runs upwards in the posterior part of the spermatic cord, and traverses the inguinal canal to the deep inguinal ring. Here it separates from the other structures of the spermatic cord, curves round the lateral side of the inferior epigastric artery, and ascends for about 2·5 cm. in front of the external iliac artery. It is next directed backwards and slightly downwards, and, crossing the external iliac vessels obliquely, enters the pelvic cavity, where it is continued backwards between the peritoneal membrane and the lateral wall of the pelvis, and on the medial side of the obliterated umbilical artery, the obturator nerve and vessels, and the vesical vessels (fig. 1223). It then crosses in front of the ureter (fig. 1235), and, reaching the medial side of this tube, bends at an acute angle, and runs medially and slightly forwards between the base of the bladder and the upper end of the seminal vesicle. Reaching the medial side of the seminal vesicle, it is directed downwards and medially in contact with it, and gradually approaches the opposite vas. Here it lies between the base of the bladder and the rectum, from which it is separated by the rectovesical fascia. Lastly, it passes downwards to the base of the prostate, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct (fig. 1236), which traverses the prostate behind its median lobe and opens into the prostatic portion of the urethra, close to the orifice of the prostatic utricle. Owing to the thickness of its wall relative to the small size of its lumen, the vas deferens feels hard and cord-like when grasped by the finger and thumb. Its canal in the greater part of its extent is of ex-

tremely small calibre, but at the base of the bladder it becomes dilated and tortuous, and this portion is termed the *ampulla* ; its terminal portion, which joins the duct of the seminal vesicle, is again greatly diminished in calibre (fig. 1236).

Ductuli aberrantes.—A long narrow tube, termed the *ductulus aberrans inferior*, is frequently found connected with the lower part of the canal of the epididymis, or with the commencement of the vas deferens. Its length, when it is uncoiled, varies from 5 cm. to 35 cm., and it may be dilated towards its blind extremity, or may be of uniform diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis. A second tube, termed the *ductulus aberrans superior*, occurs in the head of the epididymis, and is connected with the rete testis.

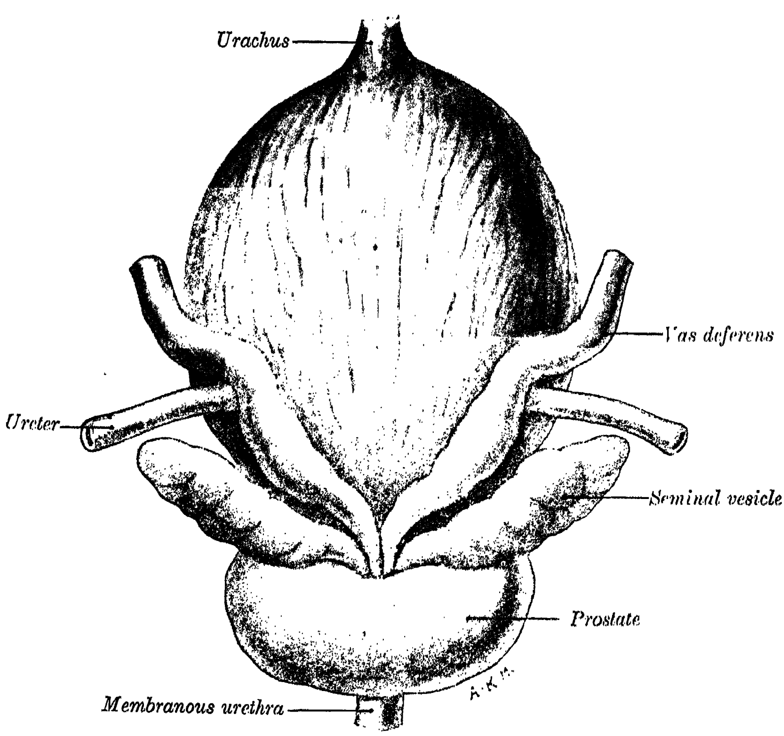
Paradidymis.—This term is applied to a small collection of convoluted tubules, situated in front of the lower part of the spermatic cord above the head of the epididymis. These tubes are lined with ciliated columnar epithelium, and probably represent the remains of a part of the mesonephros (p. 185).

Structure.—The vas deferens consists of three coats: (1) an external or areolar coat; (2) a muscular coat, which in the greater part of the tube consists of two layers of unstriped muscular fibres: an outer, longitudinal in direction, and an inner, circular; but at the commencement of the vas there is a third layer, consisting of longitudinal fibres, and placed between the circular stratum and the mucous membrane; (3) an internal, or mucous coat, which is pale, and arranged in longitudinal folds. The mucous coat is lined with columnar epithelium, which is non-ciliated throughout the greater part of the tube; a variable portion of the testicular end of the tube is lined with two strata of columnar cells, those of the superficial layer being ciliated.

The Seminal Vesicles and Ejaculatory Ducts

The **seminal vesicles** (fig. 1235) are two sacculated pouches, placed between the base of the bladder and the rectum. Each vesicle is about 5 cm.

Fig. 1235.—The bladder, seminal vesicles, etc. Viewed from above and behind.

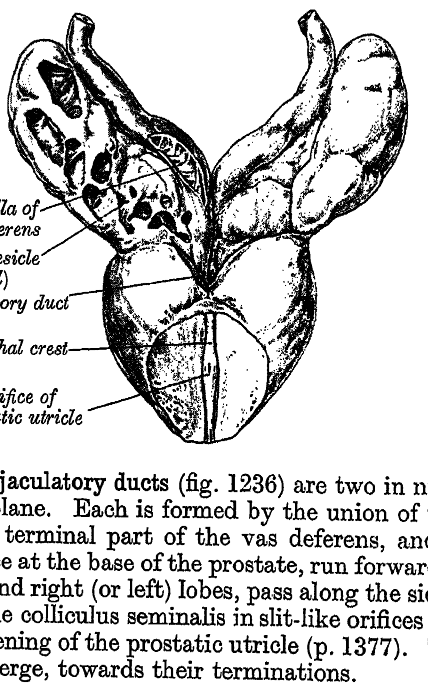


long, and is somewhat pyramidal in form, the broad end being directed backwards, upwards and laterally. It consists of a tube, coiled upon itself, and giving off several irregular diverticula (fig. 1236); the separate coils, as well as the diverticula, are connected together by fibrous tissue. When uncoiled, the tube is about the diameter of a quill, and varies in length from 10 cm. to 15 cm.;

it ends above in a cul-de-sac; its lower extremity becomes constricted into a narrow straight duct, which joins with the corresponding vas deferens to form the ejaculatory duct. The *anterior surface* is in contact with the base of the bladder, extending from near the termination of the ureter to the base of the prostate. The *posterior surface* rests upon the rectum, from which it is separated by the rectovesical fascia. The vesicles diverge from each other above, and are in relation with the vasa deferentia and the terminations of the ureters, and are partly covered with peritoneum; each is enveloped in a dense, fibromuscular sheath. Along the medial margin of the vesicle runs the ampulla of the vas deferens. Lateral to the vesicle, the veins of the prostatic venous (pudendal) plexus pass backwards to join the internal iliac vein.

Structure.—The seminal vesicles are composed of three coats: an *external* or *areolar coat*; a *middle* or *muscular coat*, thinner than that of the vas deferens and arranged in two layers, an outer longitudinal and an inner circular; an *internal* or *mucous coat*, which is pale, of a whitish-brown colour, and presents a delicate, reticular structure. The epithelium is columnar, and in the diverticula goblet-cells are present, the secretion of which forms a large part of the seminal fluid.

FIG. 1236.—The seminal vesicles, the terminal portions of the vasa deferentia, and the prostate, exposed from in front. The anterior walls of the right seminal vesicle and of the ampulla of the right vas deferens have been removed, and the prostatic part of the urethra has been opened from in front by the removal of a portion of the prostate.



Vessels and Nerves.—The *arteries* supplying the seminal vesicles are derived from the inferior vesical, and the middle rectal arteries. The *veins* and *lymph vessels* accompany the arteries. The *nerves* are derived from the pelvic plexuses.

Applied Anatomy.—The seminal vesicles are often the seat of the disease in cases of tuberculosis of the genito-urinary tract, and should always be examined from the rectum, in cases where the testes are involved. They also become affected in chronic posterior urethritis of gonorrhœal origin. An abscess of the seminal vesicle may rupture into the peritoneal cavity and cause fatal peritonitis.

The ejaculatory ducts (fig. 1236) are two in number, one on each side of the median plane. Each is formed by the union of the duct of the seminal vesicle with the terminal part of the vas deferens, and is nearly 2 cm. long. They commence at the base of the prostate, run forwards and downwards between the median and right (or left) lobes, pass along the sides of the prostatic utricle, and end on the colliculus seminalis in slit-like orifices on, or just within, the margins of the opening of the prostatic utricle (p. 1377). The ducts diminish in size, and also converge, towards their terminations.

Structure.—The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after the entrance of the ducts into the prostate; a *layer of muscular fibres*, consisting of a thin outer circular, and an inner longitudinal layer; and *mucous membrane*.

The Spermatic Cord and its Coverings

When the testis descends through the abdominal wall into the scrotum, it drags its vessels and nerves and the vas deferens with it. These structures meet at the deep inguinal ring and together form the *spermatic cord*, which suspends the testis in the scrotum, and extends from the deep inguinal ring to the posterior border of the testis; the left spermatic cord is a little longer than the right.

The spermatic cord traverses the inguinal canal (p. 571) and in so doing acquires coverings from the different layers which form the abdominal wall These coverings extend downwards into the wall of the scrotum and are named

from within outwards, the internal spermatic, cremasteric and external spermatic fasciæ.

The *internal spermatic fascia* is a thin layer which loosely invests the spermatic cord, and is derived from the transversalis fascia (p. 571).

The *cremasteric fascia* consists of a number of muscular fasciculi, united to one another by areolar tissue ; the muscular fasciculi constitute the Cremaster and are continuous with the Obliquus internus abdominis (p. 566).

The *external spermatic fascia* is a thin fibrous membrane continuous above with the aponeurosis of the Obliquus externus abdominis, and prolonged downwards from the crura of the superficial ring (p. 563).

Structure of the spermatic cord.—The spermatic cord is composed of arteries, veins, lymph vessels, nerves, and the vas deferens, connected together by areolar tissue.

The *arteries* of the spermatic cord are : the testicular artery, the artery to the cremaster and the artery of the vas deferens.

The *testicular artery*, a branch of the abdominal aorta (p. 771), escapes from the abdominal cavity at the deep inguinal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the superficial inguinal ring into the scrotum. It then descends to the testis, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens ; the others supply the substance of the testis.

The *artery to the cremaster* (external spermatic artery) is a branch of the inferior epigastric artery (p. 784). It supplies the coverings of the spermatic cord, and anastomoses with the testicular artery.

The *artery of the vas deferens*, a branch of either the inferior or the superior vesical artery (p. 777), is a long slender vessel which accompanies the vas deferens, ramifying upon its coats, and anastomosing with the testicular artery near the testis. Near its origin it sends a small branch downwards to supply the ampulla of the vas deferens and the seminal vesicle.

The *testicular veins* emerge from the back of the testis, and receive tributaries from the epididymis : they unite and form a convoluted plexus, named the *pampiniform plexus*, which constitutes the chief mass of the cord ; the vessels composing this plexus are very numerous, and ascend in front of the vas deferens ; below the superficial inguinal ring they unite to form three or four veins which pass along the inguinal canal, and, entering the abdomen through the deep inguinal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the left renal vein, at a right angle.

The *lymph vessels* of the testis are described on p. 873.

The *nerves* are (1) the genital branch of the genitofemoral nerve (p. 1113), and (2) the testicular plexus of the sympathetic (p. 1151), joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

The Scrotum

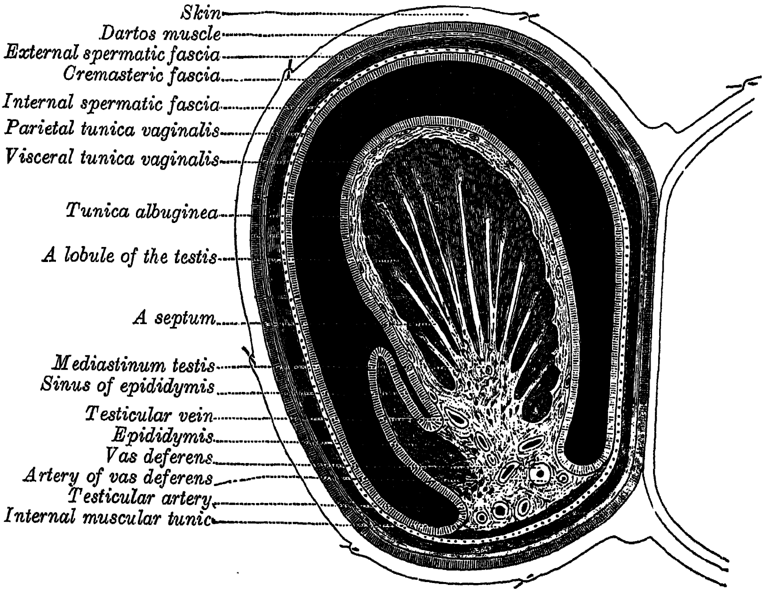
The *scrotum* is a cutaneous pouch containing the testes and the lower parts of the spermatic cords, and placed below the pubic symphysis in front of the upper parts of the thighs. It is divided on its surface into a right and a left portion by a ridge, or *raphe*, which is continued forwards to the under surface of the penis, and backwards along the middle line of the perineum to the anus ; the left portion hangs lower than the right, in correspondence with the greater length of the left spermatic cord. The external appearance varies under different circumstances : thus, under the influence of warmth, and in old and debilitated persons, the scrotum is elongated and flaccid ; but, under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes. It consists of the skin and the dartos muscle, together with the external spermatic, cremasteric and internal spermatic fasciæ, already described in connexion with the spermatic cord. The inner surface of the internal spermatic fascia is in contact with the layer of the tunica vaginalis (fig. 1237).

The *skin* is very thin, of a brownish colour, and generally thrown into folds or rugæ. It is beset with thinly scattered, crisp hairs, the roots of which are visible through the skin ; it is provided with sebaceous follicles, the secretion of which has a peculiar odour.

The *dartos muscle* is a thin layer of non-striped muscular fibres, continuous around the base of the scrotum, with the superficial fascia of the groin and of the perineum. It sends inwards a septum, which connects the raphe to the under surface of the root of the penis, and divides the scrotal pouch into two

cavities for the testes. The dartos muscle is closely united to the skin, but is connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility.

Fig. 1237.—A transverse section through the left half of the scrotum and the left testis. The sac of the tunica vaginalis is represented in a distended condition. Diagrammatic. (Delépine.)



Vessels and Nerves.—The *arteries* supplying the scrotum are: the external pudendal branches of the femoral artery (p. 789), the scrotal branches of the internal pudendal artery (p. 779), and the cremasteric branch from the inferior epigastric artery (p. 784). The *veins* follow the course of the corresponding arteries. The *lymph vessels* end in the inguinal lymph-glands (p. 862). The *nerves* are the ilio-inguinal and genital branch of the genitofemoral (p. 1113), the two scrotal branches of the perineal nerve (p. 1128), and the perineal branch of the posterior femoral cutaneous nerve (p. 1122).

Applied Anatomy.—The scrotum forms an admirable covering for the protection of the testes. These bodies, lying suspended and loose in the cavity of the scrotum and surrounded by serous membrane, are capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of œdema, to which this part is especially liable as a result of its dependent position.

The Penis

The penis is a pendulous organ suspended from the front and sides of the pubic arch and containing the greater part of the urethra. In the flaccid condition it is cylindrical in shape, but when erect it assumes the form of a triangular prism with rounded angles, one side of the prism forming the dorsum of the penis. It is composed of three cylindrical masses of erectile tissue bound together by fibrous tissue and covered with skin. Two of the masses are placed side by side, and are known as the *corpora cavernosa penis*; the third, median in position and beneath the other two, is traversed by the spongy part of the urethra, and is termed the *corpus spongiosum penis* (corpus cavernosum urethræ) (figs. 1238, 1239).

The **corpora cavernosa penis** form the greater part of the substance of the penis. Throughout the anterior three-fourths of their extent they lie in apposition with each other, separated only by the septum of the penis (fig. 1239); behind, they diverge in the form of two tapering processes, which are known as the *crura of the penis*, and are firmly connected to the rami of

the pubic arch. Traced from behind forwards each crus begins as a blunt-pointed process in front of the tuberosity of the ischium. Just before it meets its fellow it presents a slight enlargement. Beyond this point the crus undergoes a constriction and merges into the corpus cavernosum proper, which retains a uniform diameter to its anterior end. Each corpus cavernosum penis ends abruptly in a round extremity a short distance from the end of the penis.

The corpora cavernosa penis are surrounded by a strong, fibrous envelope consisting of superficial and deep fibres. The superficial fibres are longitudinal in direction, and form a single tube which encloses both corpora; the deep fibres are arranged circularly round each corpus, and form by their junction in the median plane the *septum of the penis*. This septum is thick and complete behind, but is imperfect in front, where it consists of a series of bands arranged like the teeth of a comb; it is therefore sometimes named the *septum pectiniforme*.

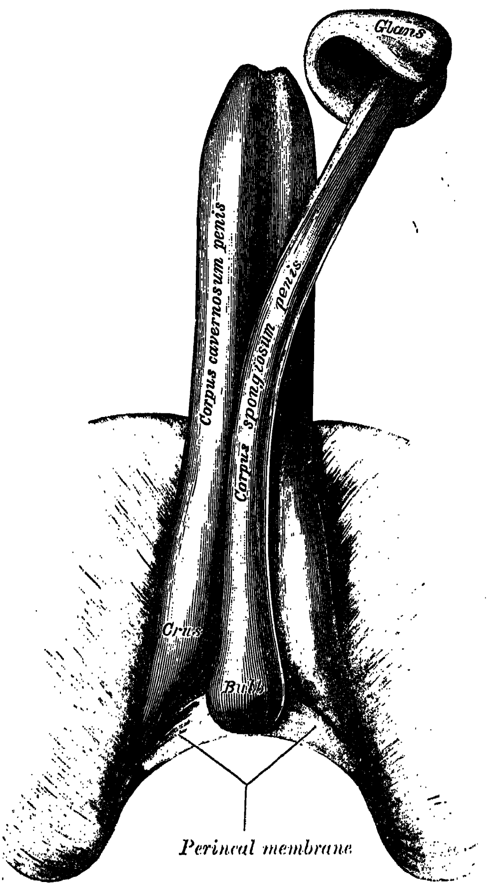


FIG. 1238.—The constituent cavernous cylinders of the penis. The glans penis and the anterior part of the corpus spongiosum penis are detached from the corpora cavernosa penis and turned to one side.

The **corpus spongiosum penis** (corpus cavernosum urethrae) contains the spongy part of the urethra. Behind, it is expanded to form the bulb of the penis, and lies in apposition with the perineal membrane, from which it receives a fibrous investment. The urethra enters the bulb nearer to the upper than to the lower surface. On the lower surface of the bulb there is a median sulcus, from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes or *hemispheres*.

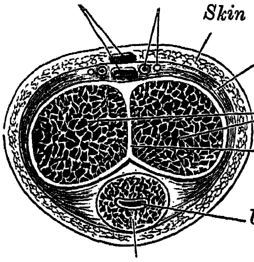
The portion of the corpus spongiosum penis in front of the bulb lies in a groove on the under surface of the conjoined corpora cavernosa penis. It is cylindrical in form and tapers slightly from behind forwards. Its anterior end suddenly expands to form an obtuse cone, named the *glans penis*.

For descriptive purposes it is convenient to divide the penis into three regions: the root, the body, and the extremity.

The **root** of the penis is triradiate in form, consisting of the diverging crura, one on each side, and the bulb of the penis in the median plane (fig. 1238). Each crus is covered with the Ischio-cavernosus, while the bulb is surrounded by the Bulbo-spongiosus. The root of the penis lies in the perineum between the perineal membrane and the membranous layer of the superficial fascia. In addition to being attached to the fasciæ and the pubic rami, it is bound to the front of the symphysis by the fundiform and suspensory ligaments. The *fundiform ligament* springs from the lower part of the linea alba and from the adjoining parts of the sheaths of the Recti abdominis; it splits into two fasciculi which pass one on each side of the penis and unite below with the septum of the scrotum. The *suspensory ligament* is triangular in shape; it is attached above to the symphysis pubis; below, it blends with the fibrous envelope of the corpora cavernosa penis.

The **body** of the penis extends from the root to the anterior end of the corpora cavernosa penis. In the body the corpora cavernosa are intimately bound to each other; a shallow groove which marks their junction on the upper surface lodges the deep dorsal vein of the penis, while a deeper and wider groove between them on the under surface contains the corpus spongiosum penis. The body is ensheathed by fascia, which is continuous above with the membranous layer of the superficial fascia of the abdominal wall above, and of the perineum below.

FIG. 1239.—A transverse section through the penis.



The **extremity** is formed by the glans penis, the expanded anterior end of the corpus spongiosum penis. The glans penis is somewhat conical in shape and its concave base covers, and is attached to, the ends of the corpora cavernosa. The projecting margin of its base is named the *corona glandis*, and the constriction behind the latter is known as the *neck of the penis*. The terminal part of the urethra runs through the glans penis, and ends in a sagittal slit on its apex.

The skin covering the penis is remarkable for its thinness, its dark colour, its looseness of connexion with the fibrous envelope of the organ, and the absence of adipose tissue. At the root of the penis it is continuous with the skin over the pubes, scrotum and perineum. At the neck of the penis it is folded upon itself to form the *prepuce* or *foreskin*, which overlaps the glans for a variable distance. The internal layer of the prepuce is confluent along the line of the neck with the thin skin which covers, and adheres firmly to, the glans, and is continuous with the mucous membrane of the urethra at the external urethral orifice. On the under surface of the glans penis a small median fold passes from the deep surface of the prepuce to a point on the glans immediately behind the external urethral orifice; this median fold is named the *frenulum* of the prepuce. The prepuce is separated from the glans penis by a potential sac—the *preputial sac*—which presents two shallow fossæ, one on each side of the frenulum. On the corona of the glans and on the neck of the penis there are numerous small *preputial glands*; these secrete a sebaceous material named the *smegma*, which possesses a very peculiar odour.

Structure of the penis.—From the internal surface of the fibrous envelope of the corpora cavernosa penis, as well as from the sides of the septum, numerous *trabeculæ* arise, and cross the corpora cavernosa in all directions, subdividing them into a number of *cavernous spaces*, and giving the entire structure a spongy appearance (fig. 1239). These trabeculæ consist of white fibrous tissue, elastic fibres and plain muscular fibres, and they contain numerous arteries and nerves. The cavernous spaces are filled with blood, and are lined with a layer of flattened cells similar to the endothelial lining of veins.

The fibrous envelope of the corpus spongiosum penis is thinner, whiter in colour, and more elastic than that of the corpora cavernosa penis. The trabeculæ are more delicate, and the meshes between them are smaller than in the corpora cavernosa penis. The envelope of the corpus spongiosum penis is formed partly of unstriped muscular fibres, and a layer of the same tissue surrounds the canal of the urethra.

Vessels and Nerves.—The arteries bringing the blood to the cavernous spaces are the deep arteries of the penis, and branches from the dorsal arteries of the penis, which perforate the fibrous capsule along the upper surface, especially near the extremity of the organ. On entering the cavernous structure the arteries divide into branches which are supported and enclosed by the trabeculæ. Some of these arteries end in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, named *helicine arteries*. They open into the cavernous spaces, and from them small capillary branches go to supply the trabecular structure. They are most abundant in the posterior parts of the corpora cavernosa.

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge from the base of the glans penis and converge on the dorsum of the penis to form the

deep dorsal vein ; others pass out on the upper surface of the corpora cavernosa and join the same vein ; some emerge from the under surface of the corpora cavernosa penis and, receiving branches from the corpus spongiosum penis, wind round the sides of the penis to end in the deep dorsal vein ; but many pass out at the root of the penis and join the prostatic plexus.

The *nerves* are derived from the second, third and fourth sacral nerves, through the pudendal nerve and the pelvic plexuses. On the glans and on the bulb of the penis some filaments of the cutaneous nerves have lamellated corpuscles connected with them, and many of them end in peculiar end-bulbs (p. 1216).

The Prostate

The **prostate** (figs. 1223, 1235) is a firm, partly glandular and partly muscular body, surrounding the commencement of the urethra. It is situated in the pelvic cavity, behind the lower part of the symphysis pubis and the upper part of the pubic arch, and in front of the ampulla of the rectum. It is about the size of a chestnut and somewhat conical in shape, and presents for examination a base, an apex, a posterior, an anterior and two inferolateral surfaces.

The *base* is directed upwards, and, for the greater part of its extent, is directly continuous with the neck of the urinary bladder : the urethra enters it nearer its anterior than its posterior border.

The *apex* is directed downwards and is in contact with the fascia on the deep surfaces of the Sphincter urethræ and the Transversus perinei profundus.

The *posterior surface* is flattened from side to side and slightly convex from above downwards ; it is separated by its sheath and some loose connective tissue from the rectum, and is distant about 4 cm. from the anus (fig. 1223). Near its upper border there is a depression through which the two ejaculatory ducts enter the prostate. This depression serves to divide the posterior surface into a lower, larger, and an upper, smaller part. The upper, smaller part constitutes the *median lobe* of the prostate and intervenes between the ejaculatory ducts and the urethra ; it varies greatly in size, and in some cases is destitute of glandular tissue. The lower larger portion sometimes presents a shallow median furrow, which imperfectly separates it into *right* and *left lobes* ; these form the main mass of the gland and are directly continuous with each other behind the urethra ; they are connected in front of the urethra by a band which is named the *isthmus* ; the latter consists of fibromuscular tissue and is devoid of glandular substance.

The *anterior surface* is narrow and convex from side to side and extends from the apex to the base. It lies about 2 cm. behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fatty tissue. Near its upper end it is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface a little above and in front of the apex of the prostate.

The *inferolateral surfaces* are prominent, and are covered by the anterior portions of the Levatores ani, which are, however, separated from the gland by a plexus of veins imbedded in connective tissue which forms the lateral part of the sheath of the organ.

The prostate measures about 4 cm. transversely at the base, about 2 cm. in its anteroposterior, and 3 cm. in its vertical, diameter. Its weight is about 8 gm. It is invested by a fibrous sheath derived from the pelvic fascia. On each side the sheath consists of connective tissue in which are imbedded the veins of the prostatic venous (pudendal) plexus (fig. 611). In front, it is continuous with the puboprostatic ligaments (p. 574) and, below, it blends with the fascia on the deep surfaces of the Sphincter urethræ and the Transversus perinei profundus, and with the perineal body (fig. 608). The posterior wall of the sheath has a different constitution and is non-vascular. In the male fœtus, at the fourth month, the rectovesical peritoneal pouch extends downwards to the pelvic floor and separates the prostate from the rectum. The lower part of this recess becomes obliterated and the fused peritoneal layers form the posterior wall of the prostatic sheath.* This fibrous membrane has been termed the *rectovesical fascia*. Above, it extends upwards over the posterior aspects of the

* G. Elliot Smith (*Journal of Anatomy*, vol. xlii.).

seminal vesicles and the vasa deferentia and is connected to the peritoneal floor of the rectovesical pouch (fig. 608). On each side, it is connected to the posterior ligament of the bladder (p. 1374) and, below, where it becomes closely adherent to the prostate, it is lost in the perineal body. The anterior portions of the Levatores ani pass backwards from the os pubis and embrace the sides of the prostate; from the support they afford to this organ they are named the *Levatores prostatæ.*

The prostate is perforated by the urethra and the ejaculatory ducts and contains the prostatic utricle. The urethra usually lies along the junction of its anterior with its middle one-third. The ducts pass obliquely downwards and forwards through the posterior part of the prostate, and open into the prostatic portion of the urethra (p. 1377).

Structure.—The prostate is enveloped by a thin but firm capsule, distinct from the sheath derived from the pelvic fascia, which contains a plexus of veins. This capsule is firmly adherent to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues, viz. non-striped muscle and fibrous tissue. The substance of the prostate is of a pale reddish-grey colour, of great density, and not easily torn. It consists of glandular substance and muscular tissue.

The *muscular tissue* constitutes the proper stroma of the prostate; the connective tissue being very scanty, and merely forming, between the muscular fibres, thin trabeculæ in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the capsule there is a dense layer, which forms an investing sheath for the gland; around the prostatic part of the urethra a dense layer of circular fibres is continuous above with the internal layer of the muscular coat of the bladder, and blends below with the fibres surrounding the membranous portion of the urethra; between these two layers strong bands of muscular tissue decussate freely, and form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no glandular tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like towards the apex.

The *glandular substance* is composed of numerous follicles the lining of which frequently shows papillary elevations. The follicles open into elongated canals which join to form from twelve to twenty small excretory ducts. They are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium which lines the canals and the follicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra, and are lined by two layers of epithelium, the inner layer consisting of columnar and the outer of small cubical cells. Small colloid masses, known as amyloid bodies, are often found in the gland tubes. The prostatic secretion and the secretion of the seminal vesicle together form the bulk of the seminal fluid.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the internal pudendal, inferior vesical and middle rectal (hæmorrhoidal) arteries. Its *veins* form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and end in the internal iliac (hypogastric) veins. The *lymph vessels* are described on p. 874. The *nerves* are derived from the pelvic plexus (p. 1152).

Applied Anatomy.—By means of the finger introduced into the rectum, the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, and is able to direct the point of a catheter, when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. The prostate is occasionally the seat of suppuration, due to either gonorrhœa or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may burst into the rectum, or more rarely in the perineum. In advanced life the prostate often becomes considerably enlarged and projects into the bladder so as to impede the passage of the urine. According to Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the condition affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases the median lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the internal urethral orifice, preventing the passage of the urine; and the more the patient strains, the more completely will it block the opening into the urethra.

The Bulbo-urethral Glands

The **bulbo-urethral glands** are two small, rounded and somewhat lobulated bodies, of a yellow colour. Each is about the size of a pea, and is placed lateral to the membranous portion of the urethra, deep to the perineal membrane. They lie above the bulb of the penis, and are enclosed by the transverse fibres of the Sphincter urethræ. They gradually diminish in size as age advances.

The excretory duct of each gland is nearly 3 cm. long ; it passes obliquely forwards beneath the mucous membrane, and opens by a minute orifice on the floor of the spongy portion of the urethra about 2·5 cm. below the perineal membrane.

Structure.—Each gland is made up of several lobules which are held together by a fibrous investment. Each lobule consists of a number of acini, lined by columnar epithelial cells. The secretion of the bulbo-urethral glands is an additional constituent of the seminal fluid, but the glands are very small in man as compared with many animals, and the part which they play is probably very subsidiary.

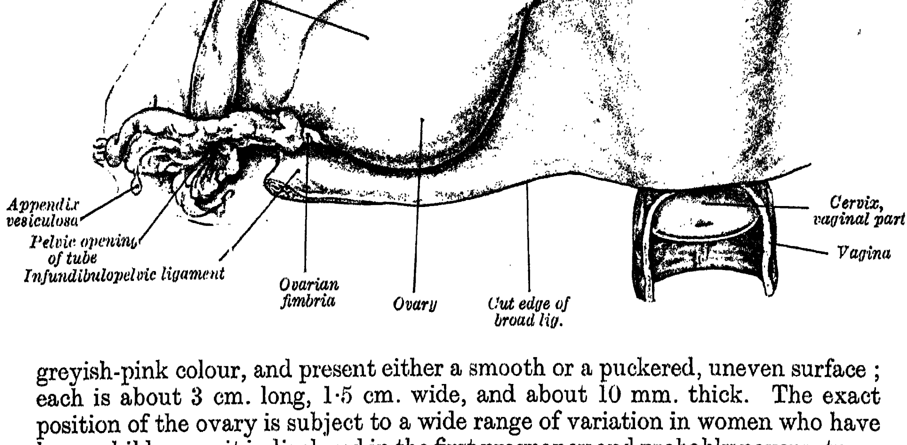
THE FEMALE GENITAL ORGANS

The female genital organs consist of an internal and an external group. The *internal organs* are situated within the pelvis, and consist of the ovaries, the uterine tubes, the uterus and the vagina. The *external organs* are placed below and in front of the pubic arch. They comprise the mons pubis, the labia majora et minora pudendi, the clitoris, the bulbus vestibuli and the greater vestibular glands.

The Ovaries

The **ovaries**, two in number, are homologous with the testes in the male. They are situated one on each side of the uterus in relation to the lateral wall of the pelvis, and attached to the posterior or upper layer of the broad ligament of the uterus, behind and below the uterine tube (fig. 1240). They are of a

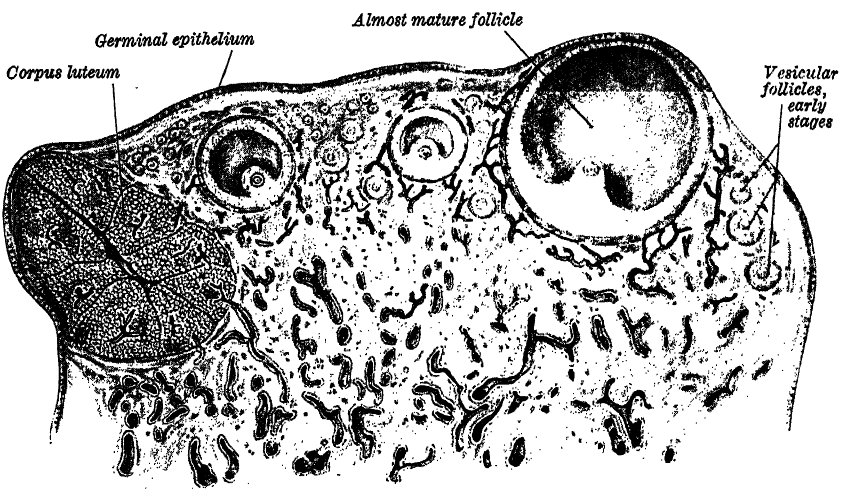
Fig. 1240.—The uterus and the left broad ligament. Posterior surface. The broad ligament has been spread out and the ovary drawn downwards.



greyish-pink colour, and present either a smooth or a puckered, uneven surface ; each is about 3 cm. long, 1·5 cm. wide, and about 10 mm. thick. The exact position of the ovary is subject to a wide range of variation in women who have borne children, as it is displaced in the first pregnancy and probably never returns

again to its original position. The description here given applies to that of the nulliparous woman. In the erect posture the long axis of the ovary is vertical, and the gland presents a lateral and a medial surface, a tubal and a uterine extremity, and a mesovarian and a free border. The ovary lies in a depression, named the *ovarian fossa*, on the lateral wall of the pelvis ; this fossa is bounded in front by the obliterated umbilical artery, and behind by the ureter and the internal iliac (hypogastric) artery. The *tubal extremity* is near the external iliac vein ; to it are attached the ovarian fimbria of the uterine tube and a fold of peritoneum, named the *infundibulopelvic ligament* (suspensory ligament of the ovary), which passes upwards over the iliac vessels and contains the ovarian vessels and nerves. The *uterine extremity* is directed downwards towards the pelvic floor ; it is usually narrower than the tubal extremity, and is attached to the lateral angle of the uterus, immediately behind and below the uterine tube, by a rounded cord termed the *ligament of the ovary*, which lies within the broad ligament and contains some non-striped muscular fibres. The *lateral surface* is in contact with the parietal peritoneum which lines the ovarian fossa ; it separates the ovary from the peritoneal tissue and the obturator vessels

Fig. 1241.—A section through the ovary. Semidiagrammatic.



and nerve. The *medial surface* is to a large extent covered with the uterine tube and the peritoneal recess between this aspect of the gland and the mesosalpinx is termed the *bursa ovarica*. The *mesovarian border* is straight and is directed towards the obliterated umbilical artery ; it is attached to the back of the broad ligament by a short fold named the *mesovarium*. Between the two layers of this fold the blood-vessels and nerves pass to the hilum of the ovary. The *free border* is convex, and is directed towards the ureter. The uterine tube arches over the ovary, running upwards in relation to its mesovarian border, curving over its tubal extremity, and then passing downwards on its free border and medial surface.

In the fœtus, the ovaries are situated, like the testes, in the lumbar region near the kidneys, but they gradually descend into the pelvis (p. 193).

Structure (fig. 1241).—The surface of the ovary is covered with a layer of cubical cells. This *germinal epithelium* gives to the ovary a dull grey colour as compared with the shining smoothness of the peritoneum ; the transition between the flattened endothelium of the peritoneum and the cubical cells covering the ovary is usually marked by a line around the anterior, or mesovarian, border of the ovary.

The ovary consists of a stroma, or framework, in the meshes of which a number of vesicular ovarian follicles are imbedded.

The *stroma* is abundantly supplied with blood-vessels, and consists for the most part of spindle-shaped cells with a small amount of ordinary connective tissue. Many of these cells are unstriped muscle-cells. On the surface of the organ there is a condensed layer known as the *tunica albuginea*. The stroma of the ovary also contains groups of *interstitial cells* resembling those of the testis.

Vesicular ovarian (*Graafian*) *follicles*.—When a section is made through an ovary, numerous vesicles of various sizes are seen; they are the follicles, or ovisacs containing the ova. Immediately beneath the tunica albuginea there is a layer of stroma, called the *cortical layer*, characterised by the presence of a large number of ova in an early stage of development. At this stage each ovum is surrounded by a single layer of smaller, cubical cells. These primitive follicles are numerous in the ovary of the child.

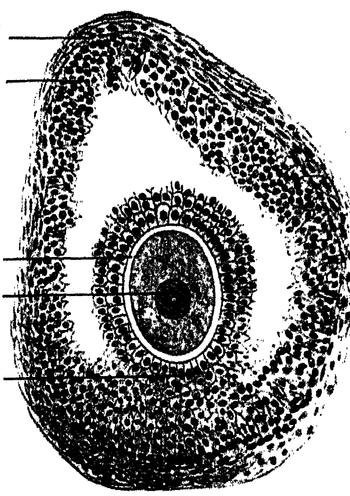
After puberty some of these primitive ovarian follicles increase in size; the cells investing the ovum multiply, and later a cavity, named the *antrum folliculi*, appears between the cells thus formed. This cavity is filled with *liquor folliculi*, a transparent, albuminous fluid which nourishes and protects the ovum. The liquor folliculi splits the investing cells into two strata, an outer named the *stratum granulosum*, and an inner named the *cumulus ovaricus*; the latter surrounds the ovum * and is attached at one spot to the stratum granulosum (fig. 1241). Thomson † is of opinion that the cumulus may be attached to the stratum granulosum at any part of the circumference of the follicle. In the earlier stages of the development of the follicle the stratum granulosum is made up of several layers of cubical cells, but in the matured follicle it consists of a single layer, and in some instances this may disappear.

Scattered amongst the cells of the cumulus ovaricus and stratum granulosum are certain structures known as the *bodies of Call and Exner*, the cells surrounding which are radially arranged; in the advanced stages of the growth of the follicle these bodies are found only in the cumulus. Each consists of a more or less homogeneous mass of protoplasm, which, in its reactions to certain stains, resembles the coagulated liquor folliculi. These bodies become vacuolated, and tend to break down, and it is therefore probable that the liquor folliculi is formed, in the first instance, by their dissolution.

A fully developed or 'ripe' ovarian follicle measures at least 10 mm. † and is surrounded by a capsule [*theca folliculi*] derived from the ovarian stroma, and composed of an internal and an external tunic. The *tunica interna* consists of loosely-arranged, round or spindle-shaped cells, and is pervaded by a capillary plexus. The vascularity of this tunic increases as the follicle matures, and the capillary vessels then extend between the cells of the attached part of the cumulus. Between the tunica interna and the stratum granulosum which lines it, there is a thin *external limiting membrane* (basal membrane). The *tunica externa* consists of firmer and less vascular tissue than the tunica interna, and contains a considerable quantity of non-striped muscular fibres.

The mature follicle approaches, and ultimately bursts on, the surface of the ovary, and the escaping ovum, surrounded by the cells of the cumulus ovaricus, is grasped by the fimbriated end of the uterine tube, and is conveyed along this tube to the cavity of the uterus.

FIG. 1242.—A section through an ovarian follicle of a cat. ×50.



Robinson ‡ has investigated the formation, rupture, and closure of the ovarian follicles in ferrets, and has shown that in these animals a fluid, named by him the *secondary liquor folliculi*, appears between the cells of the cumulus ovaricus and takes part in the final distension of the follicle which precedes rupture. It would seem probable that a similar process occurs in the human follicle and accounts both for the rupture of the follicle and for the liberation of the ovum with its cumulus from the stratum granulosum.

The maturation of the follicles and ova continues uninterruptedly from puberty to the end of the reproductive period of woman's life. In all probability only one of the numerous follicles which are visible on the surface of an ovary at any particular time gives rise to a normal mature ovum. The others undergo atretic changes and become disintegrated. In these cases the rupture of the follicle liberates an abnormal ovum.

* The ovum is described on pp. 44 to 46.

† Consult, in this connexion, articles by Arthur Thomson on "The Ripe Human Graafian Follicle," *Journal of Anatomy*, vol. liv., and by Edgar Allen and others on "Human Ova from Large Follicles," *American Journal of Anatomy*, vol. xlvi., no. 1.

‡ Arthur Robinson, *Transactions of the Royal Society of Edinburgh*, vol. lii. part ii.

Corpus luteum.—After the discharge of the ovum a series of changes occurs within the vesicular ovarian follicle which results in the formation of a structure named the *corpus luteum.* When fully developed this consists of numerous cells, separated from one another by delicate strands of vascular connective tissue; in the centre of the follicle this tissue is condensed to form a mass which is devoid of cells. The cells of the corpus luteum are of two kinds, (*a*) *lutein cells,* which are large, very numerous, and contain yellow pigment, and (*b*) *paralutein cells,* which are small and less numerous. The lutein cells are derived from the cells of the stratum granulosum, and the paralutein cells from the cells of the tunica interna, of the vesicular ovarian follicle.*

If the discharged ovum is not fertilised the corpus luteum quickly degenerates, and within two months is reduced to a small cicatrix, but if the ovum is fertilized the corpus luteum increases in size, and, by the middle of pregnancy, may measure about 2·5 cm. in diameter. During the later months of pregnancy the lutein cells lose their colour, and the size of the corpus luteum diminishes, so that by the end of pregnancy its diameter is reduced to about 1 cm.†

Vessels and Nerves.—The *arteries* of the ovaries and uterine tubes are the ovarian arteries from the aorta (p. 772). Each anastomoses in the mesosalpinx with the corresponding uterine artery: it gives some branches to the uterine tube, and others which traverse the mesovarium and enter the hilum of the ovary. The *veins* emerge from the hilum in the form of a plexus, named the *pampiniform plexus*; the ovarian vein is formed from this plexus, and leaves the pelvis in company with the artery (p. 840). The *lymph vessels* are described on p. 874. The *nerves* are derived from the hypogastric or pelvic plexus, and from the ovarian plexus, the uterine tube receiving a branch from one of the uterine nerves.

Epoöphoron (fig. 1240).—The epoöphoron lies in the lateral part of the mesosalpinx between the ovary and the uterine tube, and consists of a few short tubules [*tubuli epoöphori*] which converge towards the ovary while their opposite ends open into a rudimentary duct, named the *ductus epoöphori,* which runs in the broad ligament of the uterus, parallel with the lateral part of the uterine tube.

In a small proportion of subjects the duct of the epoöphoron can be followed alongside the uterus to near the level of the internal os. Here it pierces the muscular wall of the uterus and descends in the cervix uteri, gradually approaching the mucous membrane, without however quite reaching it. The duct then runs downwards in the lateral wall of the vagina and ends at, or close to, the free margin of the hymen.

Paroöphoron.—The paroöphoron consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the epoöphoron and the uterus.

The tubules of the epoöphoron and of the paroöphoron are remnants of the tubules of the mesonephros; the duct of the epoöphoron is a persistent portion of the mesonephric (Wolffian) duct.

The Uterine Tubes (figs. 1240, 1244)

The **uterine tubes**, two in number, transmit the ova from the ovaries to the cavity of the uterus and are situated in the upper margins of the broad ligaments of the uterus. Each tube is about 10 cm. long, and one end of it opens into the superior angle of the cavity of the uterus, the other into the peritoneal cavity close to the ovary. The opening into the uterine cavity is very small, and only admits a fine bristle; the opening into the peritoneal cavity is named the *ostium pelvinum* (ostium abdominale), and when its muscular wall is relaxed has a diameter of about 3 mm. The pelvic ostium is situated at the bottom of a trumpet-shaped expansion of the uterine tube, termed the *infundibulum,* the circumference of which is prolonged into a varying number of irregular processes, called *fimbriæ,* and therefore this extremity of the tube is sometimes called the *fimbriated end.* The inner surfaces of the fimbriæ are lined by mucous membrane, and in the larger fimbriæ this exhibits longitudinal folds which are continuous with similar folds in the mucous lining of the infundibulum. One fimbria, longer and more deeply grooved than the others, is attached to the tubal extremity of the ovary, and is named the *ovarian fimbria.* The infundibulum opens into the *ampulla* of the tube, which is thin-walled and tortuous and forms rather more than one-half the entire length of the tube. The ampulla is succeeded by the *isthmus,* which is round and cord-like and constitutes approximately the medial one-third of the tube. The part continued from the isthmus through the wall of the uterus is about 1 cm. long, and is named the *pars uterina tubæ.*

* Wilfred Shaw, *British Medical Journal,* Nov. 21, 1925, p. 952.

† Consult *The Physiology of Reproduction,* by F. H. A. Marshall, 1910.

The uterine tube is directed laterally as far as the uterine extremity of the ovary, and then ascends along the mesovarian border to the tubal extremity of the ovary, over which it arches; finally it turns downwards and ends in relation to the free border and medial surface of the ovary. In connexion with the fimbriæ of the uterine tube, or with the broad ligament close to them, there are frequently one or more small pedunculated vesicles; these are termed the *appendices vesiculosæ* (fig. 1240).

Fig. 1243.—Transverse section of a human uterine tube. Stained with hæmatoxylin and eosin. × 15.

Structure (fig. 1243).—The uterine tube consists of three coats: serous, muscular and mucous. The *external*, or *serous, coat* is peritoneal. The *middle*, or *muscular, coat* consists of an external longitudinal and an internal circular layer of non-striped muscular fibres continuous with those of the uterus. The *internal*, or *mucous, coat* is continuous with the mucous lining of the uterus. It is thrown into longitudinal folds, which in the ampulla are much more extensive than in the isthmus. The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surfaces of the fimbriæ; while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

Applied Anatomy.—Pelvic peritonitis occurs much more frequently in the female than in the male, because infective conditions of the vagina, uterus or uterine tube may involve the peritoneum by direct spread, owing to the communication which exists between the peritoneal cavity and the lumen of the tube through the pelvic ostium. When pus collects in the recto uterine pouch, it may be palpated through the posterior fornix of the vagina, on account of the peritoneal relations of the upper part of the posterior vaginal wall (p. 1405).

Tubal inflammation (*salpingitis*) is usually due to infections which have spread upwards by way of the vagina and uterus. In many cases the fimbriated end of the tube may become closed by adhesions and a collection of pus forms in the tube (*pyosalpinx*).

Fertilisation of the ovum (p. 51) is believed to occur in the uterine tube, and the fertilised ovum normally is then passed on into the uterus; the ovum, however, may adhere to and undergo development in the tube, giving rise to the commonest variety of *ectopic gestation*. In such cases the amnion and chorion are formed, but a true decidua is never present; and the gestation usually ends by extrusion of the ovum through the pelvic ostium, although it is not uncommon for the tube to rupture into the peritoneal cavity, this being accompanied by severe hæmorrhage, and necessitating surgical interference.

The Uterus (figs. 1240, 1244, 1245)

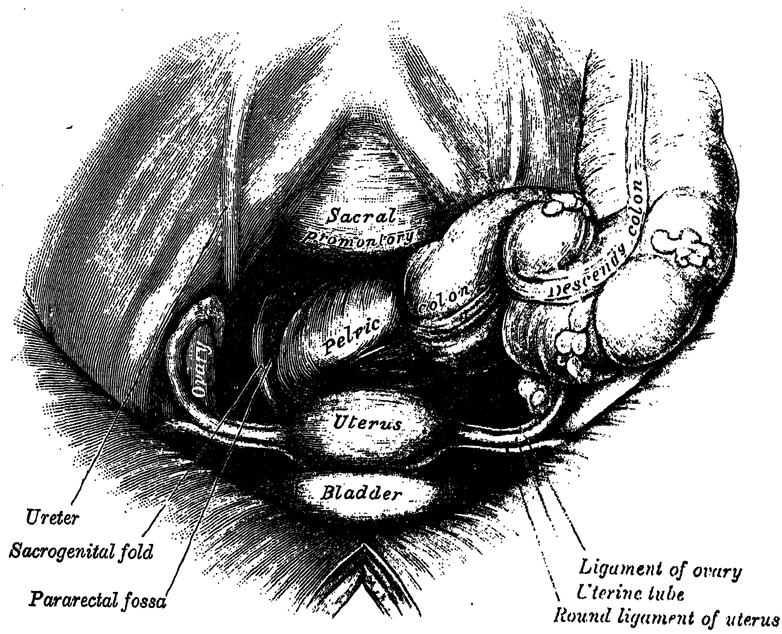
The **uterus**, or **womb**, is a hollow, thick-walled, muscular organ situated in the pelvic cavity between the urinary bladder in front and the rectum behind. Into its upper part the uterine tubes open, one on each side, while below, its cavity communicates with that of the vagina. When the ova are discharged from the ovaries they are carried to the uterine cavity through the uterine tubes. If an ovum be fertilised it imbeds itself in the uterine wall and is normally retained in the uterus until prenatal development is completed, the uterus undergoing changes in size and structure to accommodate itself to the needs of the growing embryo. After parturition the uterus returns almost to its former condition, but traces of its enlargement remain. For general descriptive purposes the adult virgin uterus is taken as the type form.

In the virgin state the uterus is flattened from before backwards and is pyriform in shape, with the narrow end directed downwards and backwards. It lies between the bladder below and in front, and the pelvic colon and rectum above and behind, and is completely below the level of the pelvic inlet. Its upper part is covered with peritoneum and lies in the peritoneal cavity, while its lower portion is imbedded in the connective tissue of the pelvis.

The long axis of the uterus usually lies approximately in the axis (p. 379) of the pelvic inlet, but as the organ is freely movable its position varies with the state of distension of the bladder and rectum. Except when much displaced by a distended bladder, it forms an angle with the vagina, since the axis of the vagina corresponds to the axes of the cavity and outlet (p. 380) of the pelvis.

The uterus measures about 7·5 cm. in length, 5 cm. in breadth at its upper part, and nearly 2·5 cm. in thickness; it weighs from 30 to 40 gm. It is divisible into two portions. On the surface, a little below the middle, there is a

FIG. 1244.—A female pelvis and its contents. Viewed from above and in front.



slight constriction, which corresponds to a narrowing of the uterine cavity, named the *internal os* of the uterus. The portion above the internal os is termed the *body*, and that below, the *cervix*. The part of the body which lies above a plane passing through the points of entrance of the uterine tubes is known as the *fundus*.

Body.—The body gradually narrows from the fundus to the internal os.

The *vesical*, or *anterior, surface* is in apposition with the urinary bladder. It is flattened and covered with peritoneum, which is reflected on to the bladder as the utero-vesical fold at the level of the internal os. The recess or pouch between the bladder and the uterus is named the *utero-vesical pouch*.

The *intestinal*, or *posterior, surface* is convex transversely, and is covered with peritoneum, which is continued downwards on the cervix uteri and the upper part of the vagina before being reflected backwards on to the rectum (fig. 1245). It is in relation with the pelvic colon, from which it is usually separated by the terminal coil of the ileum.

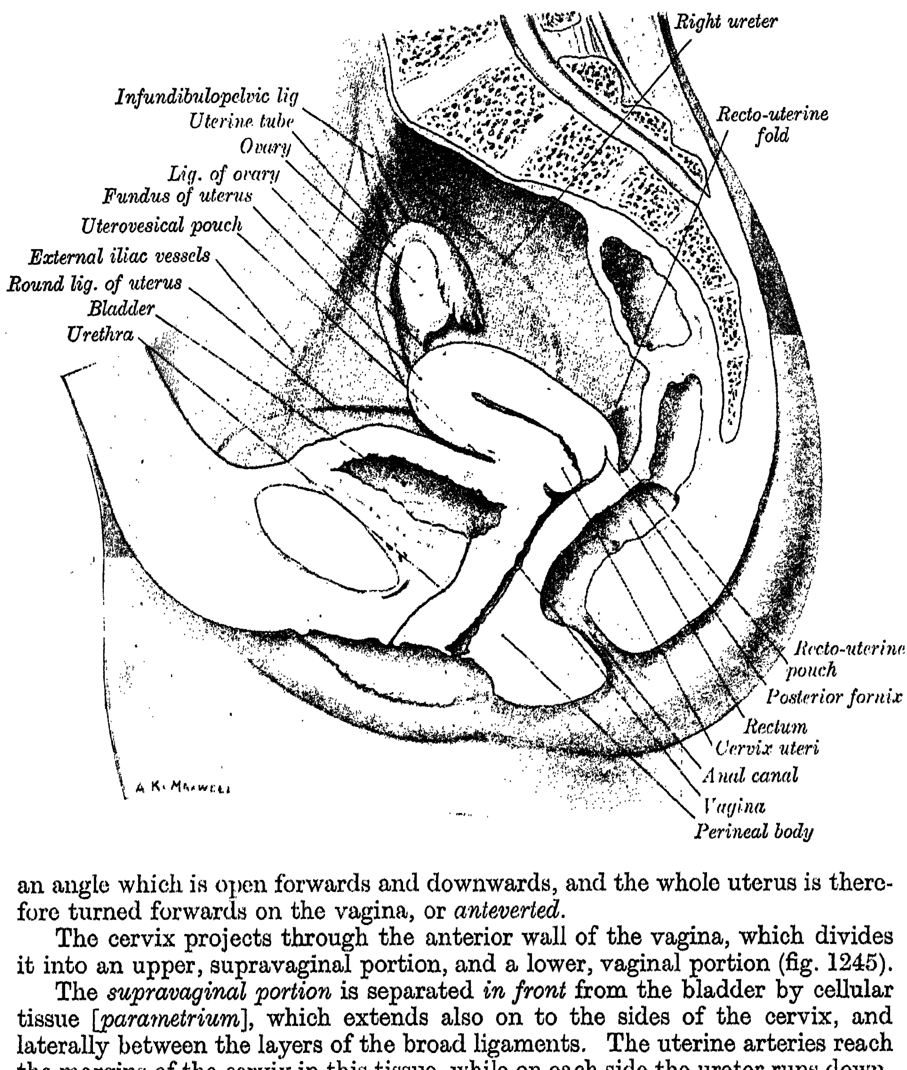
The *fundus* is convex in all directions, and covered with peritoneum continuous with that on the vesical and intestinal surfaces. Some coils of small intestine, and occasionally the distended pelvic colon rest on it.

The *margins* are slightly convex. At the upper end of each the uterine tube pierces the uterine wall. Below and in front of this point the round liga-

ment of the uterus is fixed; below and behind it the ligament of the ovary is attached. These three structures lie within a fold of peritoneum, named the broad ligament, which stretches from the margin of the uterus to the lateral wall of the pelvis.

Cervix.—The cervix is about 2·5 cm. in length; it is narrower and more cylindrical than the body, and is a little wider in the middle than above or below. Owing to its relationships it is less freely movable than the body, so that its long axis is seldom in the same straight line as that of the body. The long axis of the uterus as a whole presents the form of a curved line with its concavity forward, and the organ is described as being *anteflexed*. In extreme cases there may be an angular bend at the region of the internal os—acute anteflexion. The long axis of the cervix meets the long axis of the vagina at

FIG. 1245.—A median sagittal section through the female pelvis.



an angle which is open forwards and downwards, and the whole uterus is therefore turned forwards on the vagina, or *anteverted*.

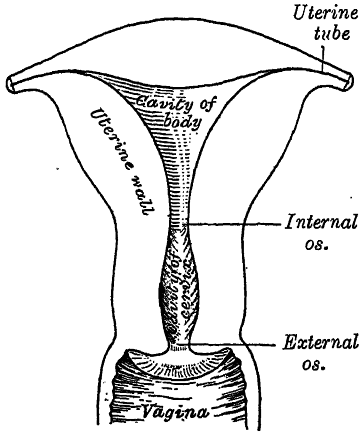
The cervix projects through the anterior wall of the vagina, which divides it into an upper, supravaginal portion, and a lower, vaginal portion (fig. 1245).

The *supravaginal portion* is separated *in front* from the bladder by cellular tissue [*parametrium*], which extends also on to the sides of the cervix, and laterally between the layers of the broad ligaments. The uterine arteries reach the margins of the cervix in this tissue, while on each side the ureter runs downwards and forwards in it at a distance of about 2 cm. from the cervix. *Posteriorly* the supravaginal cervix is covered with peritoneum, which is prolonged below on to the posterior vaginal wall, whence it is reflected to the rectum, forming the recto-uterine pouch (p. 1307). It is in relation with the rectum, from which it may be separated by the terminal coil of the ileum.

The *vaginal portion* of the cervix projects into the anterior wall of the vagina between the vaginal fornices (p. 1404). On its projecting rounded

extremity there is a small, depressed, somewhat circular aperture, termed the *external os of the uterus*, through which the cavity of the cervix communicates with that of the vagina. The external os is bounded by two lips, an anterior and a posterior, of which the anterior is the shorter and thicker, although, on account of the slope of the cervix, it projects lower than the posterior. Normally both lips are in contact with the posterior vaginal wall.

FIG. 1246.—The posterior half of the uterus and upper part of the vagina.



Interior of the uterus (fig. 1246).—The cavity of the uterus is small in comparison with the size of the organ.

The **cavity of the body** is a mere slit, flattened from before backwards. It is triangular in shape, the base being formed by the internal surface of the fundus between the orifices of the uterine tubes, the apex by the internal os of the uterus; through this orifice the cavity of the body communicates with the canal of the cervix.

The **canal of the cervix** is somewhat fusiform, flattened from before backwards, and broader at the middle than at the ends. It communicates above, through the internal os, with the cavity of the body, and below, through the external os, with the vaginal cavity. The wall of the canal presents an anterior and a posterior longitudinal ridge, from each of which a number of small oblique columns, named the *palmate folds*, proceed, giving the appearance of branches from the stem of a tree; to this arrangement the name *arbor vitæ uteri* is applied. The folds on the two walls are not opposed, but fit between one another so as to close the cervical canal.

The total length of the uterine cavity from the external os to the fundus is about 6 cm.

According to H. Stieve,* the upper third or less of the cervix, which has been termed the **isthmus**, presents certain features which differentiate it from the rest. He has pointed out that, although it is unaffected in the first month of pregnancy, it is gradually taken up into the body of the uterus during the second month and forms the '*lower uterine segment*' of English obstetricians. The fœtal membranes, though firmly blended with the rest of the uterine mucosa, are not attached to the lower uterine segment. In the non-pregnant uterus the isthmus undergoes changes associated with menstruation similar to, but less pronounced than those which occur in the body of the organ. Histologically the isthmus resembles the body more than it resembles the cervix; its lining epithelium is low cylindrical in type and is ciliated; its mucous coat is thinner; and the glands are fewer in number.

Changes affecting the uterus.—The form, size and situation of the uterus vary at different periods of life and under different circumstances.

In the fœtus the uterus projects above the inlet of the pelvis (fig. 1247). The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from 14 to 17 gms. The fundus is just below the level of the inlet of the pelvis. The palmate folds are distinct, and extend to the upper part of the cavity.

The position of the uterus *in the adult* is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is directed forwards, and is at the same time bent on itself at the junction of the body and cervix, so that the body lies upon the bladder. As the latter fills, the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be directed towards the sacrum.

During menstruation the organ is enlarged, and more vascular, and its surfaces are rounder; the external os is rounded, its lips swollen, and the lining membrane of the body is thicker, softer and of a darker colour.

During pregnancy the uterus becomes enormously enlarged, and in the eighth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscular fibres, and partly to development of new fibres.

* H. Stieve, "Der Halsteil der menschlichen Gebärmutter," Leipzig, 1927. *See also* O. Frankl, *Journal of Obstetrics and Gynecology of the British Empire*, vol. xl. 1933.

After parturition the uterus nearly regains its usual size, weighing about 42 gm.; but its cavity is larger than in the virgin state, its vessels are tortuous, and its muscular layers are more defined; the external os is more prominent, and its edges present one or more fissures.

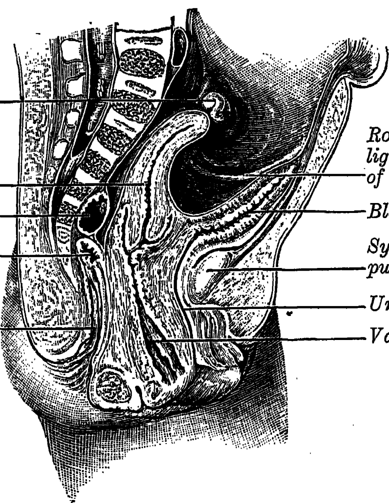
In old age the uterus becomes atrophied, and paler, and denser in texture; a more distinct constriction separates the body and cervix. The internal os is frequently, and the external os occasionally, obliterated, while the lips almost entirely disappear.

Structure.—The uterus is composed of three coats: an external or serous, a middle or muscular, and an internal or mucous.

The *serous coat* is derived from the peritoneum. In the lower one-fourth of the intestinal surface the peritoneum is not closely connected with the uterus, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the virgin it is dense, firm, of a greyish colour, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the uterine tubes. It consists of bundles of unstriped muscular fibres, intermixed with areolar tissue, blood-vessels, lymph

Fig. 1247.—A sagittal section through the pelvis of a new-born female child. Some coils of the small intestine which intervened between the uterus and the bladder have been removed.



vessels and nerves. During pregnancy the muscular tissue becomes more prominently developed, the fibres being greatly enlarged. Although the unstriped muscular fibres interlace in all directions, they are arranged in three more or less distinct layers: external, middle and internal.

The external layer consists chiefly of longitudinal fibres, which pass over the fundus, and, converging at the lateral angle on each side of the uterus, are continued on the uterine tube, the round ligament and the ligament of the ovary: some passing at each side into the broad ligament, and others running backwards from the cervix into the uterosacral ligaments. The middle layer of fibres is the thickest, but presents no regularity in its arrangement, being disposed longitudinally, obliquely and transversely; it contains the larger blood-vessels. The internal layer consists of longitudinal and circular fibres; at the internal os the circular fibres form a sphincter. The deep ends of the uterine glands come into close relation with the fibres of the internal layer.

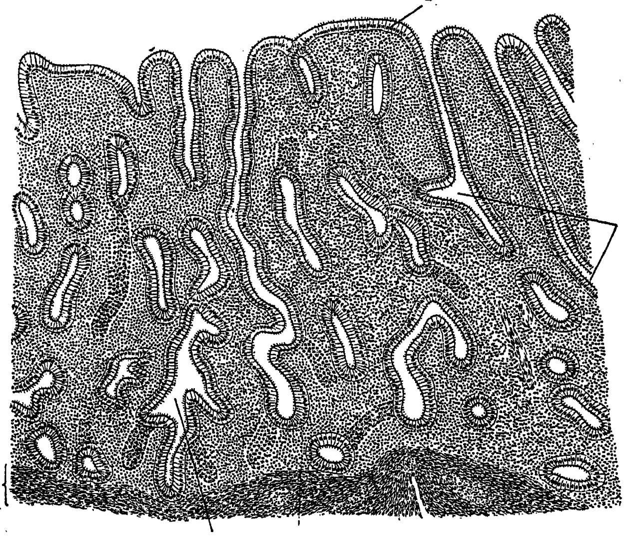
The *mucous membrane*, often named the *endometrium* (fig. 1248), lines the uterus, and is continuous, through the fimbriated extremities of the uterine tubes, with the peritoneum; and, through the external os of the uterus, with the lining of the vagina.

In the body of the uterus the mucous membrane is smooth and of pale red colour, and its free surface is covered with columnar epithelium. Prior to puberty the epithelium is ciliated, but owing to its periodic destruction in the process of menstruation and pregnancy it is usually non-ciliated over large areas in the adult uterus. The mucous membrane consists of an embryonic nucleated and highly cellular form of connective tissue in which run blood-vessels and numerous lymphatic spaces. It contains many tube-like *uterine glands*, which are lined with ciliated columnar epithelium and open into the cavity of the uterus. The glands are small in the unimpregnated uterus, but shortly after impregnation they become enlarged and elongated, presenting a contorted or waved appearance.*

* Arthur Thomson (*British Medical Journal*, January 7th, 1922) discusses whether the uterine glands possess a secretory or an absorbent function.

In the cervix uteri the mucous membrane is raised into two median elevations, one on the anterior, the other on the posterior, wall of the canal; from these median elevations numerous ridges (palmate folds) run upwards and laterally. In the upper two-thirds of the cervix, the mucous membrane is provided with numerous, deep, glandular follicles which secrete a clear, viscid, alkaline mucus; and in addition, extending through the whole length of the canal a variable number of little cysts are found, presumably follicles which have become occluded and distended with retained secretion. They are called the *ovula Nabothi*. The mucous membrane covering the lower one-half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and, close to the external os, changes to stratified squamous. On the vaginal surface of the cervix the epithelium is similar to that lining the vagina, viz. stratified squamous.

FIG. 1248.—A vertical section through the mucous membrane of a human uterus. (Sobotta.)



Vessels and Nerves.—The *arteries* of the uterus are the uterine branch of the internal iliac artery (p. 777), and the ovarian branch of the abdominal aorta (p. 772). They are remarkable for their tortuous course in the substance of the organ (fig. 1249). The termination of the ovarian artery meets that of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus. The *veins* are of large size, and correspond with the arteries. They end in the uterine venous plexuses. In the impregnated uterus the arteries carry the blood to, and the veins convey it away from, the intervillous space of the placenta (fig. 108). The *lymph vessels* are described on p. 874. The *nerves* are derived from the hypogastric and ovarian plexuses, and from the pelvic splanchnic nerves (S 2, 3, and 4).

There is reason to believe that impulses conveyed through the sympathetic nerves produce contraction of the circular, and inhibition of the longitudinal, muscle-fibres of the uterus, and that impulses conveyed through the pelvic splanchnics (parasympathetic) produce exactly opposite effects, i.e. they cause contraction of the longitudinal, and inhibition of the circular, fibres.*

Applied Anatomy.—A certain amount of anteversion or retroversion of the uterus can take place without the conditions being regarded as pathological, but when the degree of flexion at the junction of the body with the cervix becomes considerable it must be regarded as a morbid condition. This is especially true of retroversion combined with retroflexion. Retroversion alone is falling back of the whole uterus, so that the cervix points forwards towards the os pubis; retroflexion is a bending backwards of the body, the cervix remaining in its normal position. The two conditions are usually combined. Prolapse of the

* Consult (1) *The Physiology of Reproduction*, by Francis H. A. Marshall, and (2) an article on the innervation of the uterus by Beckwith Whitehouse and Henry Featherstone, *British Medical Journal*, September 1923, p. 406.

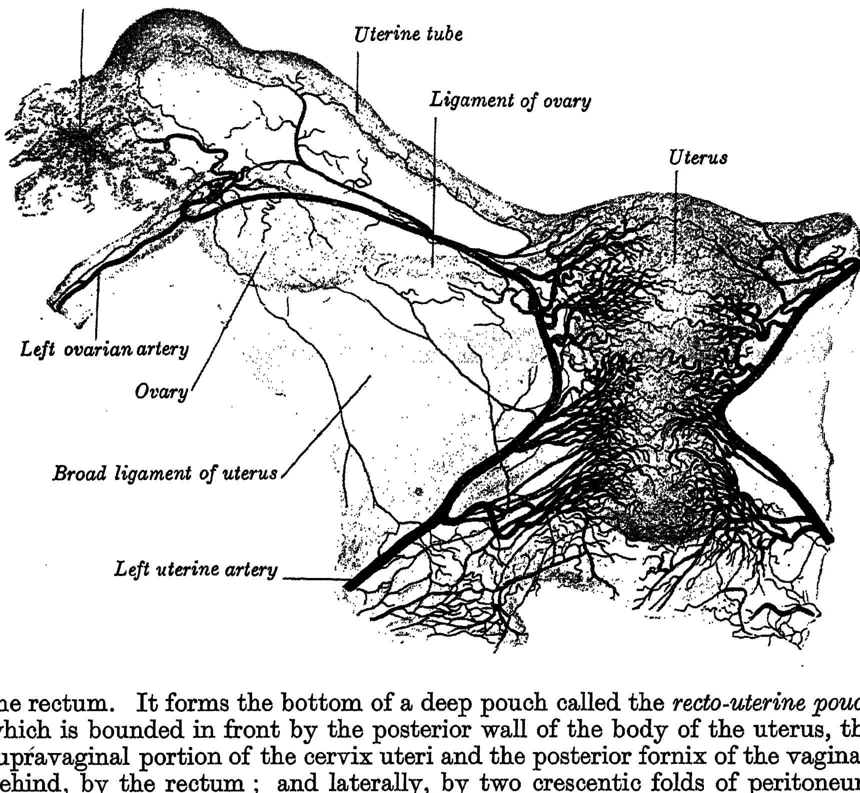
uterus is another common infirmity. The organ sinks to an abnormally low level in the pelvis, and sometimes protrudes beyond the vulva. This condition is usually due to imperfect repair of the pelvic floor following a tear of the perineum during parturition (p. 576).

Ligaments.—The uterus is connected to the bladder, the rectum and the walls of the pelvis by a number of ligaments; some of these are peritoneal ligaments or folds, while others consist of unstriped muscle and fibrous tissue.

The *anterior ligament* consists of the *utero-vesical fold* of peritoneum, which is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body.

The *posterior ligament* consists of the *rectovaginal fold* of peritoneum, which is reflected from the back of the posterior fornix of the vagina on to the front of

FIG. 1249.—The left uterine and ovarian arteries of an unmarried girl of 17½ years. Posterior aspect. (From a preparation by Hamilton Drummond.)



the rectum. It forms the bottom of a deep pouch called the *recto-uterine pouch* which is bounded in front by the posterior wall of the body of the uterus, the supravaginal portion of the cervix uteri and the posterior fornix of the vagina; behind, by the rectum; and laterally, by two crescentic folds of peritoneum which pass backwards from the cervix uteri, one on each side of the rectum, to the posterior wall of the pelvis. These folds are named the *recto-uterine folds*. They contain a considerable amount of fibrous tissue and non-striped muscular fibres, which are attached to the front of the sacrum and constitute the *uterosacral ligaments*.

The *two broad ligaments* (fig. 1240) pass from the margins of the uterus to the lateral walls of the pelvis. Together with the uterus they form a septum across the female pelvis, dividing that cavity into two portions. The anterior part contains the bladder; the posterior part, the rectum, and usually, the terminal coil of the ileum and a part of the pelvic colon.

When the bladder is empty or only slightly distended, the surfaces of the broad ligament are directed upwards and downwards and it has a free anterior and an attached posterior border. As the bladder fills, the plane of the ligament alters and its free border becomes superior in position. In this condition of the

bladder, the broad ligament consists of anterior and posterior layers, which are continuous with each other at its upper, free border, and diverge from each other below, where they reach the Levator ani muscle. The uterine tube is contained in the free border and the adjoining part of the ligament is termed the *mesosalpinx*. The infundibulum of the tube projects from the free border near its lateral extremity. The ovary is attached to the posterior layer by the mesovarium. The portion of the broad ligament which extends from the infundibulum of the tube and the upper pole of the ovary to the lateral wall of the pelvis contains the ovarian blood-vessels, nerves and lymph vessels and is termed the *infundibulopelvic ligament* (suspensory ligament of the ovary). It is continued laterally over the external iliac vessels as a distinct fold. Between the ovary and the uterine tube, the mesosalpinx contains the epoöphoron (p. 1396) and, at its medial end, the paroöphoron (p. 1396) and anastomosing branches of the uterine and ovarian vessels. The uterine artery insinuates itself between the layers of the broad ligament at its inferior border, about 1·5 cm. lateral to the cervix and after it has crossed the ureter (p. 1370). It then ascends in the medial part of the ligament and turns laterally below the uterine tube to anastomose with the ovarian artery. In addition to all the structures already enumerated, the broad ligament encloses the ligament of the ovary (p. 1394), the proximal part of the round ligament of the uterus and some unstriped muscle and fibro-areolar tissue.

The *round ligaments* (fig. 1244) are two narrow, flat bands between 10 cm. and 12 cm. long, situated between the layers of the broad ligament in front of and below the uterine tubes. Commencing at the lateral angle of the uterus each ligament is directed forwards and laterally across the vesical vessels, the obturator vessels and nerve, and the obliterated umbilical artery and over the external iliac vessels. It then passes through the deep (abdominal) inguinal ring, hooking round the commencement of the inferior epigastric artery, and traverses the inguinal canal to reach the labium majus, in which it is lost. The round ligament consists principally of muscular tissue prolonged from the uterus, but also contains some areolar tissue. It is accompanied by blood-vessels, lymph vessels and nerves, and in the fœtus a tubular process of the peritoneum [*processus vaginalis*] is carried with it for a short distance into the inguinal canal. The processus vaginalis is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It corresponds to the processus vaginalis which precedes the descent of the testis.

The round ligament and the ligament of the ovary are together homologous with the gubernaculum testis in the male.

In addition to the ligaments just described, there is a band sometimes named the *ligamentum transversale colli* (Mackenrodt) on each side of the cervix uteri. It is attached to the side of the cervix uteri and to the vault and lateral fornix of the vagina, and is continuous with the fibrous tissue which surrounds the pelvic blood-vessels.

The Vagina (fig. 1245)

The vagina is a canal which extends from the vestibule, or cleft between the labia minora, to the uterus, and is situated behind the bladder and in front of the rectum; it is directed upwards and backwards, its axis forming with that of the uterus an angle of over ninety degrees, opening forwards, but the angle varies with the conditions of the bladder and rectum. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, the transverse limb being slightly curved forwards or backwards, while the lateral limbs are somewhat convex towards the median plane; its middle part has the appearance of a transverse slit. Its length is 7·5 cm. along its anterior wall, and 9 cm. along its posterior wall; its width gradually increases from below upwards. Its upper end surrounds the vaginal portion of the cervix uteri a short distance from the external os of the uterus, its attachment extending higher on the posterior than on the anterior wall of the uterus. To the recess behind the cervix uteri the term *posterior fornix* is applied, while the smaller recesses at the sides and in front are called the *lateral* and *anterior fornices*.

The *anterior wall* of the vagina is in relation with the fundus of the bladder, and with the urethra. Its *posterior wall*, which is covered with peritoneum in its upper one-fourth, is separated from the rectum by the recto-uterine pouch above, and by some loose fibro-areolar tissue in its middle two-fourths ; the lower one-fourth is separated from the anal canal by a mass of muscular and fibrous tissue, named the *perineal body*. Its sides are enclosed between the Levatores ani muscles (p. 574). As the terminal portions of the ureters pass forwards and medially to reach the fundus of the bladder, they run close to the lateral fornices of the vagina, and as they enter the bladder are usually placed in front of the vagina (p. 1370).

Structure.—The vagina consists of an internal mucous lining and a muscular coat, separated by a layer of erectile tissue.

The *mucous membrane* is firmly fixed to the muscular coat ; on its free surface there are two longitudinal ridges, one on the anterior and the other on the posterior wall of the vagina. These ridges are called the *columns of the vagina*, and from them numerous transverse ridges or rugæ extend laterally on each side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ ; they are most numerous near the orifice of the vagina, especially before parturition. The epithelium of the mucous membrane is of the stratified squamous variety.

The *muscular coat* consists of two layers : an external longitudinal, which is by far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on each side. The two layers are not distinctly separable from one another. but are connected by oblique decussating fasciculi. In addition to this, the lower end of the vagina is surrounded by a band of striped muscular fibres, termed the *Bulbospongiosus* (p. 581).

External to the muscular coat there is a layer of areolar tissue, containing a large plexus of blood-vessels.

The *erectile tissue* is situated between the mucous membrane and the muscular coat ; it consists of a layer of loose areolar tissue, which contains a plexus of large veins, and numerous bundles of unstriped muscular fibres, derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

Vessels and Nerves.—The *arteries* of the vagina are derived from the vaginal, uterine, internal pudendal, and middle rectal branches of the internal iliac arteries (pp. 777 to 781). The *veins* form plexuses at the sides of the vagina, and these plexuses are drained through the vaginal veins into the internal iliac veins. The *lymph vessels* are described on p. 875. The *nerves* are derived from the vaginal plexuses, and from the pelvic splanchnic nerves.

The External Genital Organs of the Female (fig. 1250)

The **external genital organs of the female** [pudendum muliebre] are : the mons pubis, the labia majora et minora pudendi, the clitoris, the vestibule of the vagina, the bulb of the vestibule and the greater vestibular glands. The term *pudendum* or *vulva*, as generally applied, includes all these parts.

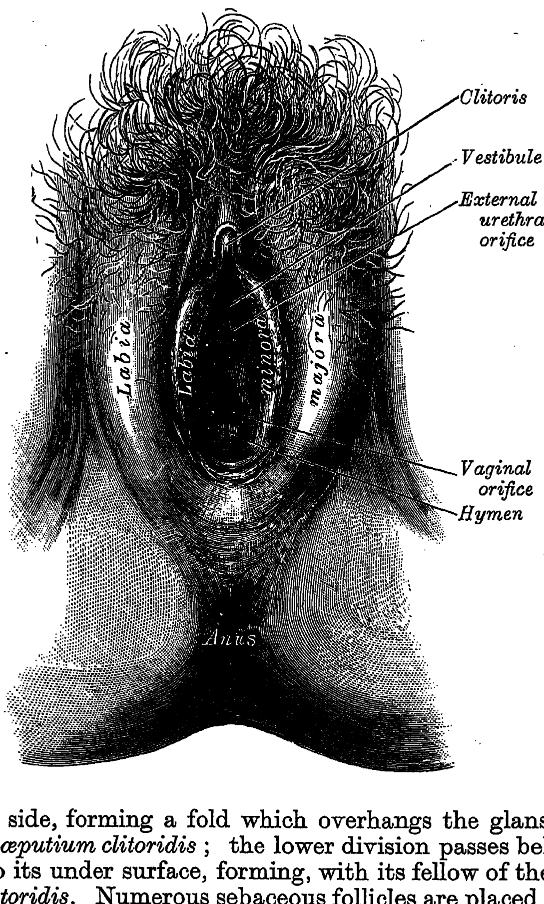
The **mons pubis**, the rounded eminence in front of the pubic symphysis, is formed by a collection of fatty tissue beneath the skin. It becomes covered with hair at the time of puberty over an area which has a horizontal upper limit, whereas in the male the pubic hair extends upwards towards the umbilicus in and near the median plane.

The **labia majora** are two prominent, longitudinal, cutaneous folds which extend downwards and backwards from the mons pubis, and form the lateral boundaries of a fissure or cleft, named the *pudendal cleft*, into which the vagina and urethra open. Each labium has two surfaces, an outer, pigmented and covered with crisp hairs ; and an inner, smooth and beset with large sebaceous follicles. Between the two surfaces there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos muscle of the scrotum, besides vessels, nerves and glands. The labia are thicker in front, where they form by their meeting the *anterior commissure*. Posteriorly they are not really joined, but appear to become lost in the neighbouring integument, ending close to,

and nearly parallel with, each other; together with the connecting skin between them, they form the *posterior commissure,* or posterior boundary of the pudendum. The interval between the posterior commissure and the anus, from 2·5 cm. to 3 cm. in length, constitutes the gynæcological perineum.

The **labia minora** are two small cutaneous folds, situated between the labia majora, and extending from the clitoris obliquely downwards, laterally and backwards for about 4 cm. on each side of the orifice of the vagina, between which and the labia majora they end; in the virgin the posterior ends of the labia minora are usually joined across the median plane by a fold of skin, named the *frenulum of the labia.* Anteriorly, each labium minus divides into two portions; the upper division passes above the clitoris to meet its fellow

Fig. 1250.—The external genital organs of the female. The labia have been drawn apart.



of the opposite side, forming a fold which overhangs the glans clitoridis and is named the *præputium clitoridis*; the lower division passes below the clitoris and is united to its under surface, forming, with its fellow of the opposite side, the *frenulum clitoridis.* Numerous sebaceous follicles are placed on the opposed surfaces of the labia minora.

The **vestibule.**—The cleft between the labia minora is named the *vestibule of the vagina*: in it the vaginal and external urethral orifices are situated, and, between them, numerous small mucous glands, termed the *lesser vestibular glands,* open on the surface of the vestibule. The part of the vestibule between the vaginal orifice and the frenulum of the labia minora consists of a shallow depression named the *vestibular fossa.*

The **clitoris** is an erectile structure, homologous with the penis. It is situated caudal to the anterior commissure, partially hidden between the anterior ends of the labia minora. The *body of the clitoris* consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, and separated along their medial surfaces by an incomplete fibrous

pectiniform septum ; each corpus cavernosum is connected to the pubic and ischial rami by a *crus*. The free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. The clitoris is provided, like the penis, with a suspensory ligament, and with two small muscles, named the Ischiocavernosi (p. 581), which are inserted into the crura of the clitoris.

The **vaginal orifice** is a median slit below and behind the opening of the urethra ; its size varies inversely with that of the *hymen.*

The **hymen vaginæ** is a thin fold of mucous membrane situated at the orifice of the vagina ; the inner surfaces of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape. When stretched, its commonest form is that of a ring, generally broadest posteriorly ; sometimes it is represented by a semilunar fold, with its concave margin turned towards the pubes. Occasionally it is cribriform or its free margin forms a membranous fringe. It may be entirely absent, or may form a complete septum across the lower end of the vagina ; the latter condition is known as an imperforate hymen. When the hymen has been ruptured, small rounded elevations known as the *carunculæ hymenales* are found as its remains.

The **external urethral orifice** is placed about 2·5 cm. behind the glans clitoridis and immediately in front of the orifice of the vagina : it usually assumes the form of a short, sagittal cleft with slightly raised margins.

The **bulb of the vestibule** is the homologue of the bulb of the penis and adjoining part of the corpus spongiosum penis of the male, and consists of two elongated masses of erectile tissue, placed one on each side of the vaginal orifice and united to each other in front by a narrow median band termed the *commissura bulborum* (pars intermedia). Each lateral mass measures about 3 cm. in length. Their posterior ends are expanded and are in contact with the greater vestibular glands ; their anterior ends are tapered and joined to one another by the commissure ; their deep surfaces are in contact with the perineal membrane ; superficially they are covered with the Bulbospongiosus.

The **greater vestibular glands** are the homologues of the bulbo-urethral glands in the male. They consist of two small, round, or oval, bodies of a reddish-yellow colour, situated one on each side of the vaginal orifice, in contact with the posterior end of the lateral mass of the bulb of the vestibule. Each gland opens by means of a duct, about 2 cm. long, immediately lateral to the hymen, in the groove between its attached border and the labium minus.

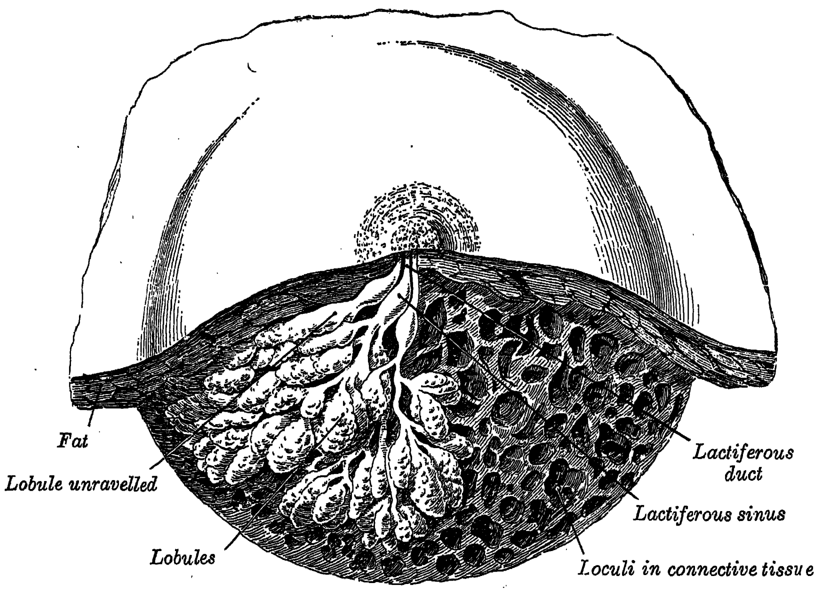
The Mammary Glands (figs. 1251, 1252)

The **mammary glands** secrete the milk, and are accessory glands of the generative system. They exist in the male as well as in the female, but in the former only in the rudimentary state. In the female they are two large, hemispherical eminences lying within the superficial fascia on the front and sides of the chest ; each extends vertically from the second rib to the sixth rib, and, transversely, at the level of the fourth costal cartilage, from the side of the sternum to near the mid-axillary line. In weight and size they differ at different periods of life, and in different individuals. Before puberty they are small, but they enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially during lactation, and become atrophied in old age. The deep surface of each is flattened, or slightly concave, and irregularly circular in outline, its longest diameter being directly upwards and laterally towards the axilla ; it is separated from the fascia covering the Pectoralis major, Serratus anterior and Obliquus externus abdominis by loose areolar tissue. The subcutaneous surface of the mammary gland is convex, and presents, just below the centre, a small conical prominence, named the *nipple.*

The **nipple** is a cylindrical or conical eminence situated about the level of the fourth intercostal space. It is capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular

fibres. It is of a pink or brownish hue, and its surface is wrinkled and provided with secondary papillæ; it is perforated by from fifteen to twenty orifices, the apertures of the lactiferous ducts. The base of the nipple is encircled by a coloured area of skin called the *areola*. In the virgin the areola is of a delicate rosy hue; about the second month of pregnancy it enlarges and acquires a darker tinge, and as pregnancy advances it may assume a dark brown, or even black colour. This colour diminishes as soon as lactation is over, but is never lost entirely. These changes in the colour of the areola are of importance in forming a conclusion in a case of suspected first pregnancy. Near the base of the nipple, and upon the surface of the areola, there are numerous sebaceous glands, termed the *areolar glands*, which become much enlarged during lactation and present the appearance of small tubercles beneath the skin; they secrete

Fig. 1251.—A dissection of the lower half of the mammary gland during the period of lactation. (Luschka.)



a peculiar fatty substance, which serves as a protection to the skin of the nipple. The nipple is traversed by the ducts of the gland, and, in addition, contains numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base, but a few fibres radiate from base to apex.

Structure (figs. 1251 to 1253).—The mammary gland consists (*a*) of gland-tissue; (*b*) of fibrous tissue, connecting its lobes; and (*c*) of fatty tissue in the intervals between the lobes. The subcutaneous tissue encloses the gland and sends numerous septa into it to support its various lobules. From that part of the fascia which covers the gland fibrous processes pass forwards to the skin and the nipple; these were named by Sir Astley Cooper the *ligamenta suspensoria*. The gland-tissue is of a pale reddish colour, firm in texture, and forms a lobulated mass which is flattened from before backwards and thicker in the centre than at the circumference. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, blood-vessels and ducts. The smallest lobules consist of a cluster of rounded alveoli which open into the smallest branches of the lactiferous ducts; these branches unite to form larger ducts which end in the excretory ducts or *ductus lactiferi*. The lactiferous ducts vary from fifteen to twenty in number; they converge towards the areola, beneath which they form dilatations, named *lactiferous sinuses*, which serve as reservoirs for the milk. At the base of the nipple they become contracted, and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue containing longitudinal and transverse elastic fibres; they are lined by columnar epithelium resting on a basement-membrane. The epithelium of the alveoli differs according to

the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk, as *colostrum corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with spherical nuclei, lining the basement membrane. When the gland is active, oil globules are found in the alveolar cells and are discharged into the lumen, constituting the milk-globules. When the acini are distended by the accumulation of the secretion the lining epithelium becomes flattened.

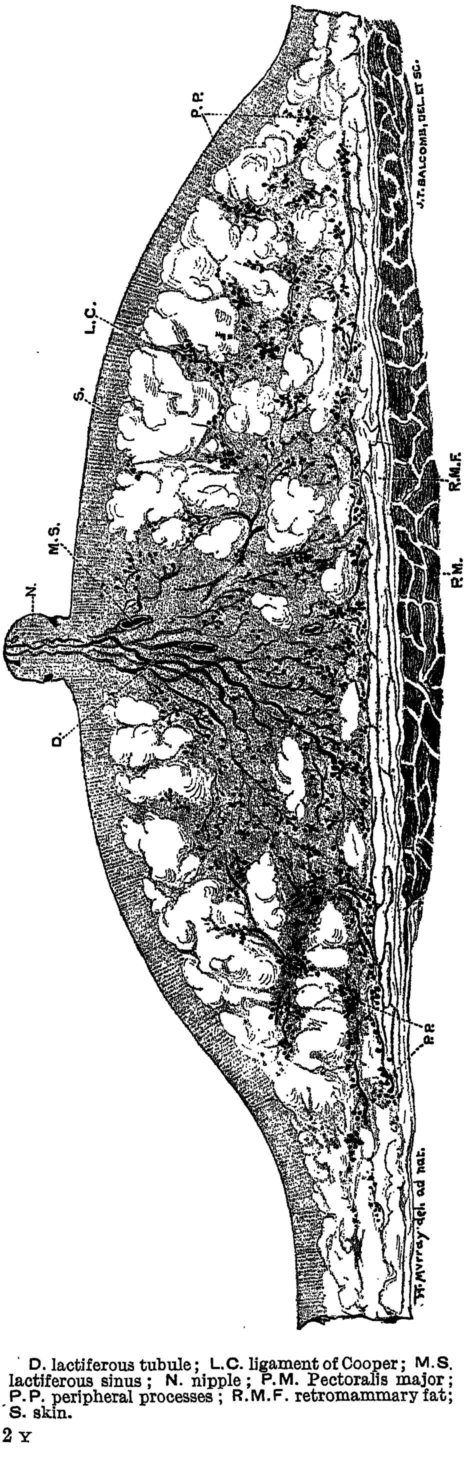
The *fibrous tissue* invests the entire surface of the mammary gland, and sends down septa between its lobes, connecting them together.

The *fatty tissue* covers the surface of the gland, and occupies the intervals between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and Nerves.—The *arteries* supplying the mammary gland are derived from the thoracic branches of the axillary artery, and from the internal mammary and intercostal arteries. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus*. From this circle, branches transmit the blood to the circumference of the gland, and end in the axillary and internal mammary veins. The *lymph vessels* are described on p. 861. The *nerves* are derived from the anterior and lateral cutaneous branches of the fourth, fifth, and sixth thoracic nerves.

Applied Anatomy.—The ducts descending from the nipple radiate through the gland, and when an incision is made into the breast the scalpel should be directed radially, from the centre to the periphery, so that it may not pass across the ducts. A milk duct may become obstructed and distended, forming a cyst known as a galactocele. Abscess frequently occurs about the mammary gland, more often in women who are lactating, especially in those who have cracks and fissures about the nipple. The abscess may be between the septa, in the gland-tissue itself, or it may lie beneath the skin by the side of the nipple and superficial to the gland, or it may form beneath the gland, between it and the deep fascia. Free incision, radiating from the nipple, is required in such cases.

Fig. 1252.—Horizontal section of the mammary gland at the level of the nipple in a multiparous female, aged forty years. (Stiles.) (From Quain's *Anatomy*, vol. iii. part iv.)

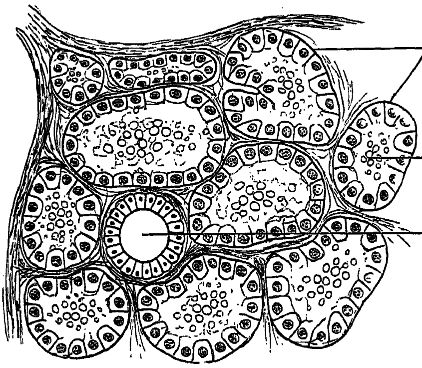


D. lactiferous tubule; L.C. ligament of Cooper; M.S. lactiferous sinus; N. nipple; P.M. Pectoralis major; P.P. peripheral processes; R.M.F. retromammary fat; S. skin.

Cystic formation of many different kinds is commonly seen in the mammary gland ; in some cases it is due to dilatation of the larger ducts or of the lymph-spaces throughout the gland ; in others the cysts occur in new growths of the gland, or as the result of obstruction of the smaller ducts by chronic inflammatory processes.

Malignant growths are seen more often in the mammary gland than in any other organ. A hard, contracting tumour-mass results, which drags on the fibrous septa between the

FIG. 1253.—A section through a portion of the non-lactating mammary gland.



lobes so that fixation or retraction of the nipple ensues, and sooner or later the malignant infiltration invades the surrounding gland-tissues, the skin, the deep fascia and Pectorales, and even the chest wall and pleura. The lymph glands beneath the Pectorales and those situated towards the apex of the axilla become involved early with secondary malignant deposit, and later the supraclavicular glands enlarge. In other cases the mediastinal glands may be involved, when the disease is situated on the medial side of the nipple.

The operation for removal of a mammary gland affected with malignant disease should be an extensive procedure, with the object of extirpating all fascial planes and lymphatic structures that may become infected.

THE DUCTLESS GLANDS

All animals possess a number of glands the secretions of which exercise an important influence on general metabolic processes, including growth. In order that they may be able to act in this way, the secretions are passed directly from the secreting cells into the blood-stream as it circulates through the capillaries of the glands, and so are carried to all parts of the body. Groups of cells in some of the other glands in the body have a similar function, although they do not constitute distinct anatomical entities. The cell-islets of the pancreas, and the interstitial cells of the testes and ovaries pass their secretions directly into the blood-stream and exert their functions in a similar manner. Glands or groups of cells which produce such internal secretions are collectively known as *endocrine organs*.

Despite the great output of literature dealing with the subject, it is still impossible to group the endocrine organs on a functional basis, and it is doubtful whether much benefit is to be derived from utilising any other basis. It may, however, prove convenient to group the hypophysis cerebri and the pineal body together, owing to their direct ectodermal origin. In the same way, the thyroid and parathyroid glands may be grouped together, as they are both derived from the pharyngeal entoderm (p. 165). The paraganglia, the medulla of the suprarenal gland, the glomera carotica and the glomus coccygeum are all (with the possible exception of the last-named) derived from primitive sympathochromaffin cell-groups (p. 108), and, therefore, indirectly ectodermal in origin. Lastly, the cortex of the suprarenal gland is developed from the cœlomic epithelium, so that it may be referred to the mesoderm.

In addition, the term ' ductless glands ' applies with equal truth to a number of glands or glandular bodies which are principally concerned with the replacement and destruction of the corpuscles of the blood and lymph. The lymph glands, the spleen and, probably, the thymus * belong to this category.

For convenience, all the ductless glands are dealt with in this section with the exceptions of the hypophysis cerebri (p. 964), the pineal body (p. 961) and the lymph glands (pp. 844 to 879), which have already been described. The following, however, have still to be considered:

The Thyroid gland.
The Parathyroid glands.
The Paraganglia.
The Suprarenal glands.
The Carotid bodies.
The Coccygeal body.
The Thymus.
The Spleen.

The Thyroid Gland (fig. 1254)

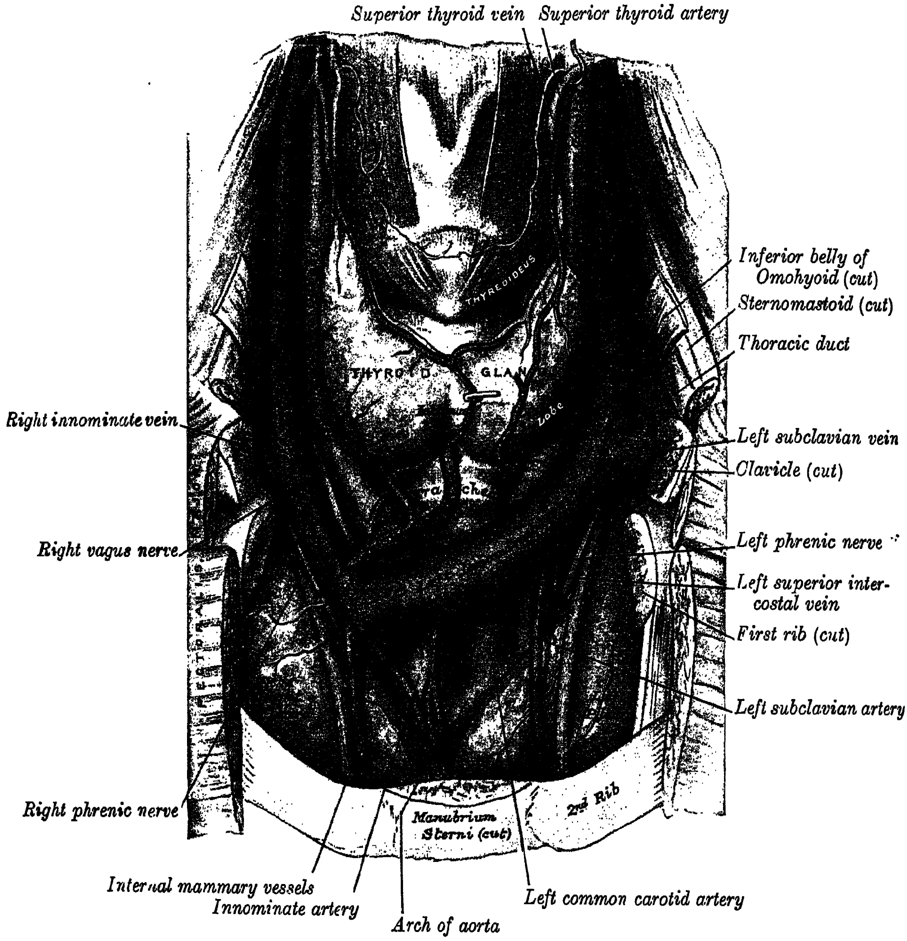
The **thyroid gland** is a highly vascular organ, situated at the front and sides of the lower part of the neck, opposite the fifth, sixth and seventh cervical vertebræ. It is ensheathed by the pretracheal layer of the deep cervical fascia (fig. 584), and consists of right and left lobes connected across the median plane by a narrow portion, termed the *isthmus*. Its weight is somewhat variable, but is usually about 30 gm. It is slightly heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The *lobes* are conical in shape, the apex of each being directed upwards and laterally as far as the junction of the middle with the lower one-third of the thyroid cartilage; the base is on a level with the fifth or sixth tracheal ring. Each lobe is about 5 cm. long; its greatest width is about 3 cm., and its thick-

* Sir E. Sharpey-Schafer (*The Endocrine Organs*, 2nd edition) is of the opinion that the thymus should not be classed as an endocrine organ.

ness about 2 cm. The posteromedial part of each lobe is attached to the side of the cricoid cartilage by a ligamentous band. The *lateral*, or *superficial*, *surface* is convex. Outside the sheath of pretracheal fascia, this surface is closely covered with the Sternothyroid and it is the insertion of this muscle into the oblique line on the lamina of the thyroid cartilage which prevents the upper part of the lobe from extending forwards on to the Thyrohyoid muscle. More superficially, this surface is covered with the Sternohyoid and the upper belly of the Omohyoid muscle, overlapped below by the anterior border of the Sternomastoid. The remaining superficial relations are formed by the deep and

FIG. 1254.—Dissection of the lower part of the neck, and the upper part of the thorax. Anterior aspect.

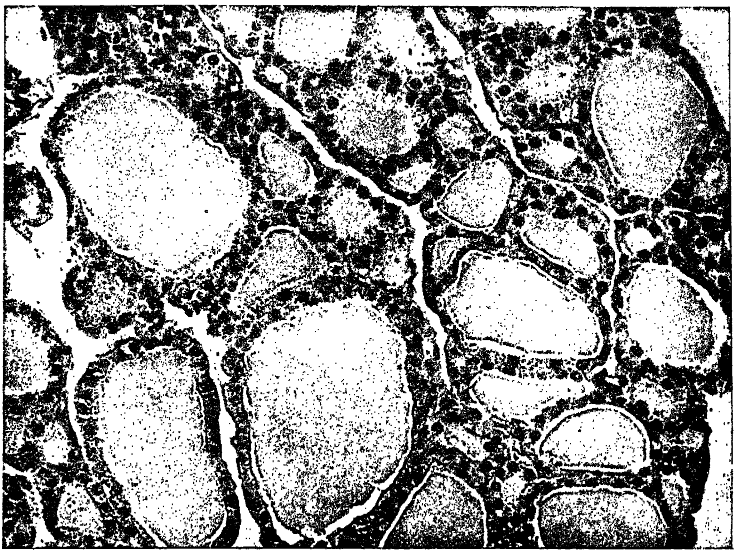


superficial fasciæ and the skin. The *medial surface* is moulded over the larynx and trachea. Above, it is in contact with the Inferior constrictor of the pharynx and the posterior part of the Cricothyroid muscle, which intervene between the gland and the posterior part of the lamina of the thyroid and the side of the cricoid cartilage. The external laryngeal nerve passes deep to this part of the gland on its way to the Cricothyroid muscle. Below, it is related to the side of the trachea, in front, and to the recurrent laryngeal nerve and (particularly on the left side) to the œsophagus, behind. The *posterior*, or *posterolateral*, *surface* is related to the carotid sheath and overlaps the common carotid artery. The *anterior border*, which is closely related to the anterior branch of the superior thyroid artery, is thin and inclines obliquely from above downwards and medially. The *posterior border*, which is blunt and rounded, intervenes between the posterior and the medial surfaces and is closely related below to the inferior

thyroid artery and an anastomosing branch which connects that vessel to the posterior branch of the superior thyroid artery. In addition the parathyroid glands are related to this border, although they may be found in association with the posterior surface.

The *isthmus* connects together the lower parts of the two lobes ; it measures about 1·25 cm. transversely, and the same vertically, and usually covers the second, third and fourth rings of the trachea. Its situation and size present, however, many variations. It is covered with the skin and fascia, and close to the median plane, on each side, with the Sternothyroid. An anastomotic branch uniting the two superior thyroid arteries runs along its upper border ; at its lower border the inferior thyroid veins leave the gland. Sometimes the isthmus is altogether wanting.

FIG. 1255.—Section of thyroid gland of cat. (E. Sharpey-Schafer.) ×400. Photograph. (From Sharpey-Schafer's *Essentials of Histology.*)



The vesicles are occupied by colloid, which has partly shrunk away from the epithelium.

A third lobe, of conical shape, called the *pyramidal lobe*, frequently extends from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly the left, to the hyoid bone. It is occasionally quite detached, or may be divided into two or more parts.

A fibrous or muscular band is sometimes attached, above, to the body of the hyoid bone, and below, to the isthmus of the gland, or its pyramidal lobe ; when muscular, it is termed the *Levator glandulæ thyreoideæ.*

Small detached portions of thyroid tissue are sometimes found in the vicinity of the lobes or above the isthmus ; they are called *accessory thyroid glands.*

Structure.—The thyroid gland is closely invested by a thin capsule of connective tissue, which sends incomplete septa into its substance, dividing it into masses of irregular form and size. The gland is of a brownish-red colour, and is made up of a number of closed vesicles, just visible to the naked eye, containing a yellow, glairy fluid, and separated from each other by intermediate connective tissue (fig. 1255). The vesicles are arranged in groups or gland-units, each unit being enclosed in an endothelial lymph-sac.

The vesicles of the thyroid of the adult are generally closed spherical sacs ; but in some young animals (e.g. dogs) they are more or less tubular and branched. Each is lined with a single layer of cubical epithelium. There does not appear to be a basement-membrane, so that the epithelial cells are in direct contact with the connective tissue reticulum. The vesicles are of various sizes, and contain a viscid, homogeneous, semi-fluid, slightly yellowish, colloid material ; red blood-corpuscles are found in various stages of disintegration and decolorisation, the yellow tinge being probably due to hæmoglobin, which is set free from the corpuscles. The colloid material contains an iodine compound, *thyroxin* or *iodothyro-*

globulin, and, when coagulated by hardening reagents, is readily stained by eosin and other dyes. It passes out between the cubical cells and is absorbed into the blood or lymph.

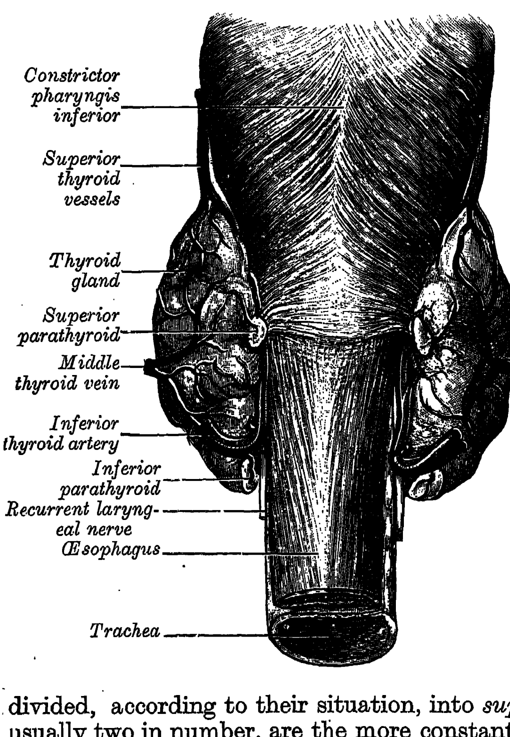
Vessels and Nerves.—The *arteries* supplying the thyroid gland are the superior (p. 704) and inferior thyroid arteries (p. 737); sometimes there is an additional branch (a. thyreoidea ima) from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The *veins* form a plexus on the surface of the gland and on the front of the trachea; from this plexus the superior, middle and inferior thyroid veins arise; the superior and middle end in the internal jugular vein, the inferior in the innominate vein. The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph vessels which surround a greater or smaller part of the circumference of the vesicle. The *lymph vessels* run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany and communicate with a network in the capsule of the gland; they may contain colloid material. They end in the thoracic duct and the right lymphatic duct. The *nerves* are derived from the middle and inferior cervical ganglia of the sympathetic.

G. Scott Williamson * states there is a free anastomosis between the branches of the superior thyroid arteries and the larger surface veins of the gland. He also describes a very definite system of lymph vessels which leaves each lobe at the point of entrance of the branches of the inferior thyroid artery, and passes directly into the lymph-spaces of the lobes of the thymus.

Applied Anatomy.—Any enlargement of the thyroid gland is called a goitre. When a goitre continues to grow, and especially when there are commencing symptoms of tracheal pressure, operative interference becomes necessary.

Partial extirpation of the thyroid, viz. the removal of one lobe with division of the isthmus, may be required in cases of parenchymatous goitre, and in the diffuse form of adenomatous disease. It is a more radical proceeding, and carries with it a much greater risk of hæmorrhage; there is also a danger of wounding the recurrent laryngeal nerve. The whole gland must never be removed, as such a procedure is followed by the development of myxœdema. In dealing with the inferior thyroid artery, the position of the recurrent laryngeal nerve (p. 737) must be borne in mind, lest it should be ligatured or divided. Temporary aphonia not uncommonly follows from bruising of the nerve, and if nothing more serious has occurred soon passes off.

FIG. 1256.—The parathyroid glands. Posterior aspect.



THE PARATHYROID GLANDS

The parathyroid glands (fig. 1256) are small, brownish-red bodies, situated as a rule between the posterior borders of the lobes of the thyroid gland and its capsule. They measure on an average about 6 mm. in length, and from 3 mm. to 4 mm. in breadth, and usually present the appearance of flattened oval discs. They are divided, according to their situation, into *superior* and *inferior*. The superior, usually two in number, are the more constant in position, and are situated one on each side, at the level of the lower border of the cricoid cartilage, behind the junction of the pharynx and œsophagus. The inferior, also usually two in number, may be applied to the lower edges of the lobes of the thyroid gland, or may be placed at some little distance below the thyroid gland, or in

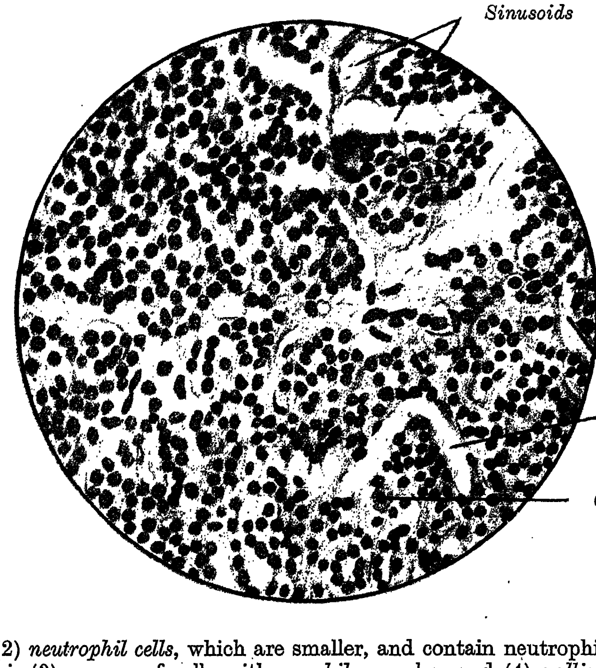
* Arris and Gale lecture on "The Applied Anatomy and Physiology of the Thyroid Apparatus" (*British Journal of Surgery*, January 1926, page 466).

relation to one of the inferior thyroid veins. * According to Walton, † the inferior parathyroid is found as a rule in one of three positions : (1) within the fascial sheath of the thyroid gland, below the inferior thyroid artery and near the lower pole of the lobe : (2) posterior to the fascial sheath of the thyroid gland, immediately above the inferior thyroid artery : and (3) within the substance of the lobe of the thyroid gland near the lower end of its posterior border.

In man, they number four as a rule ; fewer than four were found in less than 1 per cent. of over a thousand persons (Pepere ‡), but more than four in over 33 per cent. of 122 bodies examined by Civalleri. In addition numerous, minute islands of parathyroid tissue may be found scattered in the connective tissue and fat of the neck round the parathyroid glands proper, and quite distinct from them.

Structure.—Microscopically the parathyroid glands consist of intercommunicating columns of cells supported by connective tissue containing a rich supply of blood-capillaries (sinusoids). Four types of cells have been described: (1) *principal cells*, large, clear and polygonal, with distinct cell outlines and dark nuclei which show a definite chromatin

FIG. 1257.—A section of a human parathyroid gland. Stained with hæmatoxylin and eosin. ×400.



network, (2) *neutrophil cells*, which are smaller, and contain neutrophil granules and very dark nuclei, (3) groups of cells with *oxyphil* granules, and (4) *pallisade cells*, which are principal cells forming a pallisade on the borders of the sinusoids (fig. 1257). Vesicles containing colloid are sometimes found.

Vessels and Nerves.—The parathyroid glands receive a very rich *blood-supply* from the inferior thyroid arteries or from the anastomoses between the superior and inferior thyroid arteries. Their *lymph* vessels are numerous, and are associated with those of the thyroid and thymus glands. Their *nerve-supply* is derived from the sympathetic, either directly from the superior or middle cervical ganglia, or indirectly through a plexus in the fascia on the posterior surface of the lobes of the thyroid gland.

The Paraganglia

The paraganglia are found in two chief groupings : (1) as small masses of chromaffin cells (p. 124) placed either within the capsules of the sympathetic ganglia or in close contact with them ; (2) as small groups of chromaffin cells scattered throughout the sympathetic plexuses. The two largest masses in this latter group are the aortic bodies.

* Consult an article by D. A. Welsh, *Journal of Anatomy and Physiology*, vol. xxxii.

† A. James Walton, *British Journal of Surgery*, vol. xix. 1931-32.

‡ Consult *Le Ghiandole paratiroidee*, by A. Pepere, Turin, 1906.

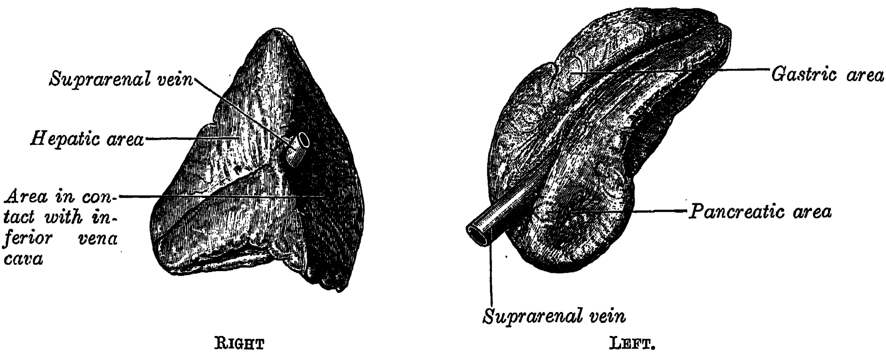
The *aortic bodies* are two small brownish-coloured bodies which lie one on each side of the abdominal aorta at the level of the origin of the inferior mesenteric artery, in intimate relationship with the abdominal aortic plexus of the sympathetic. They are of considerable size (8-10 mm. long) in the new-born child, and may be united to one another across the front of the abdominal aorta. After birth they gradually atrophy, and they become invisible to the naked eye shortly after puberty.

Structure.—The aortic bodies consist of masses of polygonal or cubical epithelium, imbedded in a wide-meshed capillary plexus. The cell-bodies stain brown or yellow when treated with chromic salts.

The Suprarenal Glands (figs. 1258, 1259)

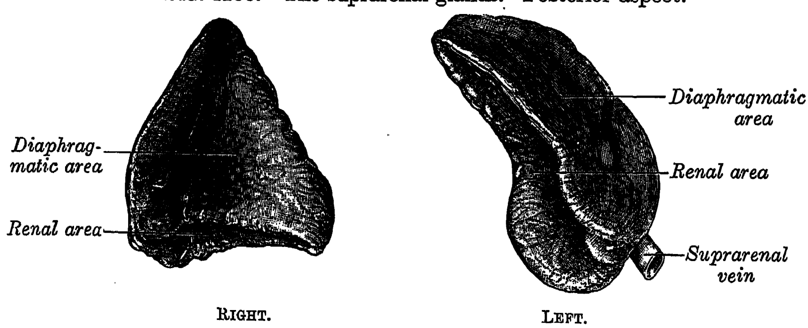
The **suprarenal glands** are two small, flattened bodies of a yellowish colour, situated, one on each side of the median plane, at the posterior part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of the kidney. They are surrounded by areolar tissue containing a

Fig. 1258.—The suprarenal glands. Anterior aspect.



considerable amount of fat. Each gland consists of an outer cortical portion, which is rich in lipoids and contains no chromaffin tissue, and an inner medullary portion, which stains deeply with chromic salts. It would appear that the two parts of the gland are functionally distinct from each other, although even that is not yet certain. They are derived from different sources in the embryo

Fig. 1259.—The suprarenal glands. Posterior aspect.



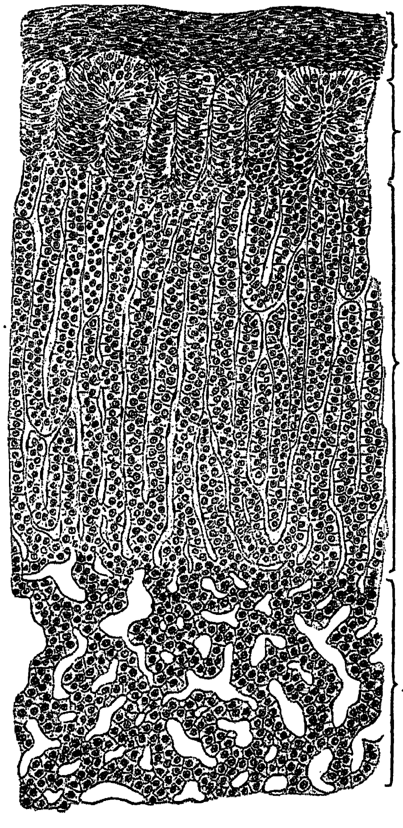
(p. 125) and in many fishes they exist as separate entities. In man it is not uncommon to find small masses of tissue, identical with the suprarenal cortex, in the neighbourhood of the gland or in other situations. They are termed 'cortical bodies.' Ontogenetically, phylogenetically, structurally, and, probably, functionally, the cortex and the medulla of the suprarenal gland are distinct from each other, but anatomically they constitute a single entity and are therefore described as such in this section.

The right gland is somewhat pyramidal in shape, bearing a resemblance to

a cocked hat; the left is semilunar, and is usually larger and extends to a higher level than the right. They measure from 30 mm. to 50 mm. in height; about 30 mm. in breadth, and from 4 mm. to 6 mm. in thickness. The average weight of each is from 3 gm. to 4 gm.

Relations.—The *right suprarenal gland* is situated behind the inferior vena cava and the right lobe of the liver, and in front of the Diaphragm and upper end of the right kidney. It is roughly triangular in shape; its base, usually directed downwards, is in contact with the medial and anterior surfaces of the upper end of the right kidney. Frequently the base is related to the upper part of the medial border of the right kidney and not to its upper pole. Its *anterior surface* looks forwards and laterally, and has two areas: a medial, narrow and non-peritoneal, which lies behind the inferior vena cava; and a lateral, somewhat triangular, in contact with the liver. The upper part of the latter surface is devoid of peritoneum, and is in relation with the lower and medial angle of the bare area of the liver, while its inferior portion may be covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament; occasionally the duodenum overlaps the inferior portion. A little below the apex, and near the anterior border of the gland, there is a short furrow termed the hilum, from which the right suprarenal vein emerges to join the inferior vena cava. Its *posterior surface* is divided into upper and lower parts by a curved ridge; the upper, slightly convex, rests upon the Diaphragm; the lower, concave, is in contact with the upper end and the adjacent part of the anterior surface of the right kidney. The thin *medial border* of the gland is related to the right coeliac ganglion, which lies medial to its lower part, and to the right (inferior) phrenic artery, as the vessel courses upwards and laterally on the right crus of the Diaphragm.

Fig. 1260.—Vertical section of cortex of suprarenal gland of dog. (Böhm and V. Davidoff.) (From Sharpey-Schafer's *Essentials of Histology*.)



The *left suprarenal gland* is crescentic in shape, its concavity being adapted to the medial border of the upper part of the left kidney. Its medial border is convex, its lateral concave; its upper end is narrow, its lower rounded. Its *anterior surface* has two areas: an upper, covered with the peritoneum of the lesser sac, which separates it from the cardiac end of the stomach and sometimes from the superior extremity of the spleen; and a lower, which is not covered with peritoneum, but is in contact with the pancreas and splenic artery. The hilum, which is directed downwards and forwards, is placed near the lower part of the anterior surface. From it the left suprarenal vein emerges to join the left renal vein. Its *posterior surface* is divided into two areas by a ridge; the lateral area rests on the kidney, the medial and smaller, on the left crus of the Diaphragm. The convex *medial border* is related to the left cœliac ganglion, which lies medial to its lower part, and to the left phrenic and left gastric arteries, as they run upwards on the left crus of the Diaphragm.

Small *accessory suprarenal* glands are often found in the areolar tissue round the suprarenal glands; they are sometimes present in the spermatic cord and epididymis, and in the broad ligament of the uterus.

Structure.—The suprarenal gland is closely invested by a capsule of fibro-areolar tissue from which trabeculæ pass into the substance of the gland; the capsule may contain smooth muscular fibres. On section, the gland is seen to consist of two portions (fig. 1260): an external, the cortex, and an internal, the medulla. The cortex constitutes the larger part of the organ, and is of a deep yellow colour; the medulla is soft, pulpy and of a dark red or brown colour.

The *cortex* (fig. 1260) consists of a fine connective tissue network, in which is imbedded the glandular epithelium. The epithelial cells are polyhedral in shape and possess rounded nuclei; many of the cells contain coarse granules, others lipoid globules. Owing to the differences in the arrangement of the cells three distinct zones can be made out: (1) The *zona glomerulosa*, situated beneath the capsule, consists of cells arranged in rounded groups, with here and there indications of an alveolar structure. (2) The *zona fasciculata*, continuous with the zona glomerulosa, is composed of columns of cells arranged in a radial manner; these cells contain fine granules and in many instances globules of lipoid material. (3) The *zona reticularis*, in contact with the medulla, consists of cylindrical columns of cells irregularly arranged; these cells often contain pigment-granules which give this zone a darker appearance than the rest of the cortex.

The *medulla* is extremely vascular, and is composed of a mass of large, finely granular chromaffin cells, permeated by venous sinusoids. This portion of the gland is richly supplied with non-medullated nerve-fibres, and here and there sympathetic ganglion cells are found.

The suprarenal gland is large in the fœtus, owing to the great development of the inner layer of the cortex. This layer has been named the *boundary zone* by Elliott and Armour. Its cells contain no lipoid granules. This zone disappears soon after birth and is absent in anencephalic fœtuses.

In connexion with the development of the medulla from the sympathochromaffin tissue, it is to be noted that this portion of the gland secretes a substance, named *adrenalin*, which has the property of stimulating all sympathetic nerve-endings.

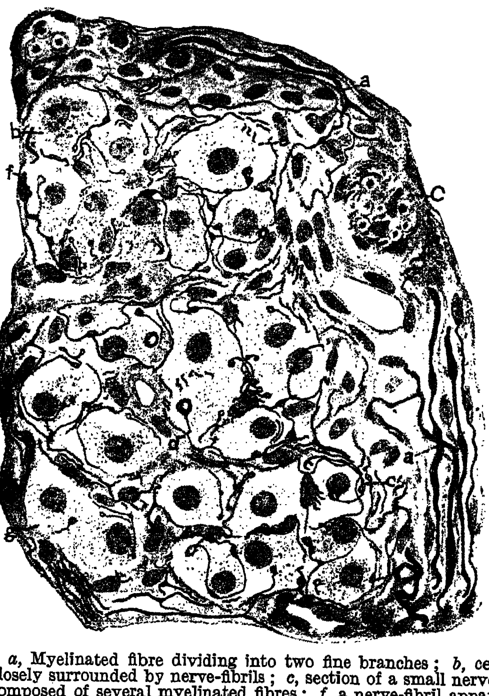
Vessels and Nerves.—The *arteries* supplying the suprarenal glands are numerous and of comparatively large size; they are derived from the aorta, and the phrenic and renal arteries. In the cortical part of the gland they break up into capillaries which end in the sinusoids of the medullary portion; the latter open into the veins near the centre of the medulla.

The *suprarenal vein* emerges from the hilum of the gland; that of the right gland opens into the inferior vena cava, that of the left into the left renal vein.

The *lymph* vessels end in the lateral aortic glands.

The *nerves* are exceedingly numerous, and are derived from the splanchnic nerves through the cœliac and renal plexuses, and, according to Bergmann, from the phrenic and vagus nerves. They enter the lower and medial part of the capsule, traverse the cortex, and end around the cells of the medulla. They have numerous small ganglia developed upon them in the medullary portion of the gland.

FIG. 1261.—A section of the carotid body, showing nerve-fibres distributed to the cells. (de Castro.) (From Sharpey-Schafer's *Essentials of Histology*.)



a, Myelinated fibre dividing into two fine branches; *b*, cell closely surrounded by nerve-fibrils; *c*, section of a small nerve, composed of several myelinated fibres; *f*, a nerve-fibril apparently ending within the cytoplasm of a cell; *g*, a nerve-fibril ending between the cells.

The Carotid Bodies

The carotid bodies, two in number, are situated one on each side of the neck, behind the common carotid artery at its point of bifurcation into the external and internal carotid

trunks. They are reddish-brown in colour, and oval in shape, the long diameter measuring about 5 mm.

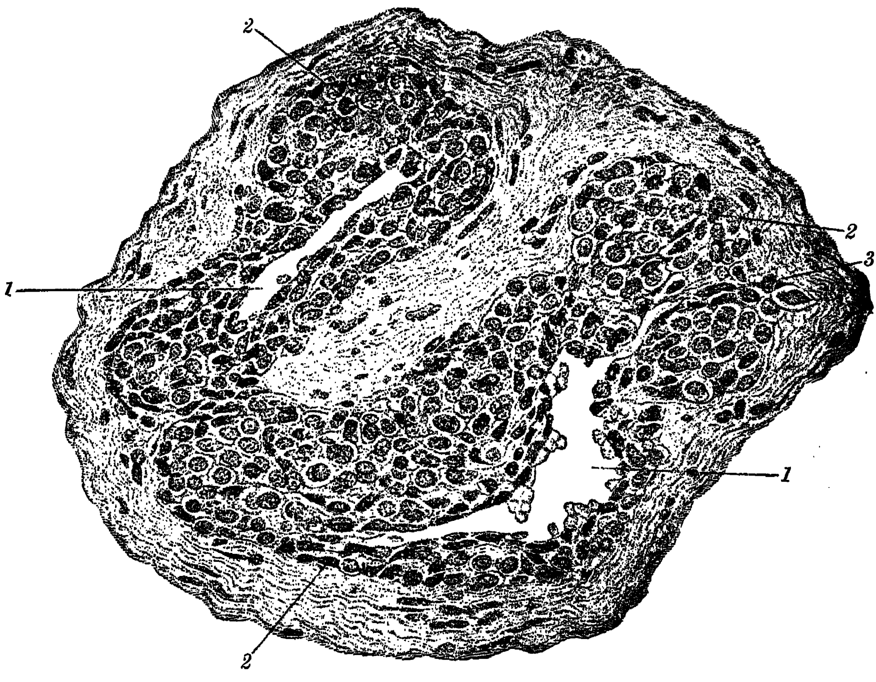
Structure.—Each is invested by a fibrous capsule and consists largely of spherical or irregular masses of chromaffin cells (fig. 1261)—the masses being more or less isolated from one another by septa which extend inwards from the deep surface of the capsule. The cells are polyhedral in shape, and each contains a large nucleus imbedded in finely granular protoplasm. Numerous nerve-fibres, derived from the superior cervical ganglion of the sympathetic trunk, and from the glossopharyngeal nerve, are distributed throughout the organ, and a network of large, sinusoidal capillaries ramifies amongst the cells. De Castro believes that the nervous constituents have a higher functional value than the chromaffin cells, and he regards the gland, not as an endocrine organ, but as a sensory organ associated with the vascular system and, possibly, concerned with the regulation of blood-pressure. It is not improbable that some functional significance may be attached to the intimate topographical relationship of the carotid body to the carotid sinus (p. 700).

The carotid bodies are derived from the masses of sympathochromaffin cells which give origin to the superior cervical ganglia of the sympathetic trunks.

The Coccygeal Body

The coccygeal body is placed in front of, or immediately below, the tip of the coccyx. It is about 2·5 mm. in diameter and is irregularly oval in shape; several smaller nodules are found around or near the main mass.

Fig. 1262.—A section through the coccygeal body. (Walker.) (From Sharpey-Schafer's *Essentials of Histology.*)



1, Blood-sinusoids; 2, gland-cells; 3, connective tissue stroma.

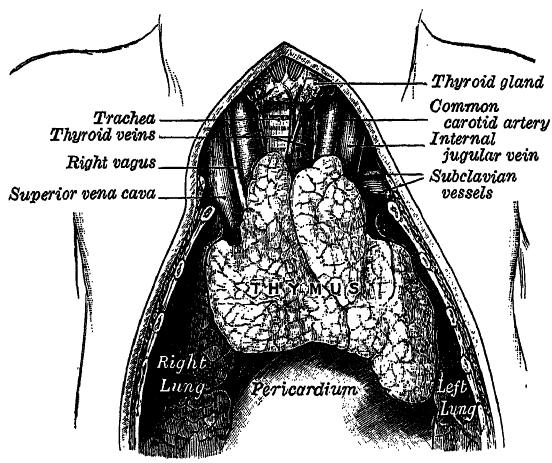
Structure.—The coccygeal body consists of irregular masses of round or polyhedral cells (fig. 1262), the cells of each mass being grouped around a dilated, sinusoidal capillary vessel. Each cell contains a large, round or oval nucleus, the protoplasm surrounding which is clear and is not stained by chromic salts.* The coccygeal body probably has a sympathochromaffin origin but, owing to the fact that it cannot be identified before the fourth month, the details of its development are uncertain.

* Consult the following article: "Über die menschliche Steissdrüse," von J. W. Thomson Walker, *Archiv für mikroskopische Anatomie und Entwickelungsgeschichte*, Band 64, 1904.

The Thymus (fig. 1263)

The **thymus** increases in size until the age of puberty, after which it dwindles and undergoes a gradual involution. Hammer maintains that it may persist and function even in advanced life. If examined when its growth is most active, it will be found to consist of two lobes placed in close contact along the median plane, situated partly in the thorax, partly in the neck, and extending from the fourth costal cartilage upwards, as high as the lower border of the thyroid gland. It is covered by the sternum, and by the origins of the Sternohyoid and Sternothyroid muscles. Below, it rests upon the pericardium, being separated from the aortic arch and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sternohyoid and Sternothyroid muscles. The two lobes generally differ in size; they are occasionally united by connective tissue, so as to form a single mass; sometimes they are separated by an intermediate lobe. The thymus is of a pinkish-grey colour,

Fig. 1263.—The thymus of a full-time fœtus. Exposed *in situ.*



soft, and lobulated on its surfaces. At birth it weighs about 13 gm., and at puberty between 35 and 40 gm.; it is heavier in the male than in the female. Small nodules of thymic tissue may be found in the neighbourhood of the thyroid gland, and are frequently closely associated with the parathyroid glands.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size and are made up of a number of small nodules or follicles, which are irregular in shape and are more or less fused together, especially towards the interior of the gland. Each follicle (fig. 1264A) is from 1 mm. to 2 mm. in diameter and consists of a cortical and a medullary portion; it is enclosed in a connective tissue capsule, from which septa pass into its substance, but do not extend as far as the medullary portion of the follicle. The *cortical portion* is mainly composed of lymphocytes, supported by a network of finely branched cells, which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the *medullary portion* the lymphoid cells are fewer, and the reticulum is coarser than in the cortex; it contains nest-like bodies, termed the *concentric corpuscles* of Hassall. These corpuscles are composed of a central mass, consisting of one or more granular cells, and of a capsule which is formed of concentrically arranged epithelioid cells (fig. 1264B). Eosinophil and polymorphonuclear leucocytes are also found in the gland.

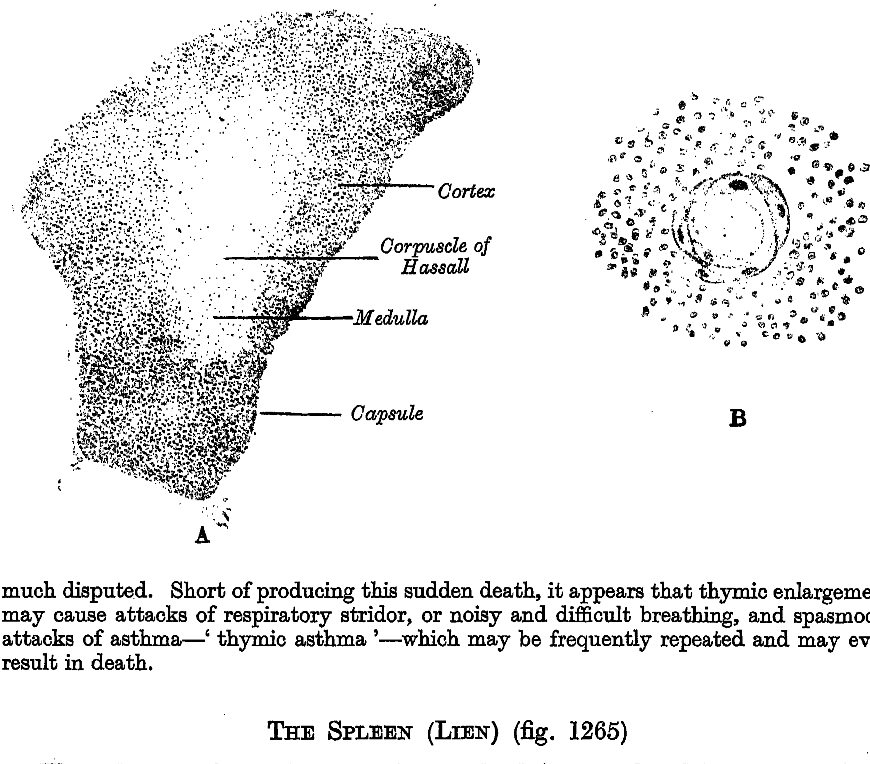
Each follicle is surrounded by a vascular plexus, from which vessels pass into the interior, and radiate from the periphery towards the centre, forming a second zone just within the margin of the medullary portion. In the centre of the medullary portion there are very few vessels, and they are of minute size.

The cortical part begins to atrophy before the medullary part, and its decrease in size is mainly owing to a diminution in the number of lymphocytes.

Vessels and Nerves.—The blood-supply of the thymus is scanty. The *arteries* are derived from the internal mammary, and the superior and inferior thyroids. The *veins* end in the left innominate vein, and in the thyroid veins. The *lymph vessels* are described on p. 879. The *nerves* are exceedingly minute; they are derived from the vagi and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule but do not penetrate the substance of the gland.

Applied Anatomy.—Sudden death—'thymus death'—with heart-failure, and with or without acute respiratory embarrassment, has been recorded in a number of infants and children in whom the thymus was considerably enlarged, and the lymphatic tissues throughout the body showed general hypertrophy, but who showed no other evidence of disease. Such deaths have often occurred during the administration of anæsthetics, particularly chloroform. How far the enlarged thymus was responsible for the death of these patients, and, if it was responsible, how far its action was mechanical, are points that have been

FIG. 1264.—A, A section through a follicle of the thymus of a kitten. ×60 B, a corpuscle of Hassall. ×350. Stained with picrocarmine.



much disputed. Short of producing this sudden death, it appears that thymic enlargement may cause attacks of respiratory stridor, or noisy and difficult breathing, and spasmodic attacks of asthma—'thymic asthma'—which may be frequently repeated and may even result in death.

THE SPLEEN (LIEN) (fig. 1265)

The spleen is situated principally in the left hypochondriac region of the abdomen, but its upper end extends into the epigastric region; it lies between the fundus of the stomach and the Diaphragm. It is the largest of the ductless glands, and is of an oblong, flattened form, soft, of very friable consistence, highly vascular, and of a dark purplish colour.

Relations.—The *diaphragmatic surface* is convex, smooth and faces upwards, backwards, and to the left, except at its upper end, where it faces slightly medially. It is in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side, and the intervening lower borders of the left lung and pleura.

The *visceral surface* (fig. 1265) is directed towards the abdominal cavity, and presents gastric, renal, pancreatic and colic impressions.

The *gastric impression*, directed forwards, upwards, and medially, is broad and concave. It is in contact with the posterior wall of the stomach, from which it is separated by a recess of the greater sac. It presents near its lower limit a long fissure, termed the *hilum*. This is pierced by several irregular apertures for the entrance and exit of vessels and nerves.

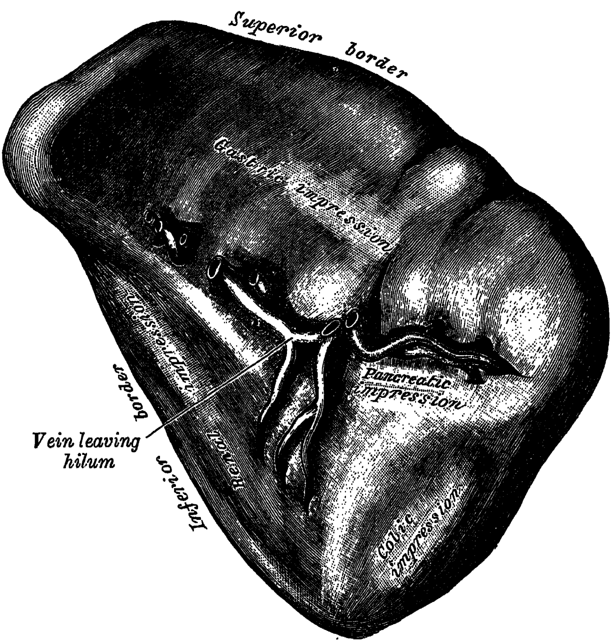
The *renal impression*, which is very gently concave, is placed on the lower part of the visceral surface and is separated from the gastric impression above by a raised margin. It is directed medially, downwards and a little backwards, and is related to the upper and lateral part of the anterior surface of the left kidney and, sometimes, to the upper pole of the left suprarenal gland.

The *colic impression* is placed at the lateral extremity of the spleen and is usually flattened. It is related to the left colic flexure.

The *pancreatic impression*, when present, is small and is placed between the colic impression and the lateral part of the hilum. It is directly related to the tail of the pancreas.

The *superior border* separates the diaphragmatic surface from the gastric impression. It is usually convex upwards and is marked, near its lateral end,

FIG. 1265.—The visceral surface of the spleen.



by one or two notches of variable depth. The *inferior border* separates the renal impression from the diaphragmatic surface and lies between the Diaphragm and the upper part of the lateral border of the left kidney. It is blunter and more rounded than the superior border and corresponds to the lower margin of the eleventh rib.

The *medial end* of the spleen is blunt and rounded in most cases. It is directed towards the vertebral column and lies on a level with the twelfth thoracic vertebra. The *lateral end* is more expanded, and commonly takes the form of a margin connecting the lateral ends of the upper and lower borders. It is related to the left colic flexure and to the phrenicocolic ligament.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule. Recesses of the greater sac intervene between the spleen and the stomach, and between the spleen and the left kidney. It develops in the upper part of the dorsal mesogastrium (p. 179) and remains connected to the stomach and to the posterior abdominal wall by two folds of peritoneum. One, termed the *lienorenal ligament*, is derived from the peritoneum where the wall of the general peritoneal cavity comes into contact with the lesser sac between the left kidney and spleen ; the splenic vessels pass between its two layers (fig. 1162). The other fold, termed the *gastrosplenic ligament*, also consists of two layers, and is formed by the meeting of the walls of the greater and lesser sacs between the spleen and stomach (fig. 1162) ; the short gastric and left

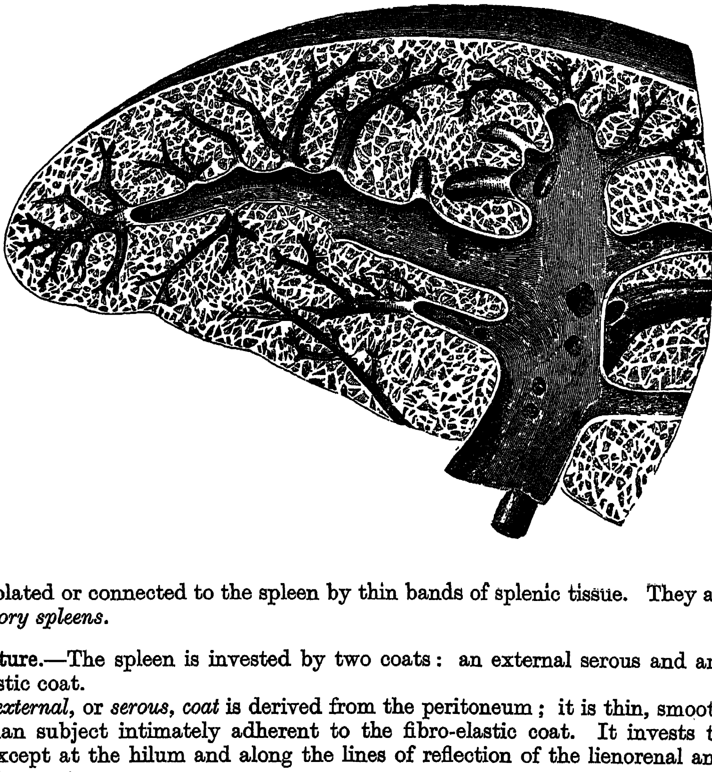
gastro-epiploic branches of the splenic artery run between its two layers. The lateral part of the lateral end of the spleen is in contact with the phrenico-colic ligament (p. 1314).

The size and weight of the spleen vary at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult* it is usually about 12 cm. in length, 7 cm. in breadth, and 3 or 4 cm. in thickness, and weighs about 200 gm., but it tends to diminish in size and weight with advancing age.

The size of the spleen slowly increases during digestion, and varies according to the state of nutrition of the body, being large in highly fed, and small in starved, animals. In malarial fever it is greatly enlarged, and may weigh as much as 9 kilos.

Frequently in the neighbourhood of the spleen, and especially in the gastrosplenic ligament and greater omentum, small encapsulated nodules of splenic tissue may be found,

FIG. 1266.—A transverse section through the spleen, showing the trabecular tissue and the splenic vein and its tributaries.



either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *accessory spleens.*

Structure.—The spleen is invested by two coats: an external serous and an internal fibro-elastic coat.

The *external,* or *serous, coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the hilum and along the lines of reflection of the lienorenal and gastrosplenic ligaments.

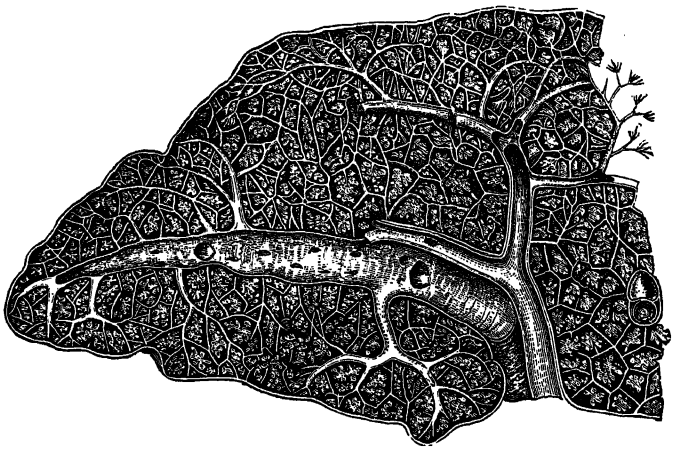
The *fibro-elastic coat,* or *tunica albuginea,* invests the organ, and at the hilum is reflected inwards upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, termed *trabeculæ* (fig. 1266), are given off in all directions; these unite to form the framework of the spleen, in the interspaces of which the *splenic pulp* is contained.

The fibro-elastic coat, the sheaths of the vessels, and the trabeculæ, are composed of white, and yellow elastic, fibres, the latter predominating. It is owing to the presence of the elastic tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents there is a small amount of non-striped muscular fibre. In some mammals (e.g. dog, pig, and cat) the trabeculæ consist chiefly of muscular tissue.

The *splenic pulp* is a soft mass of a dark reddish-brown colour; it consists of a fine reticulum of fibres, continuous with those of the trabeculæ, to which flat, branching cells are applied. The meshes of the reticulum are filled with blood, in which, however, the white corpuscles are found to be in larger proportion than they are in ordinary blood. Large, rounded cells, termed *splenic cells,* are also seen; these are capable of amœboid movement, and often contain pigment and red blood-corpuscles in their interior. The

cells of the reticulum possess round or oval nuclei, and like the splenic cells they may contain pigment-granules in their cytoplasm; they do not stain deeply with carmine, and in this respect differ from the cells of the lymphatic nodules. In the young spleen

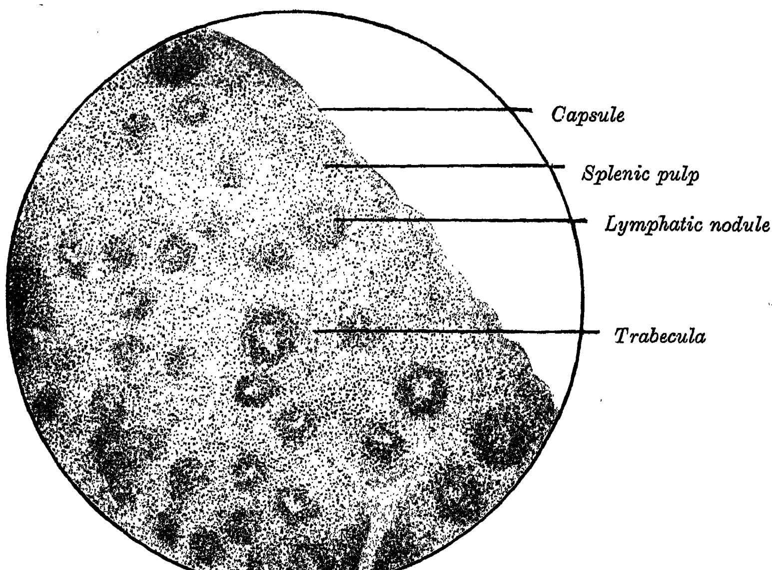
FIG. 1267.—A transverse section through the human spleen, showing the distribution of the splenic artery and its branches.



giant cells may be found, each containing numerous nuclei or one compound nucleus. Nucleated red blood-corpuscles have also been found in the spleen in young animals.

Blood-vessels of the spleen.—The splenic artery (p. 765) is remarkable for its large calibre in proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance

FIG. 1268.—A section through a portion of the human spleen. Stained with hæmatoxylin and eosin. × 15.



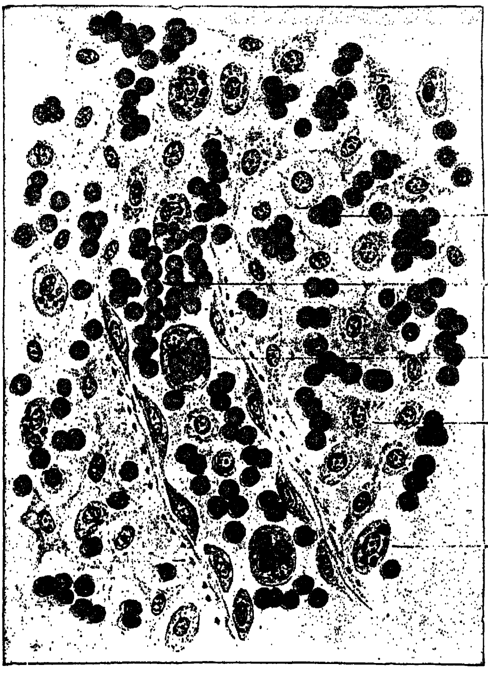
(fig. 1267), receiving sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ, from within outwards, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior, part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of

minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. The branches of the splenic artery are 'end arteries' (p. 690).

The *arterioles* differ in structure from the larger arterial vessels in that their outer coat consists of lymphoid tissue. This coat exhibits localized spheroidal thickenings, termed the *lymphatic nodules* (*Malpighian bodies*) of the spleen (fig. 1268). These bodies vary in size from about 0·25 mm. to 1 mm. in diameter. In transverse sections the artery, in the majority of cases, is found in an eccentric position. The lymphatic nodules are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute semi-opaque dots of a whitish colour in the dark substance of the pulp. The reticulum of the lymphoid tissue is made up of extremely fine fibrils, and is comparatively open in the centre of the body, but closer at its periphery.

FIG. 1269.—Thin section of spleen-pulp of child, highly magnified, showing the mode of origin of a small vein in the interstices of the pulp. (E. Sharpey-Schafer.) ×400. (From Sharpey-Schafer's *Essentials of Histology*.)



a, Blood in pulp ; *a′*, blood in vein ; *b*, phagocyte in vein ; *c*, branched cell of pulp ; *d*, phagocytic splenic cell.

The arterioles end by opening freely into the splenic pulp ; their walls become much attenuated, they lose their tubular character, and the endothelial cells ramify, their processes being directly connected with those of the reticular cells of the pulp. The blood thus finds its way into the interstices of the reticulated tissue of the splenic pulp. It is then collected by the rootlets of the veins, which begin much in the same way as the arteries end (fig. 1269). The connective tissue corpuscles of the pulp arrange themselves in rows, in such a way as to form an elongated space or sinus. They become elongated and spindle-shaped, and overlap each other at their extremities, and thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these sinuses delicate transverse lines or markings, which are due to minute elastic fibrils arranged in a circular manner, are seen. Thus the channel obtains an external investment, and gradually becomes converted into a small vein, which after a short course acquires a coat of ordinary connective tissue, lined with a layer of endothelial cells continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones : these do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form six or more vessels. These emerge from the hilum and, uniting, constitute the splenic vein (p. 842), which is the largest radicle of the portal vein.

The veins are remarkable for their numerous anastomoses.

The lymph vessels are described on p. 868.

The *nerves* are derived from the cœliac plexus and are chiefly non-medullated. They are distributed to the blood-vessels and to the smooth muscle of the capsule and trabeculæ.

Applied Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connexions. It may be ruptured by direct or indirect violence; torn by a broken rib; or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hæmorrhage, owing to the vascularity of the organ and the absence of a proper system of capillaries. The injury, however, is not necessarily fatal, and this would appear to be due, in a great measure, to the contractile power of the capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear, and the symptoms indicate danger to life, laparotomy must be performed, and the spleen removed. When removing the spleen it must be remembered that the tail of the pancreas is in contact with it, and should be avoided when the vessels are ligatured.

SURFACE ANATOMY

SURFACE anatomy deals with the relationships of structures to the surface of the body, and, in order that these relationships may be determined, use is made of surface landmarks which can be identified easily. Many subcutaneous as well as many deeper structures produce irregularities in the surface contour of the body which can be appreciated on inspection ; others, while yielding no visible sign of their presence, can be felt through the skin, and are therefore capable of identification by means of palpation. Most of the deeper structures can neither be seen nor felt through the skin, but a knowledge of their topographical relations in the body makes their reference to visible or palpable landmarks a matter of relatively little difficulty.

Bones, cartilages, muscles and tendons provide most of the visible and palpable landmarks. When bony or cartilaginous landmarks are being sought, their recognition is facilitated by the relaxation of the muscles in their neighbourhood. On the other hand, muscles and tendons can be identified most easily when they are thrown into contraction and, preferably, when they are working under load. In cases where arteries are placed superficially and lie on bone, their position can be indicated accurately as their pulsations render their identification easy. Nerves, similarly placed, can be rolled under the skin against the bone and can be identified in that way. A few other structures, e.g. the parotid duct, the spermatic cord, etc., can also be felt through the skin.

In the succeeding pages the subject-matter is treated regionally, and in each case a description of the visible and palpable landmarks precedes the description of the surface relations of the other structures in the region. It would be possible to enumerate the surface relations of all the structures in the human body, but, while all the important visible and palpable landmarks will be included, the surface relations of other structures will be described only in those cases where the information is likely to be of practical value and may be utilised in connexion with the examination or treatment of patients.

THE SURFACE ANATOMY OF THE UPPER LIMB

The Shoulder and Axillary Regions

Surface landmarks.—The *clavicle* forms a landmark which is both visible and palpable. Its outline can be traced from its expanded sternal end, which is the lateral boundary of the suprasternal notch, to its flattened acromial extremity. The line of the *acromioclavicular joint* is anteroposterior, but it is not easy to identify except in those cases where the upper border of the lateral end of the clavicle presents a well-marked ridge. The small depression which lies below the clavicle at the junction of its two curves constitutes the *infraclavicular fossa* (deltoideopectoral triangle) (fig. 1283) and intervenes between the surface elevations produced by the clavicular origins of the deltoid and the pectoralis major muscles.

The rounded lower, or lateral, border of the *pectoralis major* forms the anterior axillary fold and is rendered more conspicuous when the abducted arm is adducted against resistance ; it extends from the lower end of the lateral lip of the bicipital groove (intertubercular sulcus) of the humerus downwards and medially to the chest wall. When the arm is flexed to a right angle and maintained in that position against gravity, the *clavicular head* of the muscle is thrown into contraction, while the sternocostal head is relaxed. The lower border of the clavicular head can then be traced from the sternal end of the clavicle to the lower border of the anterior axillary fold, and it corresponds to the line of separation of the two heads of the muscle. When the flexed arm is extended against resistance, the clavicular head becomes relaxed, but the *sternocostal head* stands out in bold relief.

The *acromion* can be traced forwards along its medial margin from the acromioclavicular joint to its tip, and then backwards along its lateral margin across the top of the shoulder until it meets the crest of the scapular spine at the prominent *acromial angle*. From this angle the *crest of the scapular spine* (fig. 1286) runs downwards and medially to reach the medial border of the bone opposite the spine of the third thoracic vertebra. It is subcutaneous and is both visible and palpable. The *medial border* of the scapula is hidden in its upper part by the trapezius muscle, but, below the spine, it can be traced downwards and slightly laterally to the *inferior angle* (fig. 1286), which usually overlies the seventh intercostal space at the level of the spine of the seventh thoracic vertebra. When the arm is raised above the head, the position of the medial border is indicated by an oblique furrow. Although it is covered by the teres major and latissimus dorsi muscles, the inferior angle can easily be felt when it is approached from below, and it can be seen moving laterally and forwards round the chest wall when the arm is raised above the head.

The rounded contour of the normal shoulder is caused by the bulky *deltoid muscle* (fig. 1286), the limits of which can be determined accurately when the arm is maintained in the abducted position against gravity. The tendon of insertion can be identified about half-way down the lateral aspect of the humerus, and from its anterior aspect the anterior border of the muscle can be traced upwards and medially, across the tendon of the pectoralis major, to form the lateral boundary of the infraclavicular fossa. The posterior border of the muscle runs upwards and medially from the posterior aspect of the tendon of insertion and crosses the back of the shoulder to reach the crest of the scapular spine near its medial end. As it passes from its origin to its insertion the deltoid muscle is spread out over the lateral aspect of the greater tuberosity of the humerus, and it is actually this bony relationship which accounts for the normal rounded contour of the shoulder. When the greater tuberosity is displaced medially—a condition which is present in dislocation of the shoulder joint—the deltoid descends vertically to its insertion and the normal, rounded contour is lost.

The apex of the *coracoid process* can be made out indistinctly under cover of the anterior fibres of the deltoid. It lies 2·5 cm. vertically below the clavicle at the junction of the lateral fourth with the rest of the bone.

The posterior fold of the axilla, which reaches a lower level on the humerus than the anterior fold, is produced by the *latissimus dorsi* and the underlying *teres major* muscle. Both take part in adduction of the arm and, when attempts are made to adduct the abducted arm against resistance, the posterior fold of the axilla is accentuated and the lower, or lateral, border of the latissimus dorsi can be traced downwards to its attachment to the iliac crest.

When the arm is raised above the head, the lower five or six serrations of the *serratus anterior* muscle (fig. 1270) can be seen on the lateral aspect of the chest; they point downwards and forwards and interdigitate with the serrations of the external oblique muscle along a zigzag line.

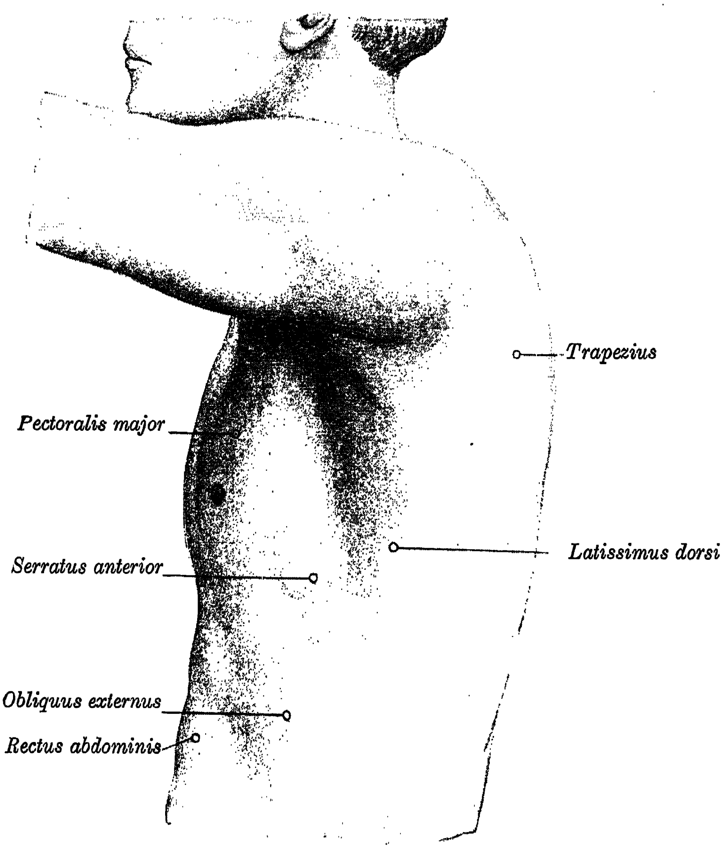
The *greater tuberosity* of the humerus constitutes the most lateral bony point in the shoulder region (fig. 1287, and Pl. III) and projects laterally below and in front of the acromial angle. It can be felt indistinctly on deep pressure through the deltoid muscle. The *lesser tuberosity* lies on the anterior aspect of the shoulder, 3 cm. below the tip of the acromion. If deep pressure is made through the deltoid at this point, the resistance due to the lesser tuberosity can be felt, and the bony prominence slips away from the examining finger when the humerus is rotated laterally, or medially.

The pulsation of the lower part of the *axillary artery* can be felt on palpation of the medial side of the arm, just in front of the posterior axillary fold, and in this situation the great nerves derived from the brachial plexus can be felt as tense cords when the arm is abducted. On deep pressure the *median nerve* can be rolled against the humerus, and tingling sensations are induced thereby in the central part of the palm of the hand.

The skin covering the shoulder is smooth and freely movable on the underlying structures. In the axilla there are numerous hairs and many sudoriferous and sebaceous glands.

Surface relations of other structures.—The *axillary artery* can be mapped out most conveniently when the arm is raised to a right angle with the trunk. It can be represented by a broad line drawn laterally from the middle of the clavicle to the point at which the pulsation of the vessel is felt. The *axillary vein* is closely applied to the medial side of the artery. In the upper part of its course the *cephalic vein* can be indicated by a line drawn upwards along the anterior border of the deltoid muscle, across the infraclavicular fossa, to end under cover of the clavicular head of the pectoralis major.

FIG. 1270.—The left side of the thorax.



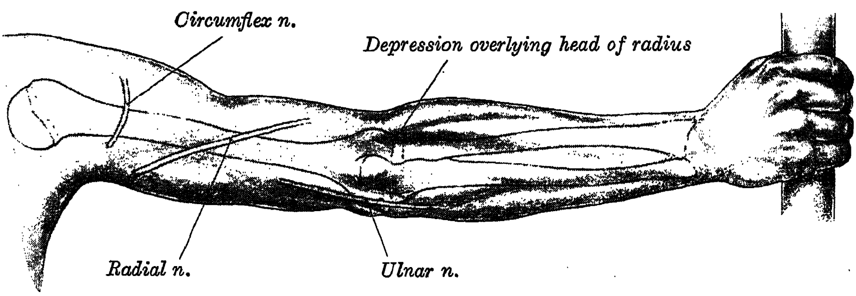
When the arm is by the side the anterior edge of the glenoid cavity can be marked out on the front of the shoulder by a line, 3 cm. long, drawn downwards from a point just lateral to the tip of the coracoid process. This line, which should be very slightly concave laterally, lies over the lower half of the shoulder joint.

The *mammary gland* covers a somewhat circular area, but its periphery is irregular and can be represented best by a wavy line. This line commences at the margin of the sternum opposite the sternal angle and runs downwards to the sternal end of the sixth costal cartilage. It is continued laterally, with a gentle convexity downwards, to the midaxillary line and then upwards into the axilla, where the tail of the gland reaches as far as the axillary vessels under cover of the pectoralis major muscle. Finally, the line curves medially along the second rib and cartilage to the sternum. In the male, the *nipple* lies over the fourth intercostal space (fig. 1291), rather more than 10 cm. from the median plane ; in the female, especially when the breast is pendulous, it is found at a lower level.

The Arm and Elbow Region

Surface landmarks.—When the arm is grasped firmly, the *shaft of the humerus* can be made out, but the strong muscles that clothe it obscure its outline and render it indistinct. At the lower end of the bone the *medial epicondyle* (fig. 1271) forms a conspicuous landmark and can be examined readily, especially when the elbow is flexed passively. The *ulnar nerve* lies posterior to the base of the epicondyle and can be rolled from side to side against the bone. The *lateral epicondyle*, which lies on a more anterior plane when the arm is by the side (p. 346), is not so prominent, but its posterior surface can be felt, and its lateral margin can be traced up into the *lateral supracondylar ridge*, when deep pressure is exerted. If the extended elbow is viewed from behind, a well-marked depression can be seen to the lateral side of the middle line. It is bounded laterally by the fleshy elevation formed by the superficial group of the extensor muscles of the forearm, and medially by the lateral side of the olecranon. The floor of the depression contains, in its upper part, the posterior surface of the *lateral epicondyle* and, in its lower part, the *head of the radius.*

Fig. 1271.—The back of the right upper limb, showing the surface markings for the bones and nerves.



Although covered with the annular ligament and the anconeus muscle, the head of the radius can be felt to rotate when the forearm is alternately pronated and supinated. Between the lateral epicondyle and the head of the radius a transverse depression can be felt; it corresponds to the *humeroradial part of the elbow joint.*

When the elbow is extended, the apex of the *olecranon* can be felt on, or just above, the line joining the two epicondyles, nearer to the medial than to the lateral side (fig. 1271). When the elbow is flexed, the apex of the olecranon descends, and the three bony points form the angles of an isosceles triangle. In this position of the limb the proximal surface of the olecranon can be explored, but it is covered with the tendon of insertion of the triceps and can only be made out indistinctly. The posterior surface of the olecranon is subcutaneous and tapers from above downwards; it can be felt without difficulty immediately below the apex.

On the front of the arm, the *biceps* (fig. 1273) is a conspicuous elevation, diminishing above, where it is covered with the pectoralis major tendon, and again below where it gives place to its tendon just above the elbow. Shallow furrows indicate its medial and lateral borders. When the elbow is flexed against resistance the muscle is thrown into contraction, and its tendon of insertion can be grasped between the finger and thumb and followed down into the cubital fossa. From the medial border of the tendon the sharp, upper margin of the *bicipital aponeurosis* can be traced downwards and medially to the elevation caused by the superficial group of the flexor muscles of the forearm. The aponeurosis is crossed, almost at right angles, by the *median cubital vein*,

which can usually be seen through the skin running upwards and medially from the cephalic vein to join the basilic vein.

The *coracobrachialis muscle* forms an inconspicuous rounded ridge on the upper part of the medial side of the arm and in the lower part of the lateral wall of the axilla (fig. 1273). It overlaps the upper part of the brachial artery and can be identified by its close relationship to the vessel.

On the posterior aspect of the arm, the *lateral head of the triceps* forms an elevation, medial and parallel to the posterior border of the deltoid muscle; it stands out prominently, when the elbow is extended actively. The fleshy mass which lies to its medial side, and disappears above under cover of the deltoid muscle, is produced by the *long head of the triceps*.

The pulsation of the *brachial artery* can be felt in the furrow along the medial side of the biceps and, at its upper part, in the depression behind the coracobrachialis muscle. In its lower part, it lies close to the medial side of the biceps tendon, but on a more posterior plane, and it disappears behind the bicipital aponeurosis. It can be marked out by a line drawn from the termination of the axillary artery downwards and slightly laterally to a point at the level of the neck of the radius in the middle line of the limb. It should be noted that, although at its upper end the brachial artery lies medial to the humerus, it lies directly in front of the lower end of the shaft of the bone.

Surface relations of other structures.—The *musculocutaneous nerve* can be represented in the arm by a line drawn from the lateral side of the axillary artery 3 cm. above its termination; it passes downwards and laterally across the elevations produced by the coracobrachialis and the biceps to the lateral side of the biceps tendon of insertion. The *median nerve* is intimately related to the brachial artery throughout its course in the arm. Placed at first on the lateral side, the nerve crosses in front of the vessel about half-way down the arm and thereafter descends close to its medial side into the cubital fossa (fig. 1274). The *ulnar nerve* can be represented by a line which follows the medial side of the upper part of the brachial artery, but diverges from it half-way down the arm and runs downwards and medially to the base of the medial epicondyle. The *radial nerve* (fig. 1271) in the arm corresponds to a line drawn from the commencement of the brachial artery and carried downwards and laterally across the elevations produced by the long and lateral heads of the triceps to the junction of the upper and middle thirds of a line joining the lateral epicondyle to the insertion of the deltoid muscle. (This line represents the edge of the *lateral intermuscular septum* of the arm.) The line of the nerve is then continued downwards on the front of the arm to the level of the lateral epicondyle, where it lies 1 cm. or less to the lateral side of the tendon of the biceps. The *circumflex nerve* crosses the humerus about 2 cm. above the mid-point of a line joining the tip of the acromion to the insertion of the deltoid muscle (fig. 1287).

The level of the *elbow-joint* is situated 2 cm. below the line joining the two epicondyles (Pl. V, fig 1). It is not horizontal but slopes downwards and medially from its lateral end and this obliquity produces the 'carrying angle' (p. 467). On the posterior surface of the limb, the level of the joint can be determined more easily, as the humeroradial articulation can be felt through the skin (p. 1430).

The Forearm and Wrist

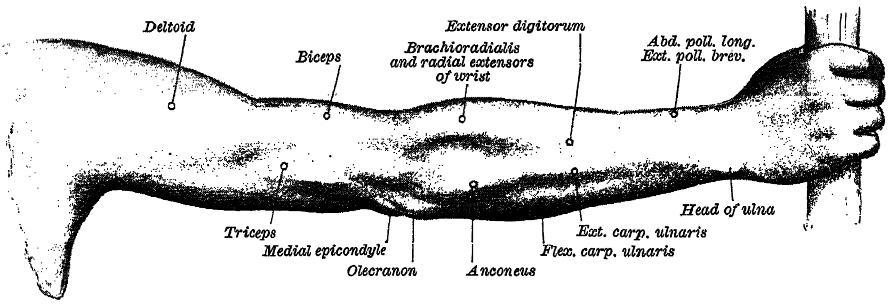
Surface landmarks.—The depression in the middle of the upper part of the front of the forearm corresponds to the *cubital fossa* (fig. 1273). The fleshy elevation which forms its medial border is formed by the *pronator teres* and the *superficial group of the flexor muscles of the forearm*; it does not extend upwards much above the level of the medial epicondyle. The elevation which forms the lateral border of the cubital fossa is formed by the *brachioradialis* and the *superficial group of the extensor muscles* of the forearm; it extends upwards to a much higher level than the medial border of the fossa. The *brachioradialis* is the most superficial of the muscles on the lateral side; it is thrown into contraction when the forearm—preferably in the semiprone position—is flexed

against resistance, and it then stands out as a prominent ridge, extending upwards beyond the level of the elbow-joint on the lateral side of the arm.

The line separating the flexors from the extensors on the back of the forearm is indicated by a longitudinal furrow, which is seen best when the elbow is fully flexed. This furrow corresponds to the *posterior border of the ulna* (fig. 1272), which is subcutaneous throughout its whole extent, from the subcutaneous surface of the olecranon above to the *styloid process* of the ulna below. The large fleshy mass on the medial side of the furrow is produced by the *flexor digitorum profundus,* covered with the aponeurosis which binds the flexor carpi ulnaris to the posterior border of the ulna. The fleshy mass on the lateral side of the furrow is produced by the *extensor carpi ulnaris, extensor digiti minimi, extensor digitorum* and the *radial extensors of the wrist,* in that order from the medial to the lateral side. The limits of the extensor carpi ulnaris can be determined during adduction of the hand, and those of the extensor digiti minimi, during extension of the little finger.

In the lower part of the forearm the fleshy bellies of the muscles merge into their tendons and the breadth of the forearm becomes diminished correspondingly (fig. 1272). An oblique elevation is visible on the lateral part of the dorsal aspect at the junction of the lower fourth with the rest of the forearm. It

FIG. 1272.—The back of the right upper limb.



becomes more conspicuous when the thumb is extended, as it is produced by the *extensor pollicis brevis* and the *abductor pollicis longus,* which come to the surface in the interval between the extensor carpi radialis brevis and the extensor digitorum, where the fleshy bellies of these muscles merge into their tendons. Although the bodies of the radius and ulna—apart from the posterior border of the latter—can only be felt indistinctly, their lower ends form landmarks which are both visible and palpable. The expanded *lower end of the radius* forms a slight surface elevation on the lateral side of the wrist, about 1 cm. above the base of the thenar eminence. Its lateral aspect is obscured by the tendons of the abductor pollicis longus and the extensor pollicis brevis, but, unless the thumb is actively extended, it can be traced downwards into the *styloid process.* The salient ridge which marks the anterior limit of the lateral aspect of the lower end of the radius is easily felt ; it gives attachment to the lateral end of the extensor retinaculum (dorsal carpal ligament). To its medial side, the *radial pulse* indicates the position of the radial artery at this level. The anterior border of the lower end of the radius projects forwards, and, despite the overlying tendons, can be felt as a transverse ridge, which lies nearly 2 cm. above the base of the thenar eminence. The posterior aspect of the lower end of the radius is also partly obscured by tendons, but can be palpated without difficulty. It presents a more or less well-marked *tubercle,* which is grooved obliquely by the extensor pollicis longus tendon and separates the groove for the extensor carpi radialis brevis from the groove for the extensor digitorum and the extensor indicis. This tubercle lies in line with the cleft between the index and the middle fingers.

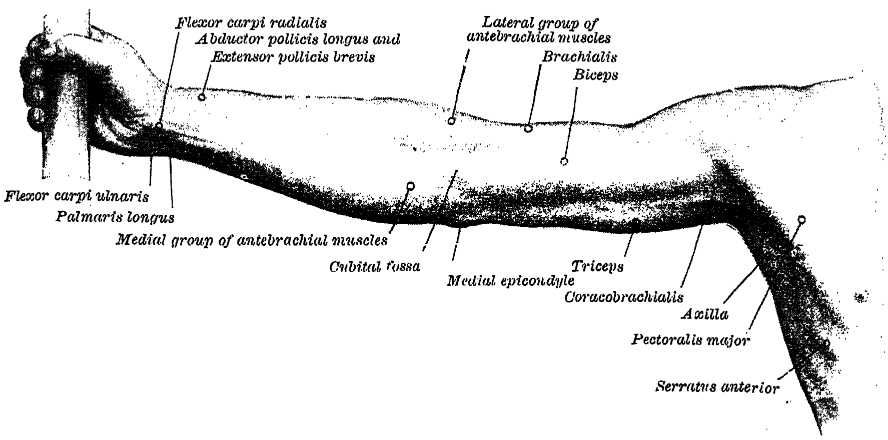
The rounded *head of the ulna* (fig. 1272) forms a surface elevation on the medial part of the posterior aspect of the wrist, when the hand is pronated ; and can be gripped between the finger and thumb, when the supinated hand

is flexed passively. The *styloid process of the ulna* projects downwards from the posteromedial aspect of the head of the bone. It lies at a higher level, and on a more posterior plane, than the *styloid process of the radius*. The relative positions of these two bony points can be determined satisfactorily, if the wrist is grasped firmly between the finger and thumb and pressure is exercised in an upward direction.

When the wrist is flexed against resistance, two tendons stand out prominently on its anterior aspect; the more lateral is the *flexor carpi radialis* and the more medial is the *palmaris longus* (fig. 1273), which lies approximately in the middle line of the limb. On the ulnar side the tendon of the *flexor carpi ulnaris* can be identified, and between it and the palmaris longus the flexor tendons for the little and ring fingers can be felt indistinctly.

When the thumb is extended, an intertendinous depression, known as the 'anatomical snuff-box,' is seen on the lateral aspect of the wrist just below the prominence caused by the lower end of the radius. It is bounded in front by the tendons of the *abductor pollicis longus* and the *extensor pollicis brevis*, which lie close to each other, and behind by the tendon of the *extensor pollicis longus*,

FIG. 1273.—The front of the right upper limb.



which stands out conspicuously. The tendons of the *radial extensors of the wrist* can be identified on the back of the carpus most easily when the fist is alternately clenched and relaxed; the extensor carpi radialis longus tendon is partly obscured by the extensor pollicis longus, but the tendon of the extensor carpi radialis brevis, which is situated more medially, can be felt without difficulty.

The *bones of the carpus* are, for the most part, obscured by the flexor tendons, the flexor retinaculum (transverse carpal ligament), and the muscles of the thenar and hypothenar eminences. Certain of them, however, can be palpated and identified. The *pisiform bone* forms an elevation which can be seen and felt on the palmar aspect of the wrist at the medial part of the base of the hypothenar eminence; it can be moved over the articular surface of the triquetral bone, when the wrist is kept passively flexed. The *hook of the hamate bone* can be identified, although it is not so prominent; it lies 2·5 cm. below the pisiform bone and is in line with the ulnar border of the ring finger. On deep pressure in this situation, the superficial division of the ulnar nerve can be rolled from side to side over the tip of the hook. The *tubercle of the scaphoid* bone is situated at the base of the thenar eminence and is crossed by the tendon of the flexor carpi radialis, by which it is partly hidden. In many subjects it forms a small elevation on the surface. Immediately beyond it, but covered with the muscles of the thenar eminence, the *crest of the trapezium* may be recognised, when deep pressure is exercised.

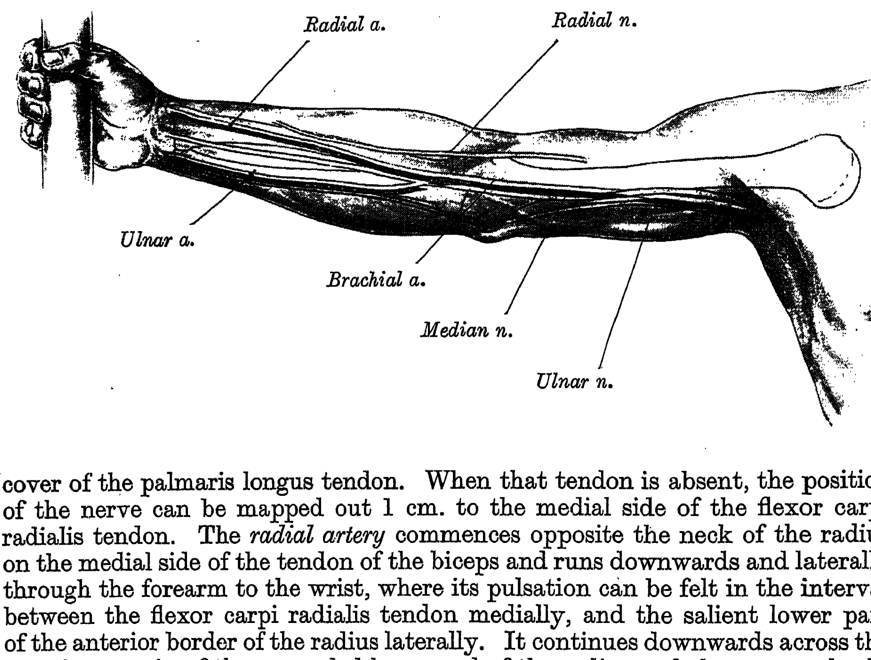
On the medial side and front of the forearm the skin is thin and smooth, and contains few hairs but many sweat glands; on the lateral side and

back of the forearm it is thicker, and contains more hairs but fewer sweat glands.

Surface relations of other structures.—The *ulnar nerve* in the forearm corresponds to a line drawn from the base of the medial epicondyle of the humerus to the lateral edge of the pisiform bone ; in the lower part of the forearm this line lies along the lateral side of the flexor carpi ulnaris tendon. The *ulnar artery* commences in the middle line of the limb, opposite the neck of the radius, and can be represented in the upper, and deepest, part of its course by a line which passes downwards and medially, across the elevation produced by the superficial flexor muscles of the forearm, to reach the lateral side of the ulnar nerve at the junction of the upper third with the lower two-thirds of the forearm. In the rest of its course in the forearm the ulnar artery lies along the lateral side of the ulnar nerve.

The *median nerve* enters the forearm on the medial side of the termination of the brachial artery (fig. 1274) and runs vertically downwards, approximately in the middle line of the limb. At the wrist it projects laterally from under

Fig. 1274.—The front of the right upper limb, showing the surface markings for the bones, arteries, and nerves.

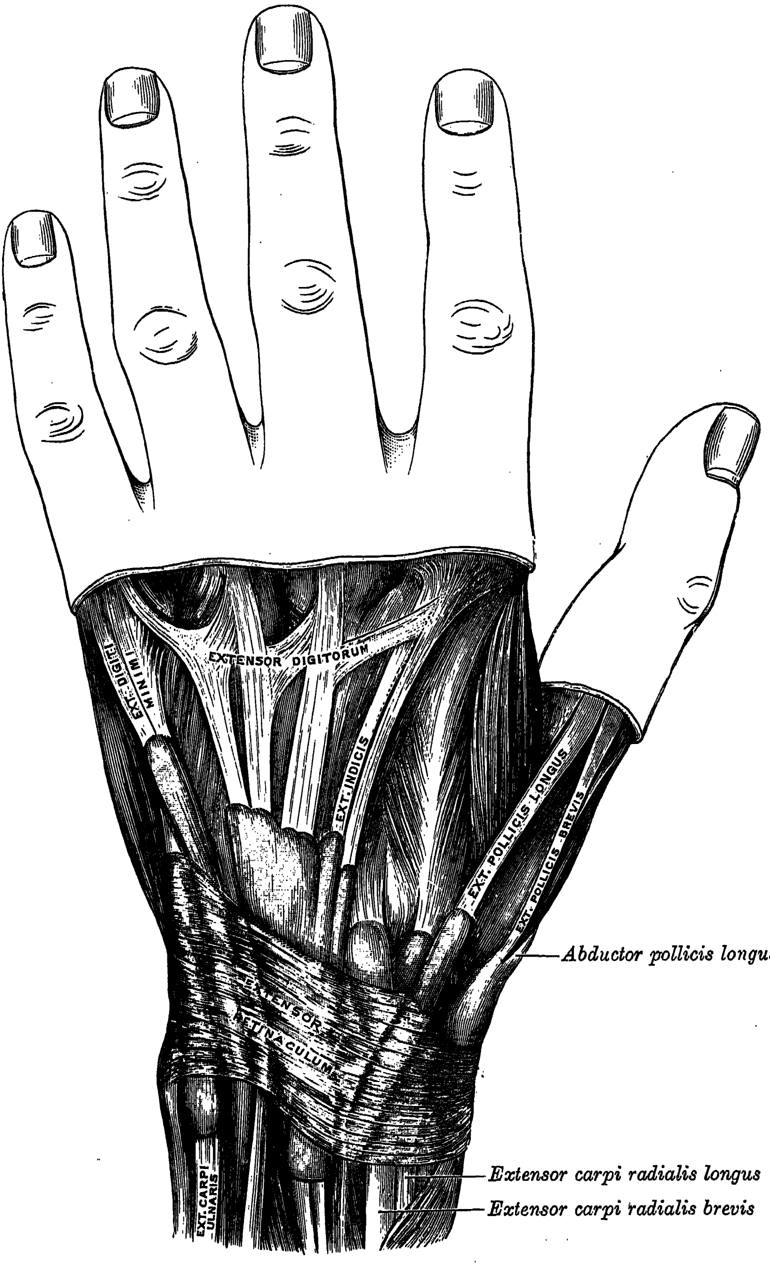


cover of the palmaris longus tendon. When that tendon is absent, the position of the nerve can be mapped out 1 cm. to the medial side of the flexor carpi radialis tendon. The *radial artery* commences opposite the neck of the radius on the medial side of the tendon of the biceps and runs downwards and laterally through the forearm to the wrist, where its pulsation can be felt in the interval between the flexor carpi radialis tendon medially, and the salient lower part of the anterior border of the radius laterally. It continues downwards across the anterior margin of the expanded lower end of the radius and then passes backwards, deep to the abductor pollicis longus and extensor pollicis brevis tendons, to gain the ' anatomical snuff-box,' where again its pulsation can be felt. The upper part of the line which represents the radial artery runs downwards across the medial part of the elevation produced by the brachioradialis and the superficial group of extensor muscles on the front of the forearm.

The *radial nerve* (fig. 1274) gives off its posterior interosseous branch at the level of the lateral epicondyle, 1 cm. to the lateral side of the tendon of the biceps and then runs vertically downwards. In the middle third of the forearm it lies along the lateral side of the radial artery, but in the lower third it inclines backwards to reach the ' anatomical snuff-box.' The *posterior interosseous nerve* can be represented by a line which passes downwards and backwards (across the elevation formed by the brachioradialis and the superficial group of the extensor muscles of the forearm), to reach the junction of the upper and middle thirds of a line joining the middle of the posterior aspect of the head of the radius to the dorsal tubercle on the lower end of the same bone. The lower two-thirds of this line roughly correspond to the rest of the course of the nerve.

The *flexor retinaculum* (transverse carpal ligament) can be outlined in the proximal part of the *hand*. Its lower border, concave downwards, can be indicated on the surface by a curved line joining the hook of the hamate bone to the crest of the trapezium ; its upper border by a curved line, concave upwards,

FIG. 1275.—The synovial sheaths of the tendons on the back of the wrist. (From a preparation by J. C. B. Grant.)



joining the pisiform bone to the tubercle of the scaphoid. The *extensor retinaculum* (dorsal carpal ligament) forms an oblique band, about 2 cm. broad, across the lateral and posterior aspects of the wrist. At its lateral extremity it is attached to the salient, lower end of the anterior border of the radius, above the styloid process and in front of the abductor pollicis longus tendon ; at its medial extremity, it reaches the medial side of the carpus and the tip of the styloid

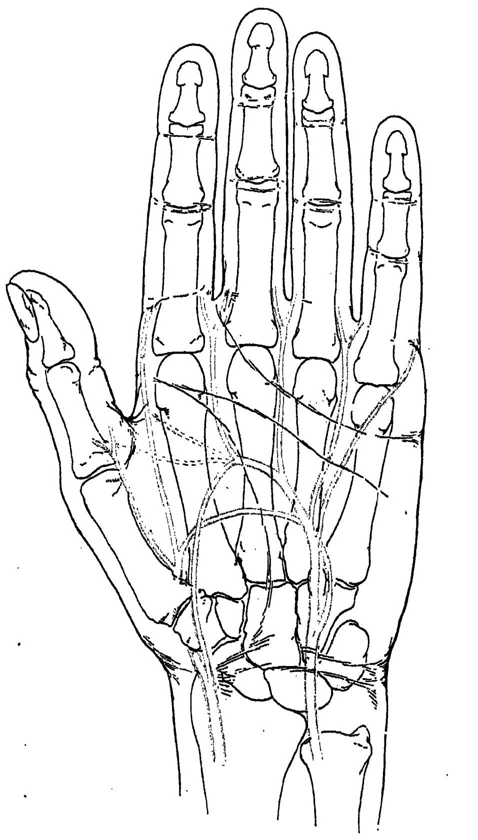
process of the ulna. The obliquity of the ligament, which is much higher on the lateral than it is on the medial side, is a very characteristic feature. The tendons which pierce or pass deep to the extensor retinaculum and their synovial sheaths are shown in fig. 1275.

The *line of the wrist joint* corresponds to a line, convex upwards, joining the styloid process of the radius to that of the ulna (Pl. VI, fig. 2).

The Hand

Surface landmarks.—The skin of the palm of the hand is marked by a number of creases, which, however, are of little value as points of reference. The *thenar eminence*, or *ball of the thumb*, is a fleshy elevation, produced by the abductor and the flexor pollicis brevis. The *hypothenar eminence* on the medial side of the palm is formed by the corresponding muscles of the little finger, but is not so prominent. Transverse skin creases cross the palmar aspects of the fingers in three situations; the most proximal crease is placed at the junction of the digit with the palm and lies nearly 2 cm. distal to the *metacarpophalangeal joint*; the intermediate crease lies opposite the *proximal interphalangeal joint*; and the distal crease is placed just *proximal* to the *distal interphalangeal joint*.

Fig. 1276.—The palm of the left hand, showing the positions of the skin creases and the bones, and the surface markings for the palmar arches.



The medial border of the hand is formed by the medial aspect of the hypothenar eminence, but the lateral border is formed by the dorsal aspect of the *metacarpal bone of the thumb*, which can be palpated throughout its whole extent (p. 363).

The lateral part of the dorsal aspect of the hand shows a fleshy elevation, which becomes more conspicuous when the thumb is adducted. It is caused by the *first dorsal interosseous muscle* and becomes firmly contracted when attempts are made to abduct the index finger actively against resistance.

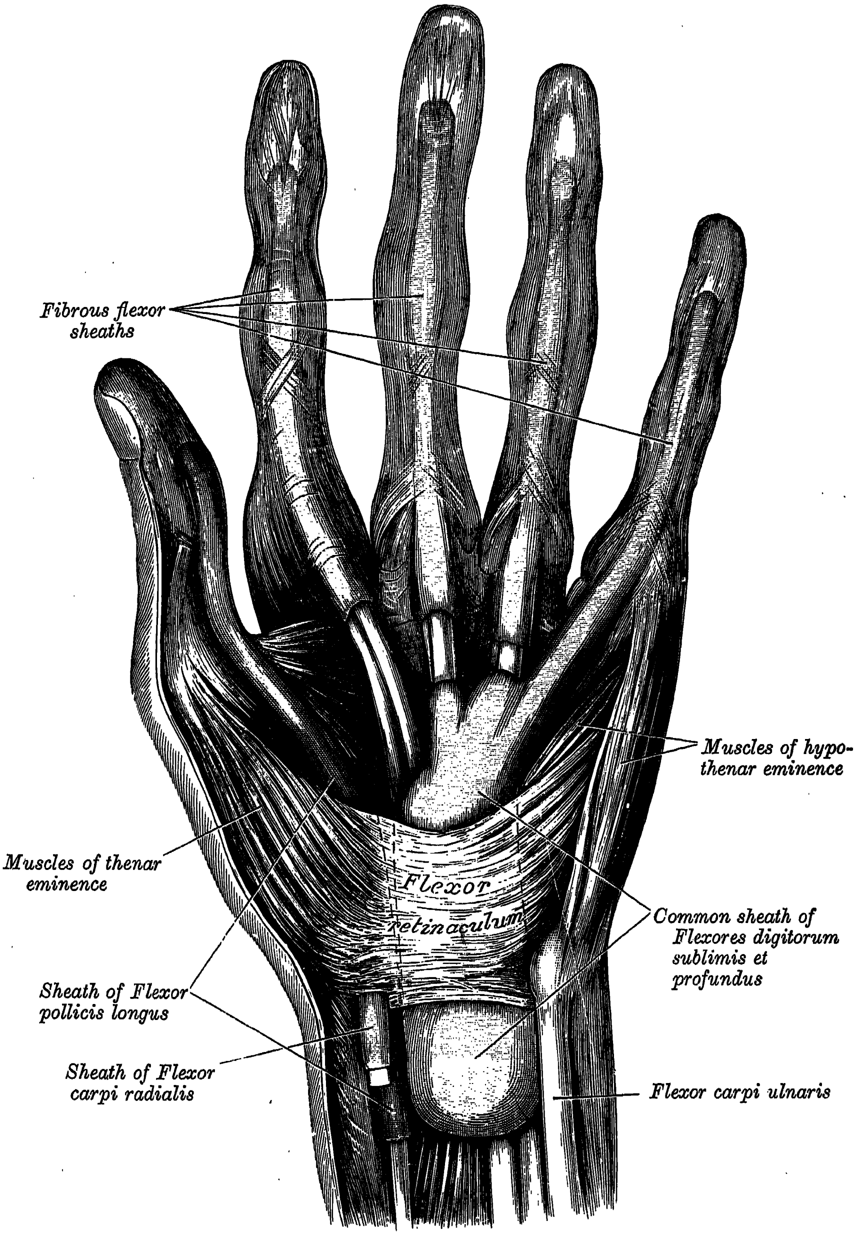
The *heads of the metacarpal bones* form the prominence of the knuckles, that of the middle finger being the most prominent. Their convex, palmar aspects can be felt on deep pressure over the fronts of the metacarpophalangeal joints and can be gripped between finger and thumb. On deep pressure over the distal aspect of the head of a metacarpal bone, the base of the corresponding proximal phalanx can be felt, and the line of the metacarpophalangeal joint can be determined on the back of the hand; its position must be noted both when the fingers are flexed and when they are extended. The dorsal aspects of the shafts of the metacarpal bones of the fingers can be felt indistinctly; only the distal portions of the third and fourth can be identified, because their proximal portions are obscured by the extensor tendons.

The *interphalangeal joints* can be felt on the dorsal aspect of the flexed finger,

just distal to the prominences caused by the heads of the proximal and middle phalanges.

The skin of the palm of the hand is tough and thick, and is covered with a thick layer of epidermis, but these characteristics are less marked on the thenar

FIG. 1277.—The synovial sheaths of the tendon on the front of the wrist and digits. (From a preparation by J. C. B. Grant.)



eminence. It is exceedingly sensitive and very vascular, but is devoid of hairs and sebaceous glands. Along the lines of the flexion creases of the digits, the skin is bound down by fibrous bands. The proximal segments of the fingers are joined to one another on the palmar aspect by folds of skin which constitute the 'web' of the fingers; these folds are placed opposite the centres of the proximal phalanges and their free margins are in line with the flexion creases at the roots of the fingers. Since the web is restricted to the palmar aspect, the fingers

appear shorter when viewed from in front than they do when viewed from behind. Over the fingers and thumb the skin is thinner, especially opposite the flexures of the joints, and over the distal phalanges ; it is disposed in numerous lines in consequence of the arrangement of the papillae which it contains. These lines form distinctive and permanent patterns, which can be used for purposes of identification. On the back of the hand and fingers, the skin is freely movable on the underlying parts.

Surface relations of other structures.—The *superficial palmar arch* is continuous with the ulnar artery opposite the lateral side of the pisiform bone. Its course can be marked out by a line drawn downwards in front of, or medial to, the hook of the hamate bone and then curved laterally, with a downward convexity, across the palm to the thenar eminence. The lowest part of its curve just reaches the level of the palmar surface of the extended thumb. The curvature of the vessel is subject to considerable variation, and it frequently forms the arc of a larger circle than it does in fig. 1276. The *deep palmar arch* can be represented by a horizontal line, 4 cm. long, drawn from a point just distal to the hook of the hamate bone ; it lies 1·2 cm. proximal to the superficial arch.

The *common synovial sheath of the flexor tendons of the digits* extends upwards into the forearm for 2·5 cm. above the flexor retinaculum (transverse carpal ligament) (fig. 1277). In this situation its medial border corresponds roughly to the lateral edge of the flexor carpi ulnaris tendon, and its lateral border to the medial edge of the flexor carpi radialis tendon. It becomes narrower as it passes behind the flexor retinaculum but it widens again in the palm. Its medial portion is continued distally along the lateral margin of the hypothenar eminence on the tendons for the little finger, but, with this exception, the common synovial sheath does not extend beyond the level of the palmar surface of the extended thumb. The *digital synovial sheaths* of the index, middle and ring fingers extend, in each case, from the base of the distal phalanx to the head of the corresponding metacarpal bone.

THE HEAD AND NECK

The Cranium

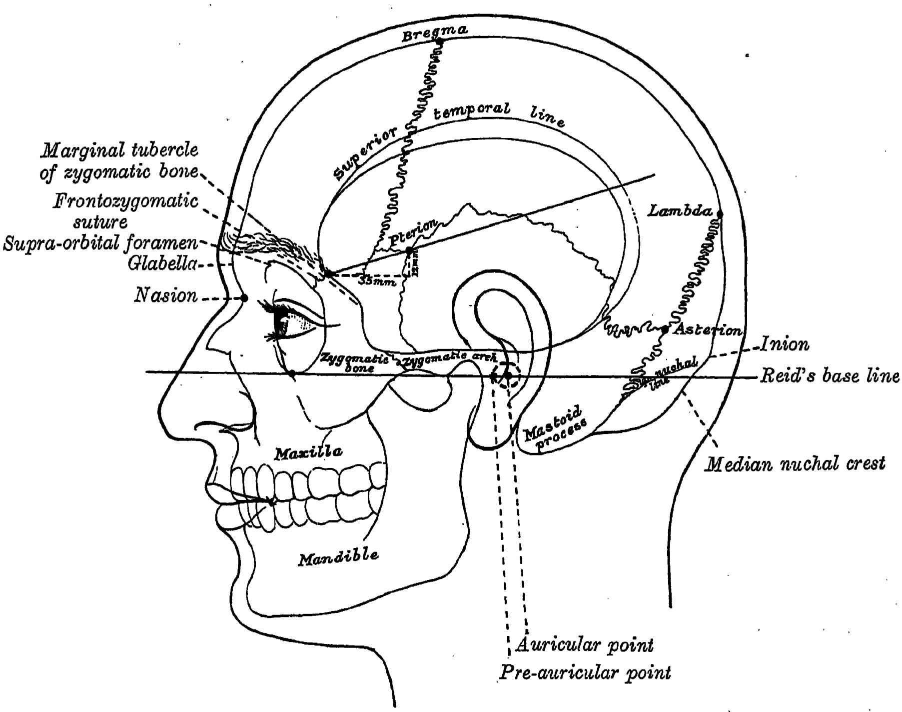
Surface landmarks (fig. 1278).—The *external occipital protuberance* is subcutaneous and can be felt at the upper end of the median *nuchal furrow,* which is plainly visible at the back of the neck ; it can be recognised without difficulty when it is approached from below. The *inion* is a point situated on the protuberance in the median plane. Above the protuberance the skull presents a backward convexity and the point of greatest curvature is named the *maximum occipital point.* Above and in front of the maximum occipital point an irregular depression, which corresponds to the *lambda* (p. 328), can be felt in the median plane.

The area between the two eyebrows overlies a slight elevation on the frontal bone which is termed the *glabella.* Below this elevation a well-marked depression can be seen and felt at the root of the nose ; it overlies the frontonasal suture and is termed the *nasion* (fig. 1278). Traced laterally, the glabella becomes continuous with the *superciliary arch,* which is a rounded, bony ridge placed a short distance above, and parallel with, the supra-orbital margin. The *frontal eminence* lies above and lateral to the superciliary arch and, although its size is subject to considerable variation, it can be felt without much difficulty. The *supra-orbital margin* can be recognised along the line of the eyebrow. Rounded in its medial third, it becomes sharper in its lateral part and the junction between the two portions is marked by the *supra-orbital notch,* which can be felt, when present, 2·5 cm. from the median plane. The *lateral margin of the orbital opening* is a sharp edge, which can easily be felt and is formed by the frontal process of the zygomatic bone. The lateral surface of this process can be felt through the skin, and the *frontozygomatic suture* (fig. 1278) can be recognised as a slight, irregular depression at its upper end. The posterior border of the *zygomatic process of the frontal bone,* although partially obscured

by the attachment of the temporal fascia, can be traced upwards from the fronto-zygomatic suture into the *temporal line*, which curves upwards and backwards to become continuous with the superior of the two temporal lines on the parietal bone. Above and behind the auricle this line turns downwards and forwards to become continuous with the *supramastoid crest*. The *parietal eminence* lies above the posterior part of the superior temporal line and can be recognised most satisfactorily when the hand is placed flat on the side of the head. The line joining the two parietal eminences is the greatest transverse diameter of the head.

The *mastoid process* is hidden by the lobule and the lower part of the concha of the auricle. Its anterior border and lateral aspect can be palpated but its tip and posterior border are obscured by the attachment of the sternomastoid

FIG. 1278.—A side view of the head, showing the surface relations of the bones.



and splenius capitis muscles. At its base, about 3 cm. to 4 cm. above its tip, the *supramastoid crest* can be felt and traced upwards and backwards into the superior temporal line.

Immediately in front of the upper part of the tragus the *superficial temporal artery* crosses the posterior root of the zygoma at the *pre-auricular point*, and its pulsation can be felt in this situation. Just in front of the pre-auricular point the two *roots of the zygoma* unite and the arch can be traced forwards to the prominence of the cheek bone; its upper border is obscured by the temporal fascia, and its lower border, by the masseter muscle. The posterior root of the zygoma is continuous with the supramastoid crest, but the continuity is hidden by the auricle. The upper border of the zygomatic arch can be traced forwards till it meets the frontal process of the zygomatic bone at the *jugal point* (p. 329).

If the hand is placed flat on the side of the head, the contraction of the temporal muscle can be appreciated when the teeth are clenched. Owing to the dense, unyielding character of the temporal fascia, the muscular elevation is limited to the region immediately within the superior temporal line.

Although the *pterion* (p. 251) does not form a visible or a palpable landmark, it is convenient at this stage to indicate that its centre corresponds to a

point, approximately 3·5 cm. or less behind, and 1·5 cm. above, the fronto-zygomatic suture (fig. 1278).

The skin of the scalp is intimately connected to the underlying epicranial aponeurosis by numerous fibres, an arrangement which makes it impossible to pick up a fold of the skin in this situation between the fingers and thumb. It can however be moved about with the epicranial aponeurosis on the skull, as the subaponeurotic layer of the scalp is loose in texture.

Surface relations of the Brain.—The *superomedial margin of the cerebral hemisphere* corresponds to a paramedian line drawn from a point a little above and a little lateral to the inion forwards to a point just above and lateral to the nasion. The *superciliary margin* of the hemisphere can be represented by a line which arches upwards and laterally a little above the eyebrow, commencing at the anterior end of the superomedial margin and reaching the zygomatic process of the frontal bone ; from the latter point the line of the margin ascends to the pterion. The *temporal pole* lies opposite to a line drawn, with a forward convexity, from the pterion to the middle of the upper border of the zygomatic arch. The *inferolateral margin* of the cerebral hemisphere corresponds to a line drawn backwards from the lower limit of the temporal pole just above the upper border of the zygomatic arch to cross the auricle a little above the external auditory meatus (fig. 1279). It then descends slightly to reach the posterior end of the superomedial margin.

The *central sulcus* can be represented by a line which commences on the superomedial margin of the hemisphere, 1·2 cm. behind its mid-point (or 1·2 cm. behind the mid-point of the line which joins the nasion to the inion in the median plane). From there it runs, with a somewhat sinuous course, downwards, forwards and laterally, making an angle of 70° with the median plane, and terminates 5 cm. vertically above the pre-auricular point. The *motor area* of the cortex occupies a strip, 1 cm. broad, in front of the central sulcus, and the somaesthetic area, a similar strip behind it.

The *lateral sulcus* ends opposite to the pterion by dividing into its three rami. Its *posterior ramus* (fig. 1279) can be represented by a line drawn backwards with an upward inclination from the pterion ; it passes just below the lower end of the central sulcus and, about 7 cm. from the pterion, turns upwards to end under the parietal eminence. The *superior temporal sulcus* lies about 1 cm. below the posterior ramus of the lateral sulcus and exhibits a similar curve. The *higher auditory centre* lies in the area between these two sulci, immediately behind the lower end of the central sulcus. The anterior and middle parts of the *inferior parietal lobule* (supramarginal and angular gyri) lie under the parietal eminence and surround the upturned ends of the posterior ramus of the lateral sulcus and the superior temporal sulcus respectively. The *higher visual centre* is situated partly on the lateral surface of the hemisphere, immediately in front of the occipital pole, but the larger part of the area lies on the medial surface.

The *inferior cornu of the lateral ventricle* lies immediately below the line which represents the superior temporal sulcus. A needle, introduced at a trephine hole the centre of which is 3 cm. behind and 3 cm. above the middle of the external auditory meatus, and passed in the direction of the tip of the opposite auricle, enters the inferior cornu at a distance of 5 cm. from the surface. In X-ray photographs of the skull, when air has been injected into the ventricles, the uppermost part of the helix rises just above the floor of the inferior cornu, the anterior end of which lies about 2 cm. vertically above the pre-auricular point. The *cerebellum* occupies the area immediately below the line of the transverse sinus (*vide infra*).

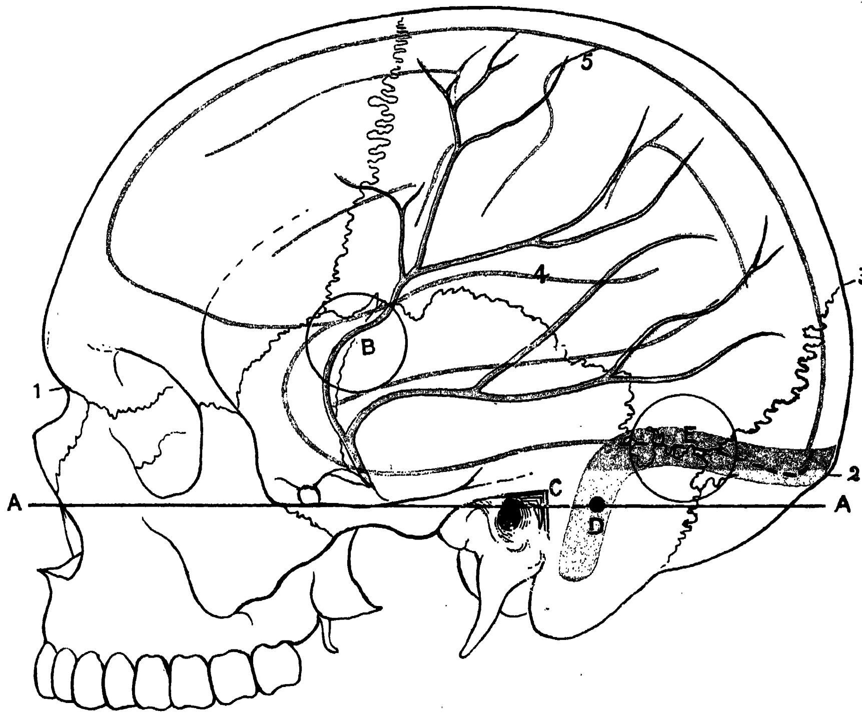
Surface relations of other structures.—The *superior sagittal sinus* commences at the glabella and can be represented by a line drawn upwards and backwards in the median plane and continued downwards, posteriorly, to the inion. Narrow in front, the line widens as it passes backwards until, near its termination, it may be 1·2 cm. broad. The *transverse sinus* (fig. 1279) commences at the inion and runs laterally, with a slight upward convexity, along the infero-lateral margin of the cerebral hemisphere. Opposite the base of the mastoid process it becomes the *sigmoid sinus*, which passes downwards close to the posterior border of the process to a point 1·2 cm. from its tip.

The lines which represent the edges of these sinuses should be at least 1·2 cm. apart.

The *middle meningeal artery* (fig. 1279) enters the skull opposite a point a little in front of the pre-auricular point and can be represented by a line drawn forwards and slightly upwards to a second point, 2 cm. above the middle of the zygomatic arch. There the artery divides and its *anterior division* runs upwards and slightly forwards to the pterion and then upwards and backwards (fig. 1279) in the direction of the mid-point between the inion and the nasion. The *posterior division* runs backwards and upwards towards the lambda.

The *trigeminal* (semilunar) *ganglion* lies at a distance of 4·5 cm. to 5 cm. from the lateral aspect of the head, a little in front of the pre-auricular point. The

FIG. 1279.—The relations of the brain and the middle meningeal artery to the surface of the skull.



1. Nasion. 2. Inion. 3. Lambda. 4. Lateral cerebral sulcus. 5. Central sulcus. AA. Reid's base-line, which passes through the lower margin of the orbital opening and the upper margin of the external auditory meatus. B. Point for trephining over the transverse sinus, exposing dura mater of both cerebrum and cerebellum. The outline of the cerebral hemisphere is indicated in blue; the course of middle meningeal artery in red.

cavernous sinus lies close to the medial side of the ganglion but extends beyond it both in an upward and in a forward direction.

The *hypophyseal fossa* is traversed by a straight line joining the nasion to the inion at a depth of 6 cm. to 7 cm. from the nasion (Pl. I, fig. 1).

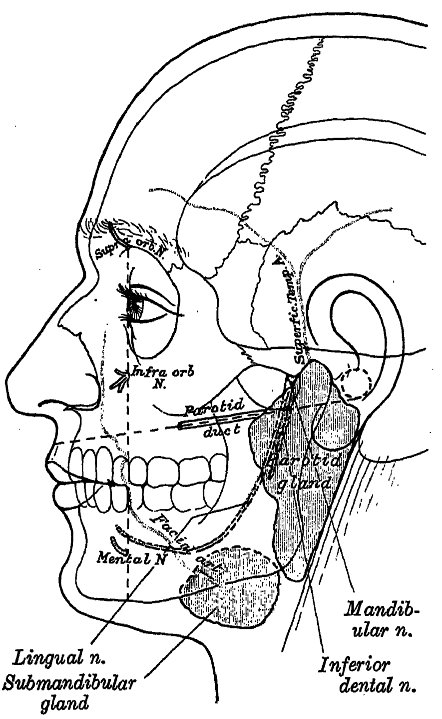
THE FACE

Surface landmarks.—The *bridge of the nose* is formed by the articulation between the two nasal bones; it ends above at the nasion, which is often termed the root of the nose. The margins of the bony *anterior nasal aperture* can be felt through the skin above the bulging ala nasi. Sharp and distinct laterally, the margin is rounded inferiorly, but, in the median plane, the *anterior nasal spine* can be recognised on upward pressure over the posterior portion of the free part of the nasal septum.

The prominence of the cheek, which lies below and lateral to the eye, is formed by the *zygomatic bone* (fig. 1280). The lateral surface of the bone can readily be felt through the skin ; it can be traced upwards into the frontal process, backwards into the zygomatic arch and forwards into the zygomatic process of the maxilla. The postero-inferior border of the bone is obscured by the masseter muscle when the teeth are clenched, but it can be determined when the muscle is relaxed and can be traced into continuity with the lower border of the zygomatic process of the maxilla, which can be felt without difficulty above the crown of the first upper molar tooth. The *infra-orbital margin* can be examined both in its lateral, zygomatic, and in its medial, maxillary portion. Below the orbit, the anterior surface and the alveolar process of the maxilla can be recognised.

Almost the whole of the outer surface of the *mandible* can be felt through the skin, although the coronoid process is hidden by the zygomatic bone and most of the ramus is covered with the masseter muscle. The *angle* can be identified below and in front of the lobule of the auricle and can be traced upwards into the posterior border of the ramus and forwards into the lower border of the body of the bone. The outer aspect of the *body* can be palpated throughout the whole of its extent and the projection of the mental protuberance is easily identified. The *condyloid process* lies immediately in front of the lower part of the tragus (fig. 1280) ; it is partly obscured by the parotid gland and the temporomandibular ligament, but it can be felt to pass forwards and downwards when the mouth is opened. The *masseter muscle* covers most of the ramus : its posterior border corresponds to a line drawn from the lower border of the zygomatic arch, just in front of the condyle, to the angle of the mandible ; its anterior border, to a line drawn downwards and backwards from the postero-inferior border of the zygomatic bone, vertically below the lateral margin of the orbit, to a point on the lower border of the mandible, 2·5 cm. in front of the angle. The outline of the muscle can be determined when the teeth are clenched, and the *parotid duct* can be rolled across its anterior border a little below the zygomatic bone. The *coronoid process* of the mandible is not easy to examine, although the lower part of its anterior border can readily be felt through the inside of the mouth. If a finger tip is placed in the angle between the masseter muscle and the zygomatic bone the anterior border of the coronoid process can be felt indistinctly when the mouth is opened.

FIG. 1280.—An outline of the side of the face, showing the chief surface markings.



The *oral fissure* lies opposite the cutting edges of the upper incisor teeth, and the *angle of the mouth* lies just in front of the first premolar tooth.

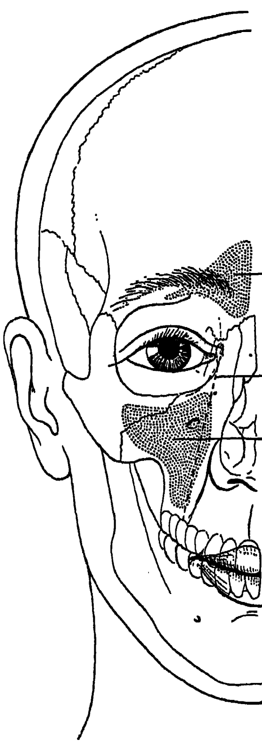
The pulsation of the *facial artery* can be felt immediately in front of the lower end of the anterior border of the masseter muscle (fig. 1280), and again opposite the angle of the mouth. In the latter situation the cheek must be gripped lightly between a finger placed inside the mouth and the thumb placed on the skin surface ; the artery will be identified 1·2 cm. or more from the angle of the mouth. When the lateral part of the lip is gripped in a similar manner, the pulsation of the corresponding *labial artery* can be felt from the mucous surface at a distance of 0·5 cm. from its free margin.

The skin of the face is thin and freely movable, except over the alæ and apex of the nose, where it is thicker and firmly adherent to the deeper tissues.

The surface anatomy of the mouth (pp. 1262 and 1284), the eye (p. 1184) and the ear (pp. 1190 and 1196) have already been described.

Surface relations of other structures.—The *parotid gland* (fig. 1280) occupies the depression behind the ramus of the mandible and extends forwards on to the masseter muscle. Its anterior border can be represented by a line drawn downwards and forwards from the upper border of the mandibular condyle to a point a little above the centre of the masseter muscle, and then downwards and backwards to a point a little behind and a little below the angle of the mandible. Its upper border lies below the external auditory meatus and is concave upwards and backwards ; it corresponds to a curved line drawn downwards and backwards from the upper border of the condyle, across the lobule of the auricle, to the mastoid process. Its posterior border follows a straight line joining the ends of its upper and anterior borders. The *parotid duct* (p. 1442) may be represented by rather less than the middle third of a line drawn from the lower border of the concha to midway between the ala of the nose and the red margin of the upper lip ; its terminal part runs almost horizontally medially and opens into the vestibule of the mouth on a small papilla opposite to the second upper molar tooth.

Fig. 1281.—An outline of the bones of the face, showing the positions of the frontal and maxillary sinuses.



The *facial nerve* enters the parotid gland as soon as it emerges from the stylomastoid foramen, which lies about 2 cm. deep to the middle of the anterior border of the mastoid process. In the gland it runs laterally and forwards and in this part of its course it can be indicated by a short horizontal line drawn on the upper part of the lobule of the auricle (fig. 1284). Its zygomatic and buccal branches pass forwards across the neck of the mandible.

The *facial artery* (fig. 1280) enters the face at the lower part of the anterior border of the masseter muscle (p. 1442). It corresponds to a line drawn from this point upwards and forwards to a point 1·2 cm. lateral to the angle of the mouth, and thence upwards to the medial angle of the eye, curving forwards almost to the ala of the nose. The *anterior facial vein* can be represented by a line drawn downwards and backwards from the medial angle of the eye to the lower part of the anterior border of the masseter muscle, just behind the facial artery.

The *mandibular notch* can be represented by a line, concave upwards, which commences at the front of the condyloid process and curves forwards to the anterior part of the zygomatic arch (fig. 1280). It is about 1·2 cm. deep and is concealed by the masseter muscle. The *mandibular nerve*, as it descends from the foramen ovale, lies opposite the posterior part of the mandibular notch at a distance of 4 cm. from the surface. The *auriculotemporal nerve* corresponds to a line drawn backwards from the mandibular nerve across the neck of the mandible and then upwards across the pre-auricular point behind the superficial temporal artery. The *inferior dental nerve* corresponds to a line drawn from the mandibular nerve to the centre of the masseter muscle. Its terminal, *mental*, branch emerges from the *mental foramen*, which lies midway between the upper and

lower borders of the mandible, in the adult, and vertically below the interval between the premolar teeth. The *lingual nerve* (fig. 1280) lies deep to the mandible in its whole course, and can be represented by a line drawn downwards and forwards from the mandibular nerve to a point a little below and behind the last molar tooth. With a finger placed inside the mouth the nerve can be pressed against the bone in this situation. Thence the line is continued forwards, with an upward concavity, along the body of the mandible.

Where the *maxillary nerve* crosses the pterygopalatine fossa, it lies about 5 cm. deep to the surface, opposite to, or just behind, the jugal point (p. 1439). Continuing forwards, it emerges, as the *infra-orbital nerve*, from the *infra-orbital foramen*, which lies vertically below the supra-orbital notch and 1 cm. below the lower margin of the opening of the orbit.

The cutaneous distribution of the divisions of the trigeminal nerve on the face and scalp is shown in fig. 949.

The *pharyngotympanic tube* (auditory tube), which lies deep to the mandibular nerve, is situated opposite to the posterior part of the mandibular notch, at a distance of 4·5 cm. from the surface.

The *tonsil* lies behind the third molar tooth and can be represented as an oval area over the lower part of the masseter muscle, i.e. just above and in front of the angle of the mandible (fig. 1284).

The *frontal sinus* (p. 1162) can be represented on the surface as a triangular area above and lateral to the root of the nose (fig. 1281). The angles of the triangle are formed by (1) the nasion, (2) a point 2·5 cm. above the nasion and (3) the junction of the medial third with the rest of the supraorbital margin. The *maxillary sinus* (p. 1163) extends upwards to the floor of the orbit, and the infra-orbital margin may be taken to represent its roof. Its inferior limit corresponds to a line drawn across the alveolus of the maxilla, opposite the second premolar and the molar teeth, on a level with the lower border of the ala of the nose (fig. 1281).

The Neck

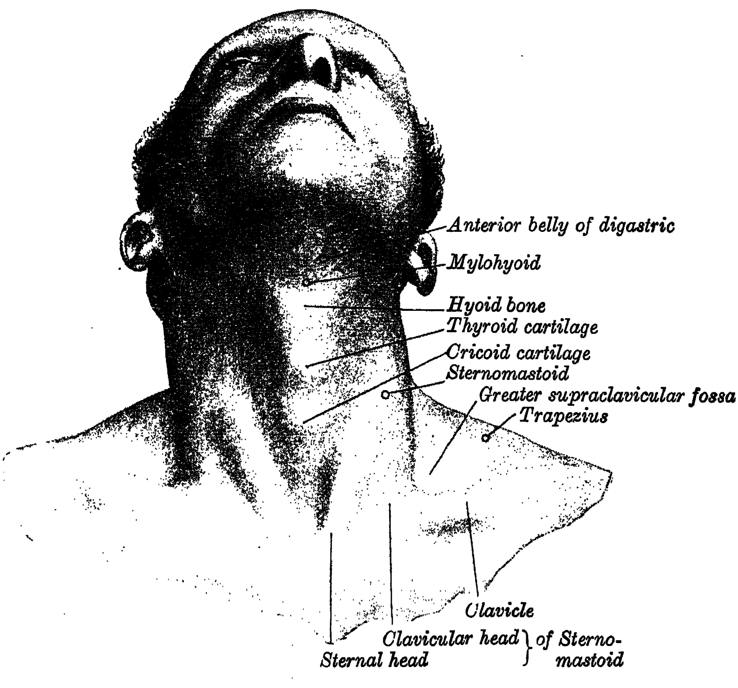
Surface landmarks.—The *sternomastoid muscle* (figs. 1282, 1283) forms a prominent, visible landmark, which intervenes between the regions of the anterior and posterior triangles of the neck. When the head is rotated to one side and tilted forwards, the muscle of the opposite side is rendered tense. Below, the sternal head stands out as a clean-cut cord crossing the sternoclavicular joint, but the clavicular head, which extends for one-third of the way along the clavicle, is not so prominent. The anterior border, which is thick and rounded, extends upwards from the sternal head to the anterior border of the mastoid process ; the posterior border, which is difficult to feel, ascends from the junction of the medial and middle thirds of the clavicle to the mid-point between the mastoid process and the inion. Inferiorly the sternal heads are separated by the *suprasternal notch*, a surface depression limited below by the upper border of the manubrium sterni and, on each side, by the prominent *sternal end of the clavicle.*

In the median plane the *laryngeal prominence* (fig. 1284), or Adam's apple, can be felt easily, and can be seen in men although it may not always be visible in women. The anterior portions of the upper borders of the two thyroid laminæ can be palpated and the thyroid notch can be identified. Above the thyroid cartilage the skin is drawn backwards below the chin to the *hyoid bone*, the body of which can be felt above and behind the laryngeal prominence. When the throat is gripped between the finger and thumb, just above the thyroid cartilage, and the opposing digits are moved upwards and downwards, the *greater cornu* of the hyoid bone can be recognised and traced backwards to its tip. Below the thyroid cartilage in the median plane the *arch of the cricoid cartilage* can be felt ; it is on a level with the lower part of the *cricoid lamina*, which lies opposite the body of the sixth cervical vertebra. The depression between the arch of the cricoid and the thyroid prominence corresponds to the cricothyroid ligament. Below the arch of the cricoid the upper rings of the trachea can be made out, but they are partly obscured by the isthmus of the thyroid gland.

When the finger tips are placed on the anterior border of the sternomastoid muscle below the level of the laryngeal prominence, the pulsation of the *common carotid artery* can be appreciated, especially if pressure is exerted backwards and laterally. Above the level of the laryngeal prominence and below the angle of the mandible no difficulty is experienced in feeling the pulsation of the *external carotid artery,* which tends to emerge from under cover of the muscle in this part of its course.

Approximately midway between the tip of the mastoid process and the angle of the mandible, the tip of the *transverse process of the atlas* offers resistance to deep pressure through the parotid gland. The tips of the other cervical transverse processes are nearer to the median plane; with the exception of the sixth, they cannot be palpated. The *carotid tubercle* on the transverse process of the sixth cervical vertebra lies at the level of the arch of the cricoid cartilage,

FIG. 1282.—A front view of the neck.



about 3 cm. from the median plane. It lies behind the common carotid artery and the sternomastoid muscle, but it can often be recognised.

Behind the sternomastoid muscle the position of the *posterior triangle* of the neck may be indicated by a shallow depression (fig. 1284) which extends from the back of the head to the middle third of the clavicle and is always deepest in its lower part [greater supraclavicular fossa]. The anterior border of the *trapezius,* which forms its posterior boundary, can be seen in muscular subjects, especially when resistance is opposed to elevation of the shoulder. In the lower part of the triangle, the inferior belly of the *omohyoid muscle* can often be seen in thin subjects; it forms an oblique ridge, running medially, forwards and upwards, which appears and disappears, as the muscle contracts and relaxes during speech.

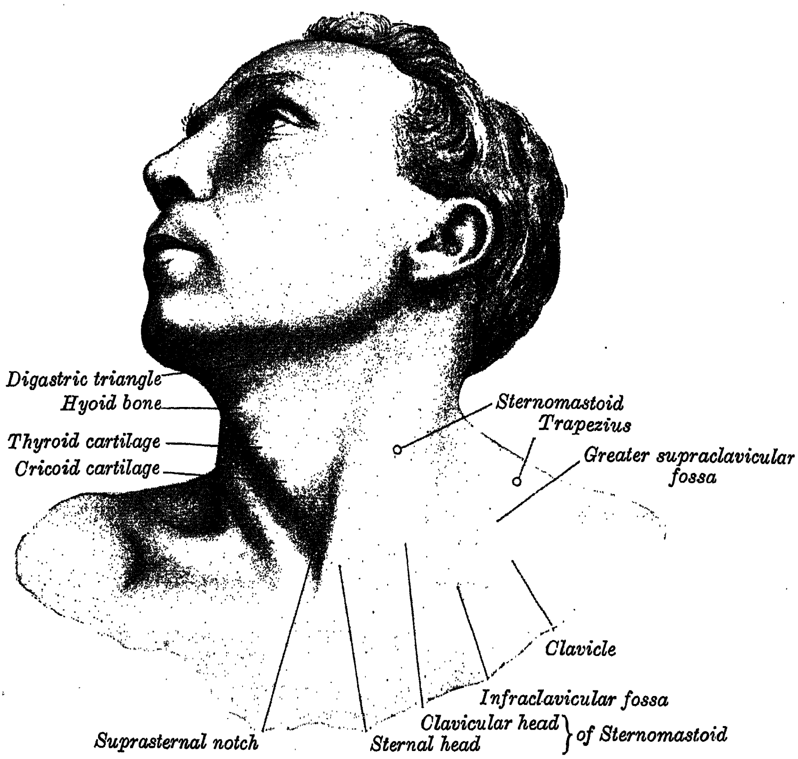
When the arm is by the side the trunks of the *brachial plexus* can be felt as a bunch of tense cords in the angle between the clavicle and the sternomastoid muscle. The *subclavian artery* is the only other important structure which can be identified in the posterior triangle of the neck. The pulsation of its terminal part can be recognised when pressure is exerted downwards behind the middle of the clavicle, and, in this situation, the artery can be compressed against the upper surface of the first rib.

At the back of the neck the nuchal furrow (p. 1438) overlies the tips of the *spines* of the cervical vertebræ. At its lower end the spine of the *seventh cervical vertebra* can be seen and can be identified from the fact that it is the highest, and sometimes the only, visible projection in this region. The spines of the other cervical vertebræ can be felt indistinctly and that of the *axis* lies about 5 cm. below the inion (p. 1438). The muscular elevation on each side of the nuchal furrow is produced by the semispinalis capitis, covered with the splenius capitis (in part) and the trapezius.

The skin of the front and side of the neck is thin and easily moved about over the underlying structures. At the back of the neck it is thicker and less movable, being bound down by numerous fibres to the deeper tissues.

Surface relations of other structures.—The *common carotid artery* (fig. 1284) can be represented by a broad line drawn upwards and backwards from the

FIG. 1283.—An anterolateral view of the head and neck.



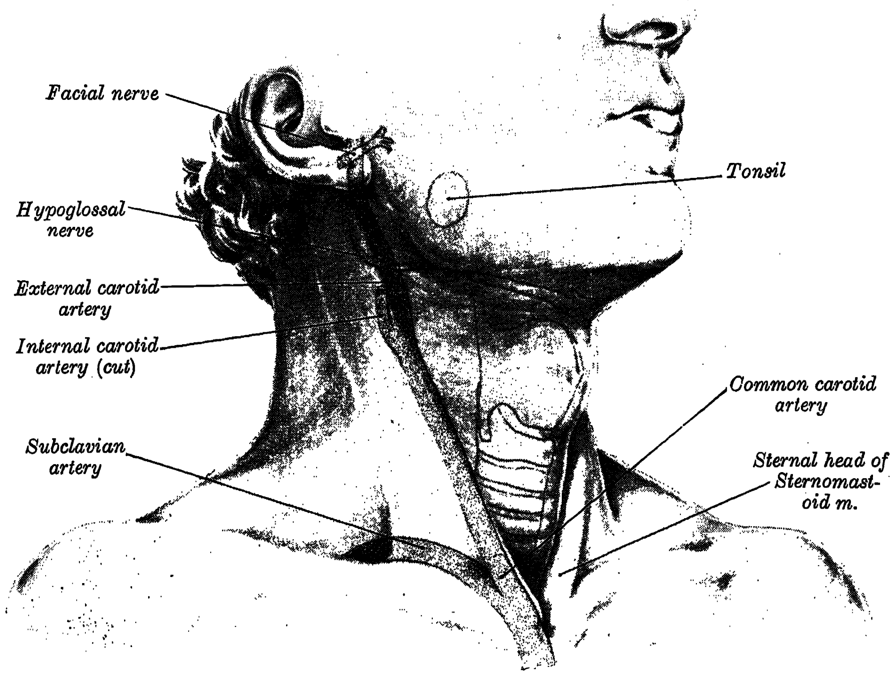
sternoclavicular joint, along the anterior border of the sternomastoid as far as the level of the upper border of the thyroid cartilage. From this point the *external carotid artery* ascends to a point midway between the tip of the mastoid process and the angle of the mandible. It should be represented by a broad line, which is gently convex forwards in its lower half and as gently concave forwards in its upper half. The origin of the *lingual artery* lies opposite the tip of the greater cornu of the hyoid bone, and its initial upward loop is crossed by the hypoglossal nerve. The *internal carotid artery* corresponds to a broad line drawn upwards from the termination of the common carotid artery to the posterior border of the condyle of the mandible.

The *internal jugular vein* (fig. 1285) can be represented by a broad line drawn downwards from the lobule of the ear to the medial end of the clavicle; its lower bulb lies behind the little depression [lesser supraclavicular fossa] which marks the interval between the sternal and the clavicular heads of the sternomastoid.

As the glossopharyngeal, vagus, accessory and hypoglossal nerves lie at the base of the skull, their position can be indicated opposite the lower and anterior

part of the tragus. The *glossopharyngeal nerve* corresponds to a line, drawn downwards and forwards from that point, passing above the angle of the mandible and then continuing forwards for a short distance along the lower border of the mandible. The *vagus nerve* can be represented by a line drawn downwards from the same point, along the medial side of the internal jugular vein, to the medial end of the clavicle. The *accessory nerve* (fig. 1285) corresponds to a line which passes downwards from the lower and anterior part of the tragus to the tip of the transverse process of the atlas. From the latter the line is continued downwards and backwards, across the elevation produced by the sternomastoid and the depression corresponding to the posterior triangle of the neck, to a point on the anterior border of the trapezius, 6 cm. above the clavicle. The *hypoglossal nerve* follows the same line as the vagus until it

FIG. 1284.—The surface relations of some of the important structures in the face and neck.



reaches a point a little above and a little behind the tip of the greater cornu of the hyoid bone. It then bends sharply forwards and curves upwards to a point approximately midway between the angle and the symphysis of the mandible when the head is tilted backwards.

The *external jugular vein* can be marked out by a line drawn downwards from a point a little below and behind the angle of the mandible to reach the clavicle just lateral to the posterior border of the sternomastoid. Behind the clavicle it joins the *subclavian vein*, which corresponds to a short but broad line, drawn along the clavicle from a little medial to its mid-point to the medial edge of the clavicular head of the sternomastoid (fig. 1285).

The *subclavian artery* (fig. 1284) can be represented by a broad line, convex upwards, drawn from the sternoclavicular joint to the middle of the lower border of the clavicle ; the summit of the curve lies 2 cm. above the clavicle.

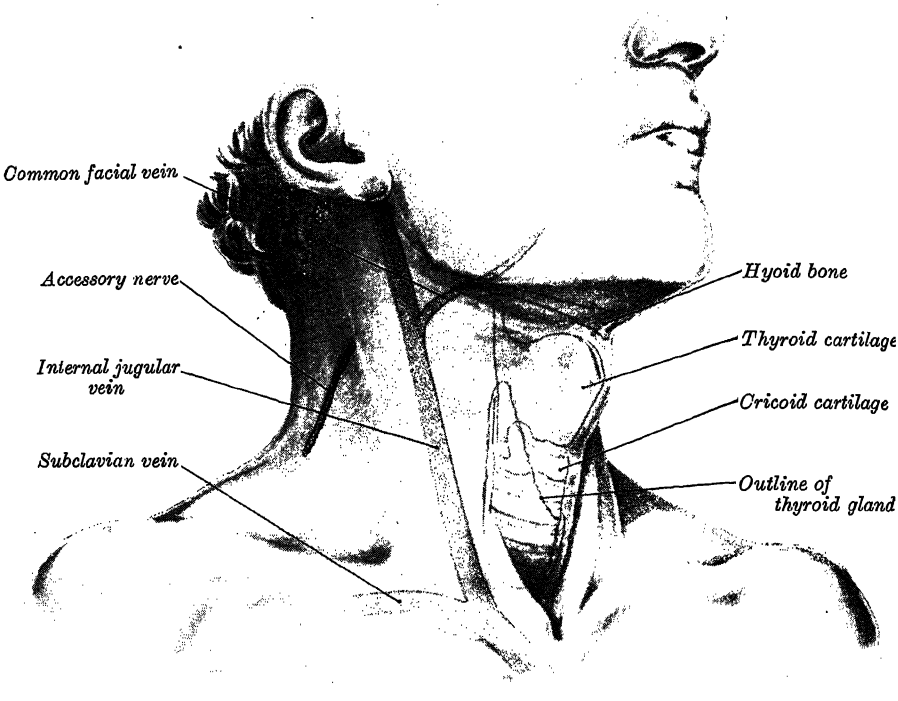
The *scalenus anterior* lies entirely behind the sternomastoid ; its lateral border corresponds to a line drawn from a point, at the level of the upper border of the thyroid cartilage and 2·5 cm. from the median plane, downwards and laterally to the lower border of the clavicle at the junction of its medial and

middle thirds ; its medial border, to a line drawn from a point, opposite the arch of the cricoid cartilage, 2·5 cm. from the median plane, downwards and laterally to a second point, 1 cm. medial to the lower end of the lateral border.

The *supraclavicular part of the brachial plexus* lies in the triangular area bounded by the upper border of the clavicle, the lateral border of the scalenus anterior and a line drawn from the arch of the cricoid cartilage to the middle of the clavicle.

The *submandibular salivary gland* (fig. 1280) can be represented on the surface as an oval area, lying partly above and partly below the posterior half of the lower border of the mandible. Its upper limit commences at the angle of the mandible and passes forwards with a gentle convexity upwards to reach a

FIG. 1285.—The side of the neck, showing some of the important surface landmarks and surface markings.



point midway between the angle and the symphysis ; it rarely extends upwards more than 1·5 cm. above the lower border of the bone. Its lower limit can be indicated by a line with a downward convexity, which reaches as low as the greater cornu of the hyoid bone.

The *thyroid gland* has such a characteristic shape that, when the position of the isthmus has been determined, there should be no difficulty about the outline of the lobes. The upper border of the isthmus corresponds to a line, 1·5 cm. long, drawn across the trachea, 1 cm. below the arch of the cricoid cartilage ; its lower border, to a similar line, 2 cm. lower down. The broad, lower pole of the lobe extends downwards for 1 cm. from the lateral end of the lower border of the isthmus and then laterally, with a downward convexity, for 2 cm. to 2·5 cm. The narrow, upper pole of the lobe lies on a level with the laryngeal prominence a little in front of the anterior border of the sternomastoid. Lines joining the upper pole to the lateral end of the upper border of the isthmus and to the lateral end of the lower pole complete the outline of the lobe of the gland (fig. 1285).

The level of the *vocal folds* can be indicated on the anterior border of the thyroid cartilage a little above its mid-point.

The *cervical plexus* lies behind the internal jugular vein above the level of the thyroid cartilage. Its cutaneous branches become superficial along the posterior border of the sternomastoid muscle. The *anterior cutaneous nerve of the neck* corresponds to a line drawn across the muscle from the mid-point on its posterior border. The *great auricular* and *lesser occipital nerves* appear at a slightly higher level; the former runs upwards towards the lobule of the auricle, while the latter ascends along the posterior border of the muscle to reach the scalp. The *descending cutaneous branches* emerge below the anterior cutaneous nerve and diverge as they run downwards. The *phrenic nerve* lies behind the sternomastoid and the internal jugular vein; it corresponds to a line drawn from a point, 3·5 cm. from the median plane and on a level with the upper border of the thyroid cartilage, downwards to the sternal end of the clavicle.

The *sympathetic trunk* can be represented by a line drawn from the sterno-clavicular joint to the posterior border of the condyle of the mandible. The *superior cervical ganglion* lies on this line, between the tip of the transverse process of the atlas vertebra and the greater cornu of the hyoid bone: the *middle cervical ganglion*, opposite, or just below, the arch of the cricoid cartilage: and the *inferior cervical ganglion*, about 3 cm. above the sterno-clavicular joint.

The *cervical pleura* (fig. 1291) rises above the clavicle and the sternal end of the first rib. It can be represented by a line, convex upwards, drawn from the sternoclavicular joint to the junction of the medial and middle thirds of the clavicle. The summit of the curve lies about 3·5 cm. above the clavicle. The same line represents the outline of the *apex of the lung*.

THE BACK

Surface landmarks.—A median furrow overlies the tips of the spines of the vertebræ; its upper or nuchal part has already been described (p. 1446). In the upper thoracic region the furrow is shallow, and elevations produced by the tips of the spines of the seventh cervical and first (and sometimes the second) thoracic vertebræ can be seen and felt. The identification of the remaining thoracic spines is not easy, even in a thin subject when the trunk is fully flexed, owing to the manner in which they overlap one another in the midthoracic region. The third thoracic spine lies opposite the root of the scapular spine (p. 1428) and the seventh lies opposite the inferior angle of the scapula, provided that the arm is at rest by the side. The twelfth thoracic spine lies opposite the mid-point of a line drawn from the inferior angle of the scapula to the iliac crest.*

The median furrow is deepest at the small of the back (fig. 1286), but it widens out below into a flattened, triangular area, the apex of which lies at the commencement of the natal cleft (p. 1469) and corresponds to the third sacral spine. The two basal angles of this triangular area are formed by two symmetrically placed dimples, which overlie the *posterior superior iliac spines*, and the line joining them passes through the *second sacral spine*. It should be observed that the posterior superior spine lies over the centre of the sacro-iliac joint.

On each side the median furrow is bounded by a broad elevation produced by the *sacrospinalis muscle* (fig. 1286). The lateral border of this elevation crosses the ribs at their angles, passing medially as it ascends. The identification of the upper ribs on the dorsal aspect is very difficult, but the *eighth rib*, which lies immediately below the inferior angle of the scapula, can be recognised with certainty. Below the eighth, the ninth, tenth and eleventh, and the twelfth when it projects beyond the sacrospinalis, can all be identified.

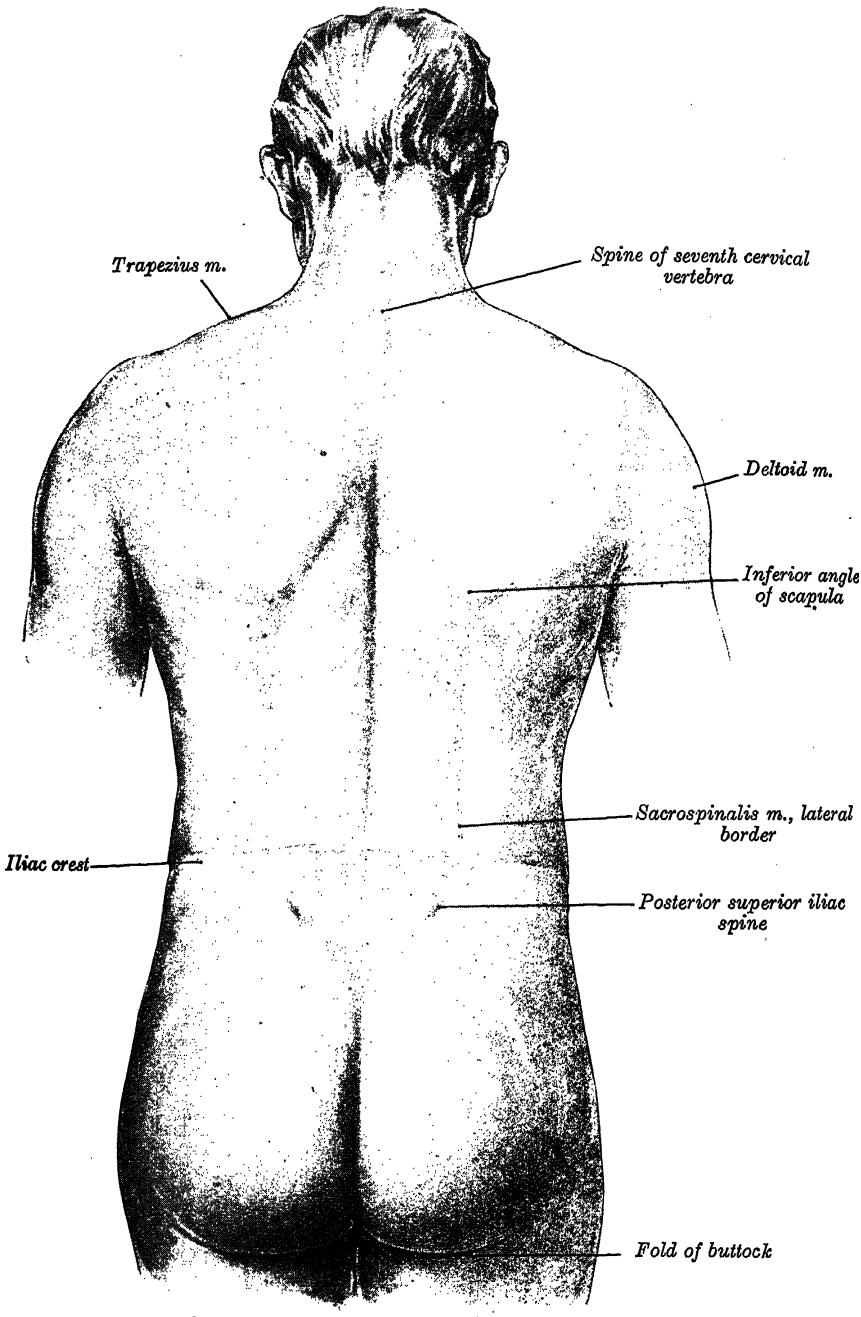
The surface landmarks of the *scapula* have been described on p. 1428.

At the lower part of the back the *iliac crest* can be palpated throughout its whole length, and can be traced backwards and upwards from the anterior

* Arthur Robinson and E. B. Jamieson, *Surface Anatomy*, London, 1928.

superior spine (p. 1465) to its *highest point*, which lies behind the mid-point of the crest and opposite the interval between the spines of the third and fourth lumbar vertebræ. From these the crest can be traced downwards and medially

FIG. 1286.—The surface anatomy of the back.



to the posterior superior iliac spine (p. 1449), which lies 5 cm. from the median plane. The *tubercle* of the crest lies 5 cm. or more behind the anterior superior spine, at the widest part of the pelvis and is on a level with the upper border of the fifth lumbar spine.

Just below the crest there is a shallow furrow, termed the *iliac furrow*; it is caused by the lateral abdominal muscles, which bulge over the crest, forming a thick, oblique roll.

Surface relations of other structures.—*The lower limit of the spinal cord corresponds to the interval between the spines of the first and second lumbar vertebræ. This corresponds approximately to the level of the elbow joint when the arm is by the side. The subarachnoid space extends downwards to the horizontal level of the upper border of the third sacral spine* (fig. 1288).

As already described (p. 1083) the roots of the spinal nerves become gradually longer from the first cervical to the coccygeal, and the levels at which they are attached to the spinal cord are therefore higher than the levels at which they emerge from the intervertebral foramina. The positions of the nerve roots relative to the vertebral column are shown in fig. 1289 and in the table attached thereto, page 1452.

Fig. 1287.—A diagram showing the relation of the spinal cord to the dorsal surface of the trunk. The bones are outlined in red.

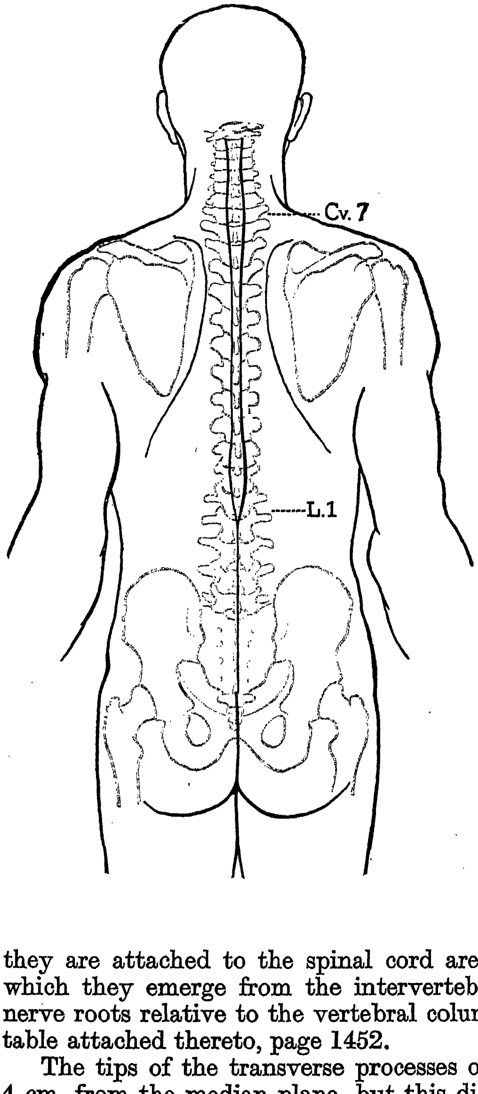


Fig. 1288.—A sagittal section through the lower part of the vertebral canal to show the lower ends of the spinal cord and subarachnoid space, and the filum terminale. (Testut.)

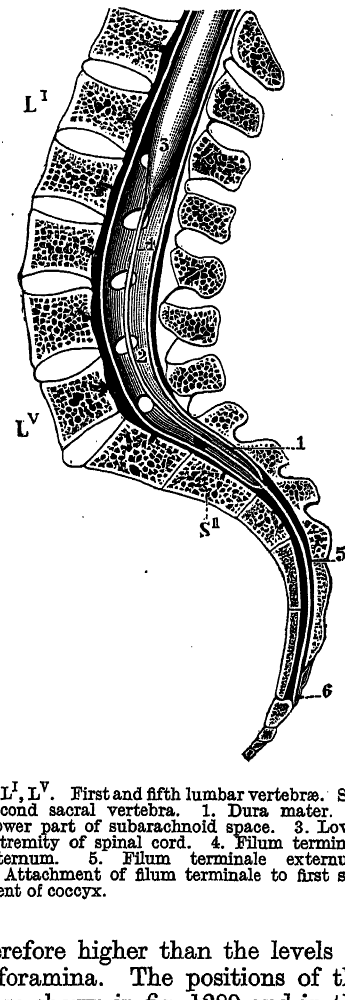

L I, L V. First and fifth lumbar vertebræ. S II. Second sacral vertebra. 1. Dura mater. 2. Lower part of subarachnoid space. 3. Lower extremity of spinal cord. 4. Filum terminale internum. 5. Filum terminale externum. 6. Attachment of filum terminale to first segment of coccyx.

The tips of the transverse processes of the thoracic vertebræ lie 3 cm. to 4 cm. from the median plane, but this distance diminishes from above downwards. The tip of the transverse process of the third lumbar vertebra, which is the longest lumbar transverse process, is 4·5 cm. from the median plane.

The *cervical pleura* and the *apex of the lung* reach the level of the seventh cervical spine at a distance of 2·5 cm. from the median plane.

The *lower limit of the pleural sac* extends down to a point 2 cm. lateral to the upper border of the twelfth thoracic spine and can be indicated by a line drawn downwards and laterally from this point to cut the lateral border of the sacrospinalis just where the tip of the twelfth rib emerges from under cover of the muscle. The *lower limit of the lung* is 5 cm. above the lower limit of the pleura in quiet respiration (fig. 1290).

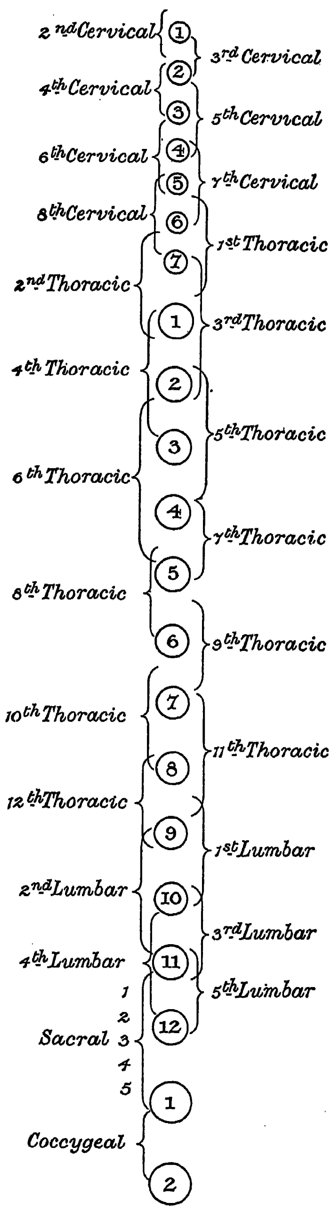

FIG. 1289.—A scheme showing the relations of the vertebral spines to the regions of attachment of the spinal nerves. (After Reid.)

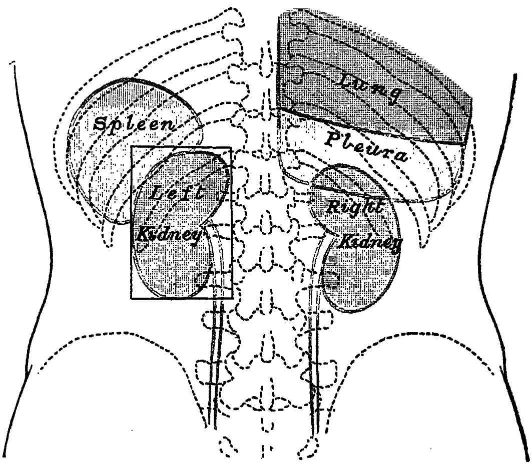
The *kidneys* can be mapped out on the dorsal aspect of the trunk within Morris' parallelogram, which is included between two horizontal lines, drawn through the eleventh thoracic and the third lumbar spines, and two vertical lines, drawn 2·5 cm. and 9·5 cm. from the median plane (fig. 1290). The centre

of the hilum lies opposite the lower border of the first lumbar spine. The *ureter* corresponds to a line drawn downwards from the lower part of the hilum, 4 cm. from the median plane, to the dimple which overlies the posterior superior iliac spine. It lies, as a rule, medial to the tips of the transverse processes of the lumbar vertebræ.

FIG. 1290.—The lower limits of the lung and pleura, viewed from behind.



The lower portions of the lung and pleura are shown on the right side

The *spleen* varies so much in its size and shape that outlines drawn on the surface of the body can be only approximately accurate. For all practical purposes it may be taken as occupying an area mapped out by a line covering the middle three-fifths of the eleventh rib of the left side and a curved line which joins its two ends and extends upwards and forwards to the ninth rib (fig. 1290). On percussion over the spleen, dulness should not extend forwards beyond the midaxillary line when the organ is of normal size.

THE THORAX

Surface landmarks.—The *sternal angle* forms a ridge which can easily be felt through the skin ; traced laterally, it leads to the *second costal cartilage*, which can be identified with certainty. The sternal end of the *first costal cartilage* may be felt immediately below the medial end of the clavicle, but it is by no means a conspicuous landmark. The third and succeeding ribs (with the possible exception of the twelfth) can all be palpated, and confusion may be avoided if the ribs are identified from above downwards, starting at the second. As the cartilages of the fifth, sixth and seventh ribs approach the sternum, the intervals between them become narrower (fig. 304) and it is best, in passing downwards, to pass gradually further from the sternum. At the sternal ends of the second, third and fourth intercostal spaces the margin of the sternum can be felt indistinctly.

The *costal margin,* which is formed by the cartilages of the tenth, ninth, eighth and seventh ribs, can be seen through the skin, except in fat subjects. The two margins enclose the *infrasternal angle* (subcostal angle), where a shallow depression is visible in most cases ; this depression overlies the xiphoid process. At the apex of the angle the xiphisternal joint may be felt as a short transverse ridge.

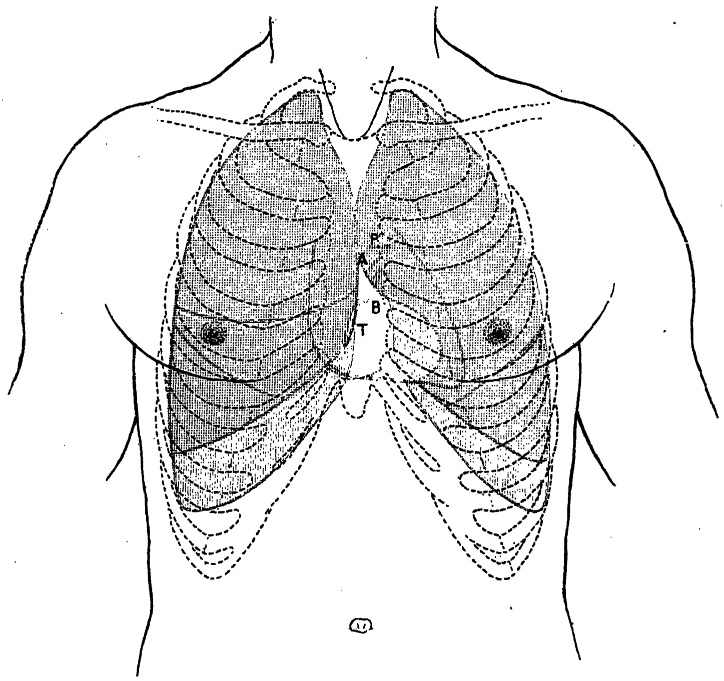
The *apex-beat* of the heart can often be seen and can always be felt a little below and a little medial to the left nipple (p. 1429). As a general rule it will be found in the fifth intercostal space about 9 cm. ($3\frac{1}{2}$ inches) from the median plane.

Surface relations of other structures.—The *internal mammary artery* can be represented by a line which begins 2 cm. above the sternal end of the clavicle

and runs downwards, 1·2 cm. from the lateral margin of the sternum or 3·5 cm. from the median plane, to the sternal end of the sixth costal cartilage.

The surface relations of the cervical pleura (p. 1449) and of the lower limit of the pleural sac dorsally (p. 1452) have already been described. The *costomediastinal lines of pleural reflection* are different on the two sides. On the right side the line commences at the sternoclavicular joint and runs downwards and medially to reach the midpoint of the sternal angle (fig. 1291); it then continues downwards, with a slight inclination to the left to reach the xiphisternal joint. On the left side, the line follows a similar course until the level of the fourth costal cartilage is reached; there it bends to the left to reach the sternal

Fig. 1291.—The front of the thorax, showing the surface relations of the bones, lungs (purple), pleuræ (blue), and heart (red outline).



A. Aortic valve. P. Pulmonary valve.
B. Mitral valve. T. Tricuspid valve.

margin, which it follows to the left extremity of the xiphisternal joint. The *costodiaphragmatic line of reflection* (fig. 1291) can be represented by a line which commences opposite the xiphisternal joint and passes downwards and backwards, gradually receding from the costal margin. In the midaxillary line it crosses the tenth rib and then ascends as it passes medially to reach the lateral border of the sacrospinalis opposite the tip of the twelfth costal cartilage (p. 1449).

The outline of the *apex of the lung* corresponds to the outline of the cervical pleura (p. 1449), and the *anterior margin of the right lung* can be regarded as identical with the costomediastinal line of pleural reflection. The *anterior margin of the left lung* corresponds also to the costomediastinal line of pleural reflection, above the level of the fourth costal cartilage. At that level it passes laterally for 3·5 cm. before curving downwards and medially to reach the sixth costal cartilage 4 cm. from the median plane (fig. 1291). The *lower border of the lung* can be represented, during quiet respiration, by a line drawn from the lower end of the anterior border to reach the eighth rib in the midaxillary line, where it lies nearly 10 cm. above the costal margin; the line is then continued medially and slightly upwards across the back to a point 2 cm. lateral to the tenth thoracic spine (fig. 1290).

The *oblique fissure* of the lung commences opposite a point 2 cm. lateral to the second thoracic spine, and can be represented by a line drawn downwards and laterally across the scapula, below and roughly parallel to the posterior border of the deltoid muscle. Attempts to continue the line uninterruptedly round to the anterior aspect of the chest are unsatisfactory. The fissure can, however, be represented on the front of the chest by a line drawn from a point, 3 cm. lateral to, and at the level of, the nipple, downwards and medially to reach the sixth costal cartilage 7·5 cm. from the median plane. When the hand is placed on the back of the head, the upper part of the oblique fissure corresponds to the vertebral border of the scapula. The *transverse fissure* of the right lung can be indicated by a line drawn from the median plane laterally along the fourth right costal cartilage. At its lateral end the transverse meets the oblique fissure, but owing to the bulk of the anterior axillary fold, attempts to carry the lines of these fissures to their meeting place in the mid-axillary line are unconvincing.

The heart.—The sternocostal surface of the heart can be projected on to the anterior chest-wall and forms an irregular, quadrangular area. The *right border* (fig. 1292) of the heart corresponds to a line drawn from the upper border of the right third costal cartilage, 1·2 cm. from the margin of the sternum, downwards to the sixth costal cartilage. This line is gently convex to the right and is at its maximum distance from the median plane—3·7 cm.—in the fourth intercostal space. It represents the lateral aspect of the right atrium. The continuation of this line in an upward direction marks the lateral border of the superior vena cava and, in a downward direction, the lateral border of the inferior vena cava.

The *lower border* of the heart can be represented by a line joining the lower end of the right border to the apex-beat (p. 1453); it passes through the xiphisternal joint, and corresponds for the most part to the lower margin of the right ventricle (p. 672). The *left border* of the heart is represented by a line drawn from the apex-beat upwards and medially to a point on the lower border of the left second costal cartilage, 1·2 cm. from the sternal margin. This line is convex upwards and to the left; with the exception of its upper part, which demarcates the left auricle, it corresponds to the left ventricle (p. 672).

It is customary to complete the quadrangular area by a line which joins the upper ends of the right and left borders, and corresponds roughly to the upper limits of the atria.

The *pulmonary orifice* (fig. 1291) lies partly behind the upper border of the left third costal cartilage and partly behind the sternum. It can be represented by a horizontal line, 2·5 cm. long. Two parallel lines, drawn from the extremities of this line upwards and slightly to the left to reach the second costal cartilage, map out the *pulmonary trunk.*

The *aortic orifice* (fig. 1291) lies below and a little to the right of the pulmonary orifice. It corresponds to a line, 2·5 cm. long, drawn from the medial end of the left third intercostal space downwards and to the right. Two parallel lines, drawn from the extremities of this line upwards and to the right as far as the right half of the sternal angle, outline the *ascending aorta.*

The *right atrioventricular,* or *tricuspid, orifice* (fig. 1291) can be represented by a line, 4 cm. long, commencing in the median plane opposite the fourth costal cartilage, and passing downwards and slightly to the right. The centre of this line should be opposite the middle of the fourth intercostal space. The *left atrioventricular,* or *mitral, orifice* lies behind the left half of the sternum opposite the fourth costal cartilage and can be represented by a line, 3 cm. long, passing downwards and to the right.

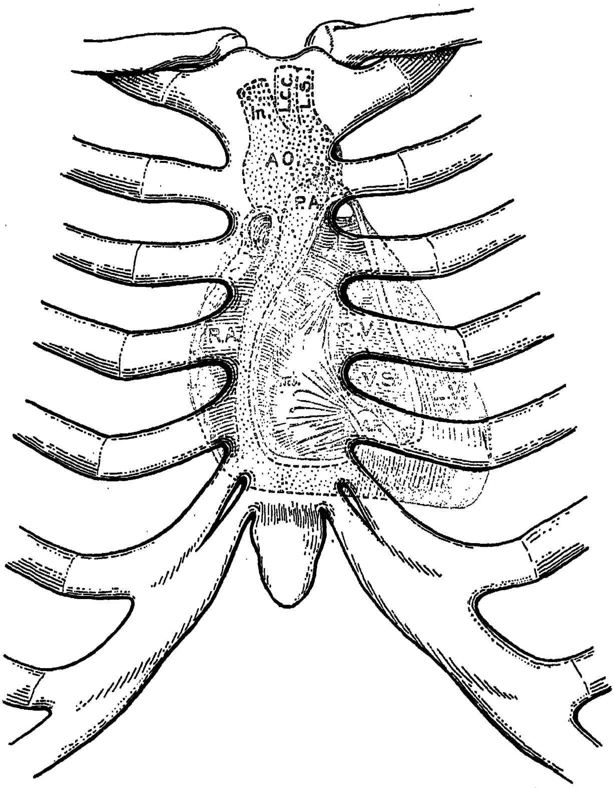
The *atrioventricular groove* can be outlined, with sufficient accuracy for all practical purposes, by joining the lower end of the line marking the tricuspid orifice to the upper end of the line marking the mitral orifice. The *anterior interventricular groove* corresponds to a line drawn downwards from the left extremity of the pulmonary orifice, parallel to the left border of the heart, to the lower border.

The *area of superficial cardiac dulness* is a roughly triangular area, bounded medially by a line drawn in the median plane from the level of the fourth costal cartilage to the xiphisternal joint; inferiorly, by a horizontal line drawn to the left for 6 cm. from the xiphisternal joint; and, superiorly, by a curved line,

convex upwards and to the left, joining the ends of the other boundaries. It corresponds to the portion of the heart which is not covered with lung.

The *arch of the aorta* (fig. 1292) lies behind the lower half of the manubrium sterni; its convex, outer border can be mapped out by a line which commences behind the right extremity of the sternal angle and arches upwards and to the left, through the centre of the manubrium, to end behind the sternal extremity of the left second costal cartilage. *Owing to its backward inclination, the arch is considerably foreshortened when projected on to the surface* (Pl. XIII, fig. 1). The *descending thoracic aorta* commences behind the sternal end of the left

FIG. 1292.—A diagram showing the relations of the opened heart to the front of the thoracic wall.



Ant. Anterior segment of tricuspid valve. AO. Aorta. A.P. Anterior papillary muscle. In. Innominate artery. L.C.C. Left common carotid artery. L.S. Left subclavian artery. L.V. Left ventricle. P.A. Pulmonary artery. R.A. Right atrium. R.V. Right ventricle. V.S. Ventricular septum.

second costal cartilage and can be mapped out as a band, 2·5 cm. broad, which runs downwards and medially to reach the median plane 2 cm. above the transpyloric plane (p. 1458).

The *innominate artery* (fig. 1292) can be represented by a broad line drawn upwards and to the right from the centre of the manubrium to the right sternoclavicular joint. The *left common carotid artery* corresponds to a broad line drawn upwards and to the left from a point a little to the left of the centre of the manubrium to the left sternoclavicular joint. The *left subclavian artery* arises immediately to the left of the origin of the preceding artery and corresponds to a line drawn upwards to the left sternoclavicular joint.

The *superior vena cava* extends from the lower border of the first to the upper border of the third costal cartilage of the right side. It is 2 cm. wide and is partly under cover of the right margin of the sternum. The *right innominate vein* is formed behind the medial end of the right clavicle and extends downwards and medially to the lower border of the right first costal cartilage close to the sternum; it should be represented by two parallel lines, 1·5 cm. apart. The *left innominate vein* commences behind the sternal end of the left clavicle

and passes downwards and to the right, behind the sternoclavicular joint and the upper half of the manubrium, to the lower end of the right innominate vein; it also should be represented by two parallel lines, 1·5 cm. apart.

The *trachea* can be mapped out by two parallel lines, 2 cm. apart, which commence immediately below the arch of the cricoid cartilage and terminate at the sternal angle, inclining very slightly to the right as they descend. From the termination of the trachea, the *right bronchus* runs downwards and to the right for 2·5 cm. to gain the hilum of the right lung opposite the sternal end of the third right costal cartilage. The *left bronchus* descends from the same point but makes a smaller angle with the trachea; it passes downwards and to the left for 5 cm. before it enters the hilum of the left lung behind the left third costal cartilage, 3·5 cm. from the median plane.

The *œsophagus* corresponds to two parallel lines, 2·5 cm. apart, which commence at the lower border of the arch of the cricoid cartilage. At first they incline to the left as they descend, but they soon curve towards the right, and a little below the sternal angle they are equidistant from the median plane. Thereafter they incline to the left again to reach the left seventh costal cartilage, where the centre of the œsophagus lies 2·5 cm. from the median plane.

The *thoracic duct* begins about 2 cm. above the transpyloric plane (*vide infra*) and very slightly to the right of the median plane. It can be represented by a line which ascends in the median plane to the sternal angle and then inclines to the left, until, about 2·5 cm. above the clavicle, it lies 2 cm. from the median plane. Finally, it passes laterally for 1·2 cm. and then turns downwards to end behind the clavicle.

In the child the *thymus* lies behind the manubrium and the upper half of the body of the sternum, and it may project for a short distance into the neck.

THE ABDOMEN

Surface landmarks.—The *linea alba* (fig. 1293) can be seen as a linear depression in the median plane. Below the umbilicus it is visible only in young, muscular subjects, but between the umbilicus and the xiphoid process it can usually be recognised without much difficulty. At its lower end the linea alba terminates at the upper border of the *pubic symphysis*, which can be felt indistinctly. From this point the *pubic crest* can be traced laterally to the *pubic tubercle*. The *linea semilunaris* (fig. 1293) is a curved groove which can be seen marking the position of the lateral border of the rectus abdominis; it crosses the costal margin at or near the tip of the ninth costal cartilage and terminates below at the pubic tubercle.

The interval between the linea alba and the linea semilunaris is occupied by the *rectus abdominis*. In lean and muscular subjects transverse depressions may be seen crossing its surface, one at the umbilicus and one midway between the umbilicus and the xiphoid process; they indicate the position of the tendinous intersections which cross the surface of the muscle (p. 568).

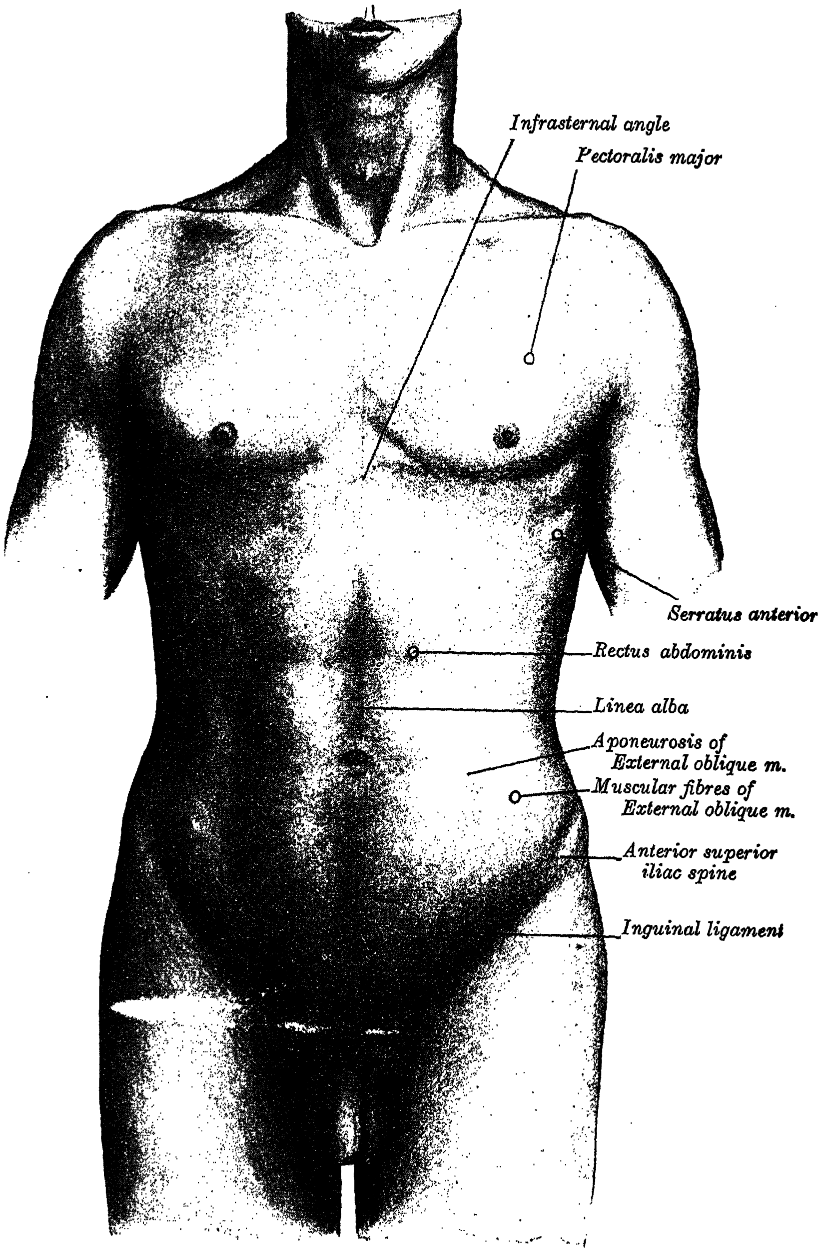
The *umbilicus* forms an important landmark. In the young adult it lies on a level with the intervertebral disc between the third and fourth lumbar vertebræ, but as age advances, it tends to sink to a somewhat lower level.

The *spermatic cord* can be grasped between the finger and thumb at the neck of the scrotum, and the *vas deferens* can be identified in its substance owing to its characteristic cordlike consistence. If the skin of the scrotum is invaginated in an upward and lateral direction the spermatic cord can be followed up to the superficial inguinal ring. If the examining finger is then directed backwards the crura of the ring can be recognised.

The costal margin and infrasternal (subcostal) angle (p. 1453), the iliac crest (p. 1449) and the inguinal ligament (p. 1465) are dealt with in other sections.

Certain artificial landmarks are helpful in facilitating the reference of abdominal viscera to the surface of the abdomen. Of these, the most useful is the *transpyloric plane* (fig. 1294), which is drawn round the body, midway between

FIG. 1293.—The surface anatomy of the front of the thorax and abdomen.



the suprasternal notch and the pubic symphysis. The right and left lateral, the subcostal and the transtubercular planes are described on p. 1303.

Surface landmarks of other structures in the abdominal wall.—The *upper limit of the rectus abdominis* can be represented by a horizontal line drawn from the xiphisternal joint to the fifth costal cartilage. A curved line, convex upwards, drawn across the muscle midway between the umbilicus and the pubic

symphysis, indicates the position of the *arcuate line* (linea semicircularis) (p. 569).

The line along which the fleshy fibres of the external oblique muscle merge into its aponeurosis is parallel with and 0·5 cm. lateral to the linea semilunaris. Just above the level of the anterior superior iliac spine, it bends laterally towards that bony point (fig. 595). It should be noted carefully that no fleshy fibres of the external oblique muscle descend below the line joining the anterior superior spine of the ilium to the umbilicus. The line along which the fleshy fibres of the internal oblique muscle merge into its aponeurosis begins near the tip of the tenth costal cartilage (fig. 599) and runs downwards and slightly medially to a point about 2·5 cm. vertically above the medial end of the inguinal ligament. The line along which the fleshy fibres of the transversus abdominis merge into its aponeurosis is curved, with its convexity laterally. It begins just medial to the costal margin below the xiphisternal joint and runs downwards and laterally, crossing the linea semilunaris at the level of the tip of the tenth costal cartilage. Opposite the umbilicus it lies 1·5 cm. to 2 cm. lateral to the linea semilunaris, and it then curves downwards and medially to a point 2·5 cm. vertically above the medial end of the inguinal ligament.

The centre of the *deep inguinal ring* lies 1 cm. above the midpoint of the line joining the anterior superior iliac spine to the pubic tubercle; the centre of the *superficial inguinal ring* lies 1 cm. above and the same distance lateral to the pubic tubercle. The line of the *inguinal canal*, which is about 3·7 cm. long, can be obtained by joining these two points (fig. 1297).

The *inferior epigastric artery* (fig. 1297) can be represented by a line drawn from the midpoint of the line joining the anterior superior iliac spine to the pubic symphysis upwards towards the umbilicus.

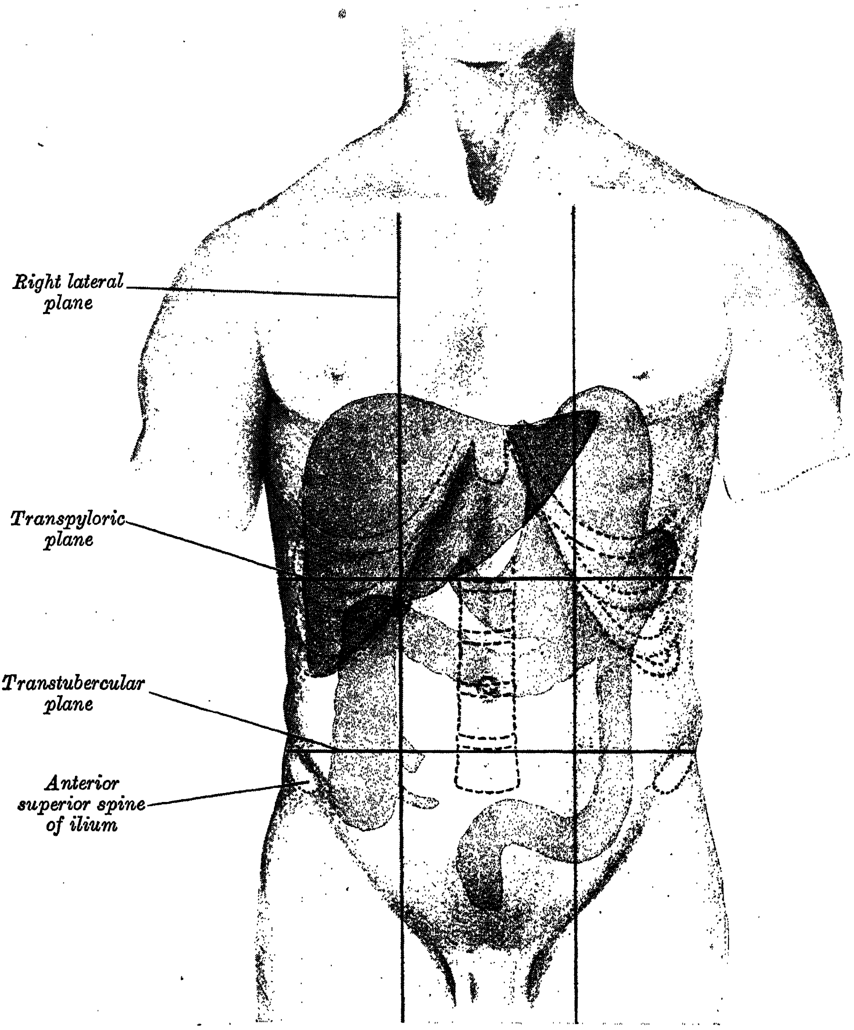
The *seventh* and *eighth intercostal nerves* (fig. 980) turn upwards as they cross the costal margin. The seventh follows the margin closely, but the eighth corresponds to a line drawn upwards and medially from the tip of the ninth costal cartilage, at a distance of 0·5 cm. medial to the costal margin. The *lower intercostal nerves* continue forwards in the lines of the corresponding intercostal spaces.

Surface relations of structures within the abdominal cavity.*—The *stomach* lies in the upper left quadrant of the abdominal cavity and part of its outline overlies the lower ribs and cartilages of the left side. The *cardiac orifice* (fig. 1294) lies behind the seventh costal cartilage 2·5 cm. to the left of the median plane and can be represented by two short, parallel lines, 2 cm. apart, inclining downwards and to the left. It is placed 10 cm. from the surface of the abdominal wall and is 40 cm. (16 inches) from the incisor teeth. The *pylorus* (fig. 1294) lies on the transpyloric plane, 1·2 cm. to the right of the median plane, and can be outlined by means of two short, parallel lines, 2 cm. apart, directed upwards and to the right. The *lesser curvature* of the stomach can be mapped out by joining the right margin of the cardiac orifice to the upper (or left) margin of the pylorus by means of a curved J-shaped line, which descends at its lowest point below the transpyloric plane. The *fundus* of the stomach corresponds to a line, convex upwards, drawn from the left margin of the cardiac orifice and reaching its summit in the left fifth intercostal space just below the nipple. A curved line, convex to the left and downwards, drawn from the fundus to the lower, or right, margin of the pylorus, outlines the *greater curvature*. It cuts the left costal margin between the tips of the ninth and tenth costal cartilages and extends downwards to the subcostal plane.

* The relations detailed in this section refer to the body in the recumbent position, but it must be remembered that posture is not the only factor which affects the position of the viscera. Respiratory movements and the condition of the hollow organs as regards contents exercise an important influence. In addition there is a wide range of individual variation, associated, in part at least, with the type of chest, and there is an appreciable range of variation in the same individual examined at different times, and independent of the factors already noted. It follows, therefore, that *in the absence of such accessories as X-ray photographs attempts to outline the viscera, especially the hollow viscera, on the surface of the living model may prove very unsatisfactory*, and that the markings given in this section, as well as the outlines shown in the accompanying figures, must be regarded as variable within very wide limits.

The *duodenum* * (fig. 1296) lies entirely above the umbilicus, and is about 2·5 cm. wide. Its *first part* passes upwards and to the right for 2·5 cm. from the pylorus (Pl. XV, fig. 1), and from its upper end the *second part* runs downwards for 7·5 cm., lying medial to the right lateral plane. The *third part* passes from the lower end of the second part transversely to the left, above the umbilicus, and after crossing the median plane, turns upwards into the *fourth part.* The latter ends at the *duodenojejunal flexure,* which is situated 2·5 cm. to the left of the median plane and 1 cm. below the transpyloric plane.

FIG. 1294.—The surface relations of the stomach, liver and large intestine.



The *pancreas* (fig. 1296) stretches obliquely across the posterior abdominal wall, lying more to the left than to the right of the median plane. Its *head* lies within the curve formed by the first, second and third parts of the duodenum and its *neck* passes upwards and to the left behind the pylorus. Its body can be represented by two parallel lines, 3 cm. apart, drawn upwards and to the left for 10 cm. to 12 cm. from the neck.

The *liver* (fig. 1296), which occupies the upper right quadrant of the abdominal cavity, is roughly triangular in shape when projected on to the anterior aspect of the trunk. Its *upper border* corresponds to a line drawn through the xiphisternal joint and ascending to the right to a point a little below the right

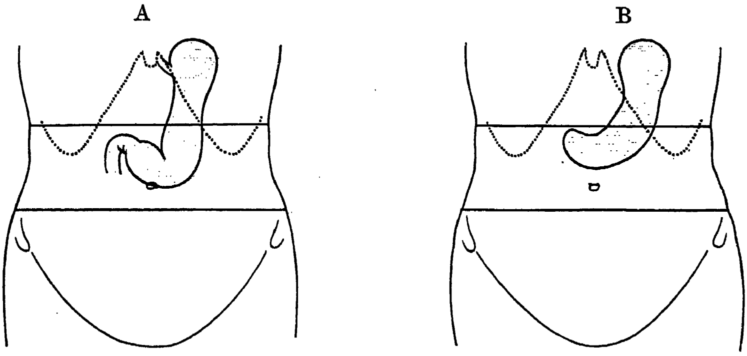
* See footnote on p. 1459.

nipple, and ascending less sharply to the left to a point a little below and medial to the left nipple. Its *right border* corresponds to a curved line, convex to the right, drawn from a point a little below the right nipple to a point 1 cm. below the right costal margin at the tip of the tenth costal cartilage. Its *lower border* can be represented by joining the lower end of its right border to the left end of its upper border ; this line should cross the median plane at the transpyloric plane, should show a slight concavity opposite the right linea semilunaris and may be slightly concave to the left in its upper part. The fundus of the *gall bladder* (fig. 1294) can be outlined on the surface in the angle between the right costal margin and linea semilunaris ; it occupies the notch indicated above on the lower border of the liver. The *bile duct* corresponds to a line which begins 5 cm. above the transpyloric plane and 2 cm. to the right of the median plane, and runs downwards for 7·5 cm., inclining to the right in its lower half.

The area which is bounded on the right by the lower margin of the left lobe of the liver, above by the left lung, on the left by the spleen and below by the costal margin, overlies the stomach and is often termed *Traube's space*.

The *cæcum* * (fig. 1294) occupies the triangular area bounded by the right lateral plane, the transtubercular plane and the fold of the groin (p. 1465). The

FIG. 1295.—Skiagrams of a half-filled stomach, showing the influence of posture. (After A. F. Hurst.)



A. With the patient in the erect posture. B. With the patient lying down.

ileocolic orifice lies opposite the point of intersection of the transtubercular and the right lateral planes, and 2 cm. below this point the *vermiform appendix* opens into the cæcum.† (Pl. XVII.)

The *ascending colon* * (fig. 1294), which is usually about 5 cm. wide, lies immediately to the right of the right lateral plane and ascends from the transtubercular plane to midway between the subcostal and the transpyloric planes.

The *transverse colon* * (fig 1294) can be represented by a band, 5 cm. wide, drawn from the upper end of the ascending colon downwards and medially to the umbilicus and then upwards and laterally to cross the transpyloric plane to the left side of the left lateral plane.

The *descending colon* * (fig. 1294) is usually contracted and is little more than 2 cm. broad ; it can be represented by a band which commences above the transpyloric plane and descends, just lateral to the left lateral plane, as far as the fold of the groin (p. 1465).

The *kidney* * lies with its upper and lateral part under cover of the costal margin, and its long axis is directed downwards and laterally, so that its upper pole is nearer to the median plane than its lower pole. The viscus measures 11 cm. long and 6·5 cm. wide, but, owing to foreshortening its width is reduced

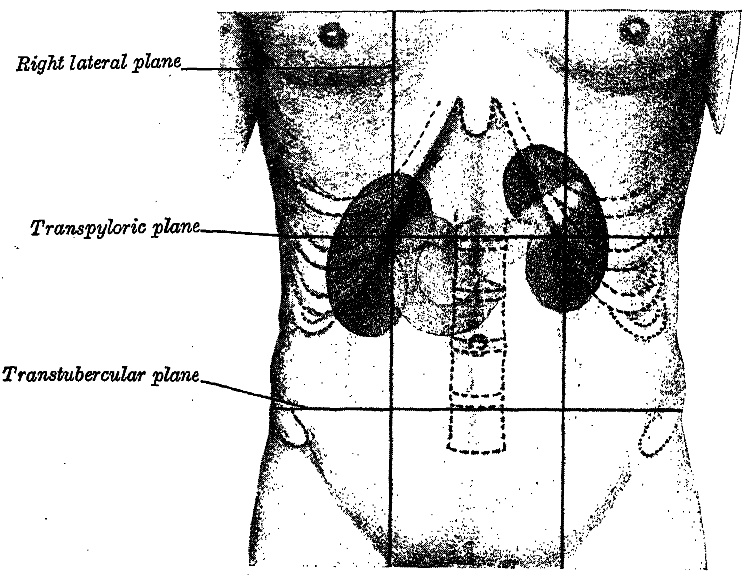
* See footnote on p. 1459.

† McBurney marked the base of the vermiform appendix opposite the junction of the lower and middle thirds of the line joining the anterior superior iliac spine to the umbilicus.

to 5 cm. when it is projected on to the anterior surface of the trunk. The centre of the hilum lies 5 cm. from the median plane ; that of the right kidney lies a little below the transpyloric plane, that of the left kidney a little above it. With the aid of these measurements the kidney can be mapped out on the anterior surface of the abdomen with sufficient accuracy for all practical purposes (fig. 1296). The outlines of the kidneys on the posterior surface of the body are described on p. 1452.

The *pelvis of the ureter* lies opposite the hilum of the kidney and extends downwards to a point 5 cm. below the transpyloric plane and the same distance from the median plane (Pl. II, fig. 2). The *ureter* can be represented by a line drawn downwards and slightly medially from the lower end of its pelvis towards the pubic tubercle ; as it enters the pelvis it crosses the termination of the common iliac artery (*vide infra*).

FIG. 1296.—The surface relations of the duodenum, pancreas and kidneys.



The *suprarenal glands* can be mapped out on the surface immediately medial to the costal margin. The left gland, which measures 4·5 cm. long and 2 cm. wide, is closely applied to the medial border of the left kidney above the hilum ; the right gland, which is triangular in outline and measures 3 cm. long and 3 cm. wide, is placed at the upper pole of the right kidney.

The *abdominal aorta* (fig. 1297) commences in the median plane 2·5 cm. above the transpyloric plane. As it descends it inclines slightly to the left and it divides into its terminal branches opposite a point 1·2 cm. below the umbilicus and the same distance from the median plane. It can be represented by two parallel lines, about 2 cm. apart.

The *common iliac artery* corresponds to the upper third of a broad line drawn from the lower end of the aorta, with a slight convexity to the lateral side, to the midpoint between the anterior superior iliac spine and the pubic symphysis. The *external iliac artery* corresponds to the lower two-thirds of the same line.

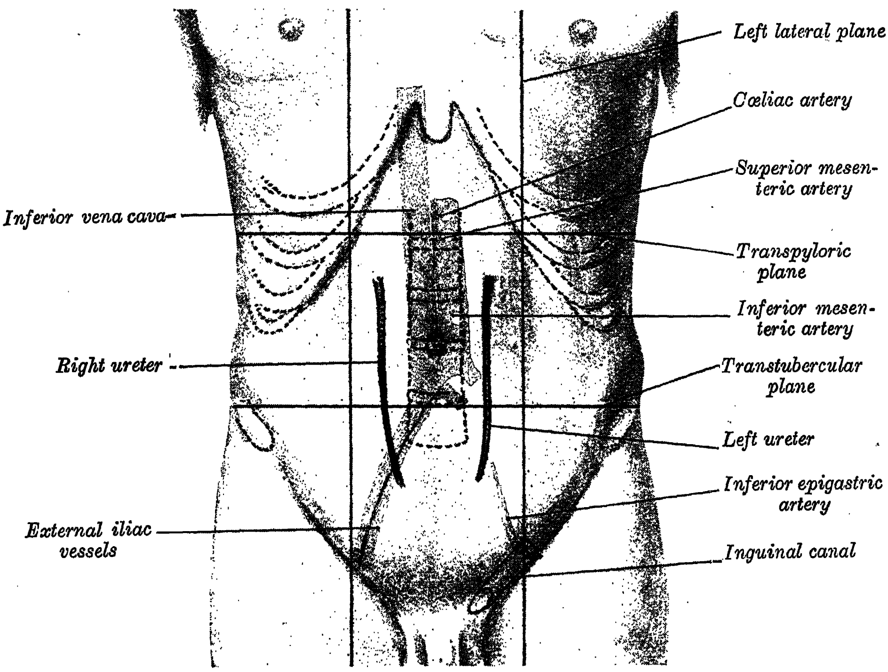
The *cœliac artery* (fig. 1297) arises opposite the commencement of the abdominal aorta. The *left gastric artery* corresponds to a line drawn from the cœliac artery upwards and to the left, in the direction of the cardiac orifice of the stomach (p. 1459). The *splenic artery* can be represented by a wavy line drawn to the left and slightly upwards for about 10 cm. from the cœliac artery. The *hepatic artery* can be marked out by a line drawn to the right and downwards from the cœliac artery for 2·5 cm. and then vertically upwards for 2 cm. to 3 cm.

The *superior mesenteric artery* (fig. 1297) begins in the median plane at, or just above, the transpyloric plane. Its course can be indicated by a line, gently convex to the left, drawn from this point to the intersection of the transtubercular and right lateral planes. The line of the artery corresponds in a general way to the line of the *root of the mesentery*, which, however, extends upwards to the duodenojejunal flexure (p. 1460).

The *renal artery* arises from the lateral aspect of the aorta, 1·5 cm. below the transpyloric plane and corresponds to a broad line drawn laterally for 4 cm. In the case of the left artery the line should incline upwards across the transpyloric plane.

The *inferior mesenteric artery* can be represented by a line which commences 2·5 cm. above the umbilicus and 1·2 cm. to the left of the median

FIG. 1297.—The surface relations of the aorta, inferior vena cava, ureters and inguinal canal.



plane, and runs downwards and slightly to the left to a point 4 cm. below the umbilicus.

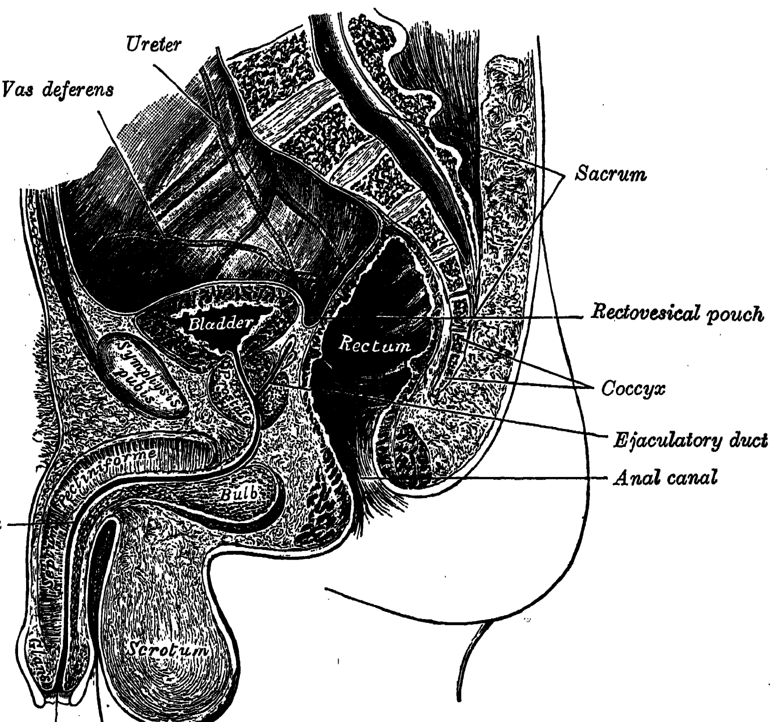
The *inferior vena cava* (fig. 1297) begins on, or just below, the transtubercular plane and its centre lies 2·5 cm. from the median plane. It can be represented by two vertical lines, 2·5 cm. apart, drawn upwards from this point to the sternal end of the right sixth costal cartilage (p. 1455). A line, drawn downwards and laterally from the lower end of the inferior vena cava to a point 1 cm. medial to the midpoint of the line joining the pubic symphysis to the anterior superior iliac spine, outlines the *common* and the *external iliac veins*. This line is slightly convex to the lateral side, the curvature being greater on the left side.

The *portal vein*, which is 1·5 cm. to 2 cm. wide, corresponds to a broad band drawn upwards and to the right for 5 cm. from a point on the transpyloric plane 1·2 cm. to the right of the median plane.

The Perineum

The *anal orifice* lies in the median plane of the posterior part of the perineum about 4 cm. in front of the *tip of the coccyx,* which can be felt at the bottom of the natal cleft. The skin around the anus is thrown into a series of converging folds, which are continued upwards into the lower part of the anal canal. The skin covering the scrotum is rough and corrugated, but over the penis it is smooth and thin. A median ridge, which indicates the position of the scrotal raphe, extends forwards from the anus, over the scrotum to the penis. The *testes* can be palpated through the skin of the scrotum, and along the posterior border of each the curved *epididymis* can be identified. The spermatic cord and the vas deferens have already been described (p. 1457).

Fig. 1298.—A median sagittal section through the male pelvis.



The external genital organs in the female have been described on pp. 1405 to 1407.

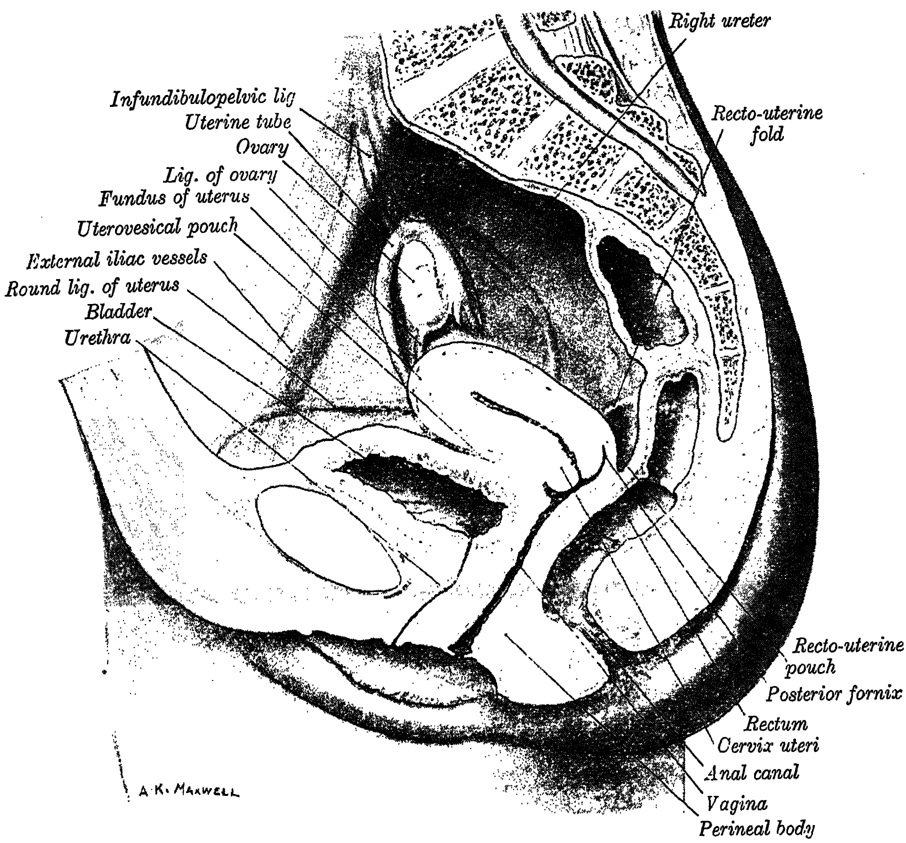
The whole outline of the *pubic arch* can be felt through the skin, from the pubic symphysis to the ischial tuberosity. Posteriorly, on each side, the edge of the *sacrotuberous ligament* can be felt on deep pressure under the medial part of the lower border of the gluteus maximus (p. 1470).

The *rectum* and *anal canal.*—A finger inserted through the anal orifice enters the anal canal, which passes upwards and forwards for about 2·5 cm. and then bends sharply backwards into the rectum. The finger is first grasped by the external and then by the internal sphincter, and at the upper end of the canal it encounters the resistance of the puborectalis; beyond this it may reach the lowest of the horizontal rectal folds. In front (fig. 1298) the *bulb of the penis* and the *membranous part of the urethra* are first identified and then, about 4 cm. above the anal orifice, the *prostate* can be felt; beyond this the *seminal vesicles,* if enlarged, and the base of the bladder may be recognised. Posteriorly the

pelvic surfaces of the lower part of the sacrum and the coccyx may be palpated.

The *vagina.*—A finger inserted into the vagina comes into contact above with the vaginal portion of the *cervix uteri*, and the lips of the *external os uteri* can be palpated. In front of the cervix, the finger passes into the anterior vaginal *fornix*, through which the base of the bladder may be examined. Behind the cervix, the finger passes into the posterior vaginal fornix, through which the contents of the recto-uterine pouch can be felt (fig. 1299). If the opposite

FIG. 1299.—A median sagittal section through the female pelvis.



hand is placed on the lower part of the abdominal wall and firm pressure exercised, the whole of the cervix and body of the uterus can be examined between the two hands, and the experienced observer can determine the condition of the ovaries and the uterine tubes.

A line drawn transversely in front of the ischial tuberosities passes through the *perineal body* ; it is situated 2·5 cm. in front of the anus, or about midway between the anus and the neck of the scrotum, in the male (midway between the anus and the vaginal orifice in the female).

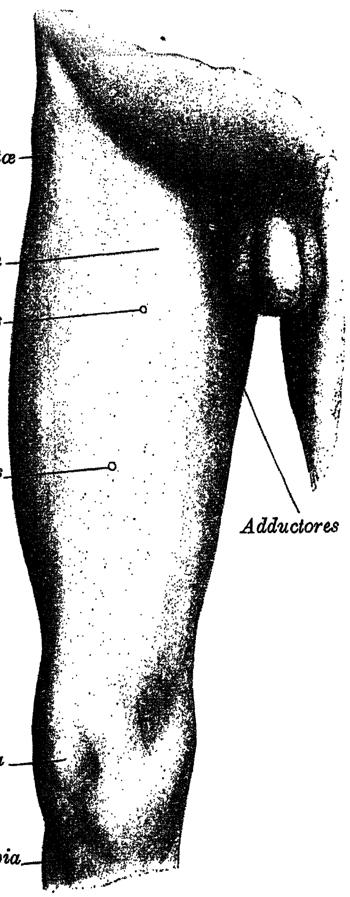
THE LOWER LIMB

The Front of the Thigh

Surface landmarks.—An oblique skin crease, which is termed the *fold of the groin* (fig. 1300), marks the junction of the front of the thigh with the anterior abdominal wall. It corresponds fairly accurately to the *inguinal ligament.* The *anterior superior spine of the ilium*, which lies at the lateral end of the fold, can always be palpated, but, on account of the normal tilt of the pelvis, the small surface elevation often visible in this situation is produced, not by the

spine, but by the adjoining part of the crest. At its medial end the fold reaches the pubic tubercle (p. 1457). Just below the midpoint of the line joining the anterior superior iliac spine to the pubic symphysis, the pulsation of the femoral artery can be felt, and in this situation the vessel can be compressed against the superior ramus of the pubis. The shallow depression which lies immediately below the fold of the groin corresponds to the *femoral triangle* (fig. 1300). It is bounded on the lateral side by the straplike *sartorius muscle*, which can be both seen and felt in the living subject, especially when the thigh is flexed against gravity and is, at the same time, slightly abducted and rotated laterally. The muscle can be traced downwards and medially from the anterior superior spine of the ilium across the front of the limb to, approximately, half-way down the medial side of the thigh (fig. 1300). In the lower part of its extent it passes vertically downwards across the medial condyle of the femur to reach its insertion. The bulky, fleshy mass at the upper part of the medial side of the thigh is formed by the *adductor group of muscles*. At its upper and medial end, the tendon of origin of the *adductor longus* can be identified immediately below the pubis.

FIG. 1300.—The front and medial surface of the right thigh.



When the thigh is flexed against gravity and the knee is extended, an angular depression becomes apparent immediately below the anterior superior iliac spine. It is bounded medially by the sartorius and laterally by the *tensor fasciæ latæ*, which forms a firm rounded prominence. This depression overlies the straight head of origin of the *rectus femoris* and the *anterior inferior iliac spine*, but neither of these structures can be palpated satisfactorily. The forward convexity of the front of the thigh is caused by the curvature of the femur, covered with the vastus intermedius and the rectus femoris. The fleshy bulge which lies medial to the upper half of the patella is produced by the lower fibres of the *vastus medialis*.

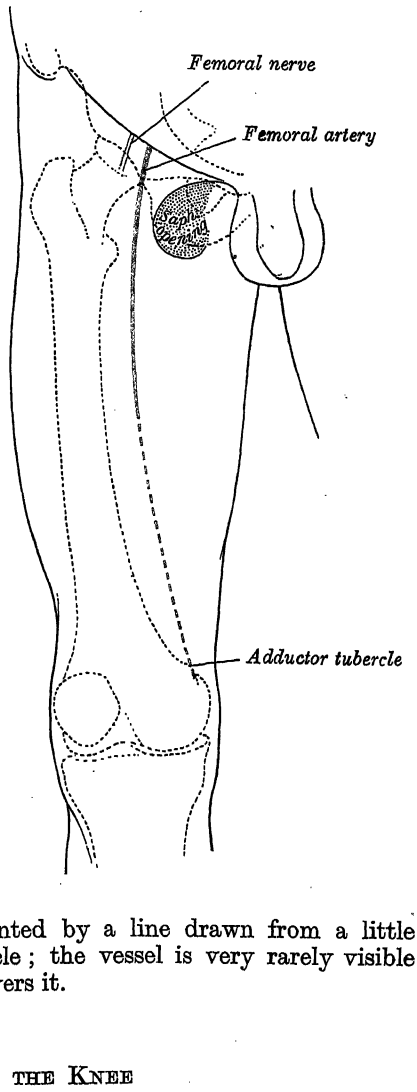
The flattened appearance of the lateral aspect of the thigh is caused by the *iliotibial tract*, which stands out as a strong, visible ridge on the antero-lateral aspect of the knee, when the leg is extended against gravity. This ridge forms the lateral boundary of the depression which lies above and lateral to the patella and is limited above by the lower fibres of the *vastus lateralis*.

The **adductor tubercle** (fig. 1301) on the medial condyle of the femur can be felt in the lower part of the thigh. It is the highest point on the medial condyle and can be identified most satisfactorily when it is approached from above. If the hand (fingers pointing downwards) is placed flat on the medial side of the thigh and carried downwards to the knee, the tip of the middle finger comes into contact with the adductor tubercle. The cord-like tendon of the *adductor*

magnus can be recognised on deep pressure immediately above the tubercle and can be traced downwards to its insertion into the bone.

Surface relations of other structures.—The *femoral artery* enters the thigh at the fold of the groin, at a point midway between the anterior superior iliac spine and the pubic symphysis. It can be represented by the upper two-thirds of a line joining that point to the adductor tubercle (fig. 1301) when the flexed thigh is abducted slightly and rotated laterally. The proximal third of this line lies in the depression corresponding to the femoral triangle and its middle third lies on the surface of the sartorius muscle. It must be remembered that, although the femoral artery lies in front of the head of the femur as it leaves the pelvis, it lies at some distance to the medial side of the shaft until it reaches the lower end of the subsartorial (adductor) canal. The *femoral vein* lies close to the medial side of the artery in the upper part of the femoral triangle, but in most of its course it lies behind the artery, inclining to its lateral side below. The *femoral nerve* enters the thigh 1·2 cm. to the lateral side of the femoral artery and can be represented by a vertical line in this situation, not more than 2·5 cm. long.

Fig. 1301.—The front of the right thigh, showing the surface markings for the bones, the femoral artery, and the femoral nerve.



The *hip-joint* lies 1·2 cm. vertically below the middle third of the inguinal ligament (Pl. VIII), which is approximately parallel to the rim of the acetabulum (fig. 1301). When the joint is extended, a part of the anterior aspect of the head of the femur lies immediately below the acetabular rim and is crossed by the femoral vessels.

The centre of the *saphenous opening* (fossa ovalis) lies nearly 4 cm. below and lateral to the pubic tubercle, and the *long saphenous vein* can be represented by a line drawn from a little below this point to the adductor tubercle; the vessel is very rarely visible in the thigh on account of the fat that covers it.

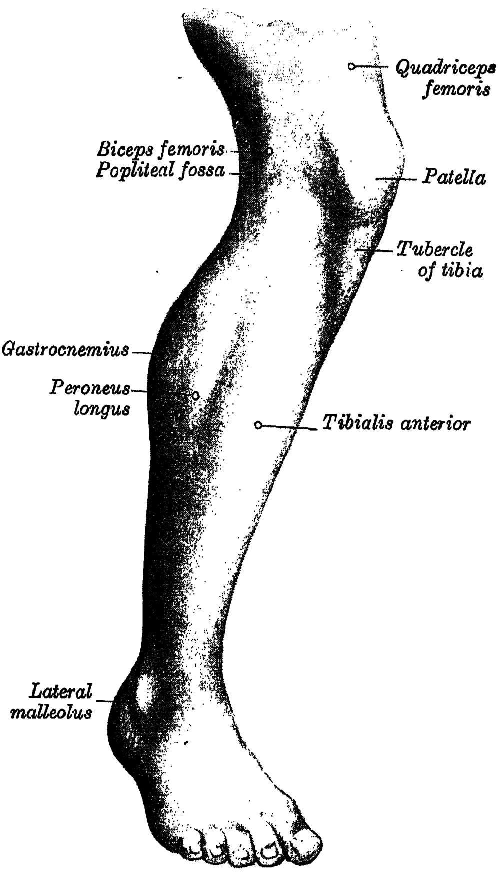
The Region of the Knee

Surface landmarks.—The *patella* can be identified readily, and, when the quadriceps is relaxed, can be tilted and moved on the lower end of the femur. Its lower limit lies more than 1 cm. above the line of the knee-joint (Pl. IX). The *ligamentum patellæ* can be traced downwards from the apex of the patella to the *tibial tubercle* (fig. 1302), and its edges can be gripped between the finger and thumb when the knee is partly extended against gravity. When the knee is flexed passively, the medial surface of the *medial condyle* and the lateral surface of the *lateral condyle of the femur* can be palpated, and portions of the femoral articular surface can be examined on each side of the lower part of the patella. When the knee is extended passively, the *sartorius* forms a slight elevation over the posterior part of the medial condyle. The *tibial condyles* form visible and palpable landmarks at the sides of the ligamentum

patellæ; the lateral condyle is the more prominent. When the knee is flexed passively the anterior margins of the tibial condyles can be felt readily, and each forms the lower boundary of a depression at the side of the patellar ligament.

The large and deep depression which can be seen at the back of the knee when the joint is actively flexed against resistance corresponds to the *popliteal fossa*. It is bounded on the lateral side by the prominent tendon of the *biceps femoris*, which can be traced downwards to the *head of the fibula* (fig. 1303). This bony point forms a slight surface elevation on the upper part of the postero-lateral aspect of the leg and lies vertically below the *posterior* part of the lateral condyle of the femur, *not less than 1 cm. below the level of the knee-joint*. The *lateral popliteal* (common peroneal) *nerve* (fig. 1303) runs downwards and laterally across the back of the head of the fibula and then curves forwards round the neck of the bone. In both situations it can be rolled against the bone, but at the neck of the fibula it is placed deep to the peroneus longus and cannot be felt so distinctly. Three tendons can be felt on the medial side of the popliteal fossa. The *semitendinosus* is the most lateral, and the *gracilis* the most medial. These two tendons stand out sharply and can be seen when the knee is flexed against resistance and the limb is adducted actively. The third tendon is the *semimembranosus*; it is more deeply situated and can be felt in the interval between the other two. In addition, it is much thicker than the others and broadens rapidly as it is traced upwards.

FIG. 1302.—The lateral surface of the right leg.



When the knee is flexed passively, the pulsation of the *popliteal artery* can be felt on deep pressure over the middle line of the popliteal fossa.

Surface relations of other structures.—The *popliteal artery* (fig. 1303) can be represented by a line which begins at the junction of the middle and lower thirds of the thigh, 2·5 cm. medial to the middle line of the back of the limb, and runs downwards and laterally to reach the middle line at the level of the knee-joint. It then descends vertically to the level of the tibial tubercle. The *medial popliteal* (tibial) *nerve* corresponds to a line which commences at the upper angle of the popliteal fossa and runs downwards in the middle line. At first lateral to the popliteal artery, the nerve gradually crosses the vessel to gain its medial side. The *lateral popliteal nerve* (fig. 1305) can be indicated by a line drawn from the upper angle of the popliteal fossa, along the medial side of the tendon of the biceps femoris to the back of the head of the fibula; it is then curved downwards and forwards round the neck of the bone.

The line of the *knee-joint* corresponds to the upper margins of the tibial condyles and can be represented by a line drawn round the limb at this level. In the angles between this line and the edges of the ligamentum patellæ the an-

terior horns of the semilunar cartilages can be indicated. The *suprapatellar bursa* extends upwards for at least 6 cm. above the patella.

The Gluteal Region and the Back of the Thigh

Surface landmarks.—The bulky prominence of the buttock is caused by three factors: (1) the forward tilt of the pelvis, which throws the ischium backwards; (2) the size of the gluteus maximus; and (3) the large amount of subcutaneous fat. The horizontal *gluteal fold* (fig. 1304) marks the upper limit of the back of the thigh; it does not correspond to the lower border of the gluteus maximus but is caused by fibrous connexions between the skin and the deep fascia. The *natal cleft*, which separates the buttocks inferiorly, commences above at the third or fourth sacral spine.

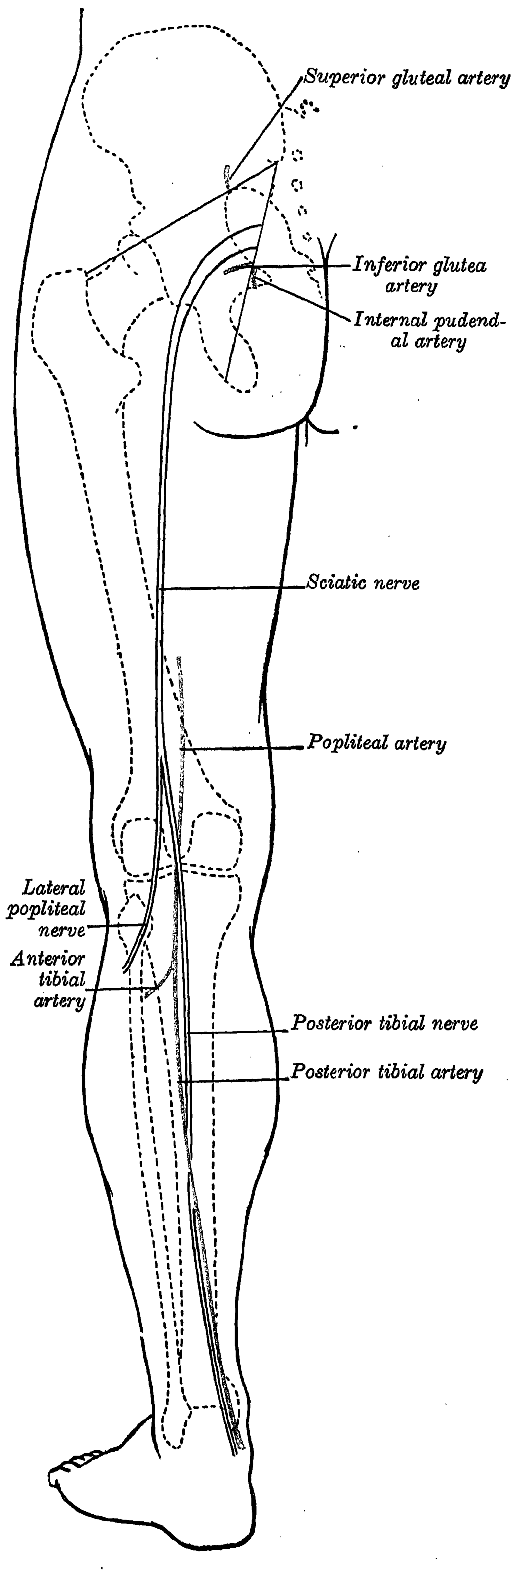
The *iliac crest*, which forms the upper limit of the buttock, has already been described (p. 1449).

The *greater trochanter* of the femur lies a hand's breadth below the tubercle of the iliac crest. When the body is in the upright posture, the lateral surface and posterior margin of the trochanter can be felt through the skin. Above and behind it there is a shallow depression, which overlies the aponeurosis of the gluteus maximus.

The *tuberosity of the ischium* is covered with the gluteus maximus when the hip-joint is extended, but it can be identified without difficulty when the joint is flexed. It is placed about 5 cm. from the median plane and about the same distance above the gluteal fold (fig. 1303).

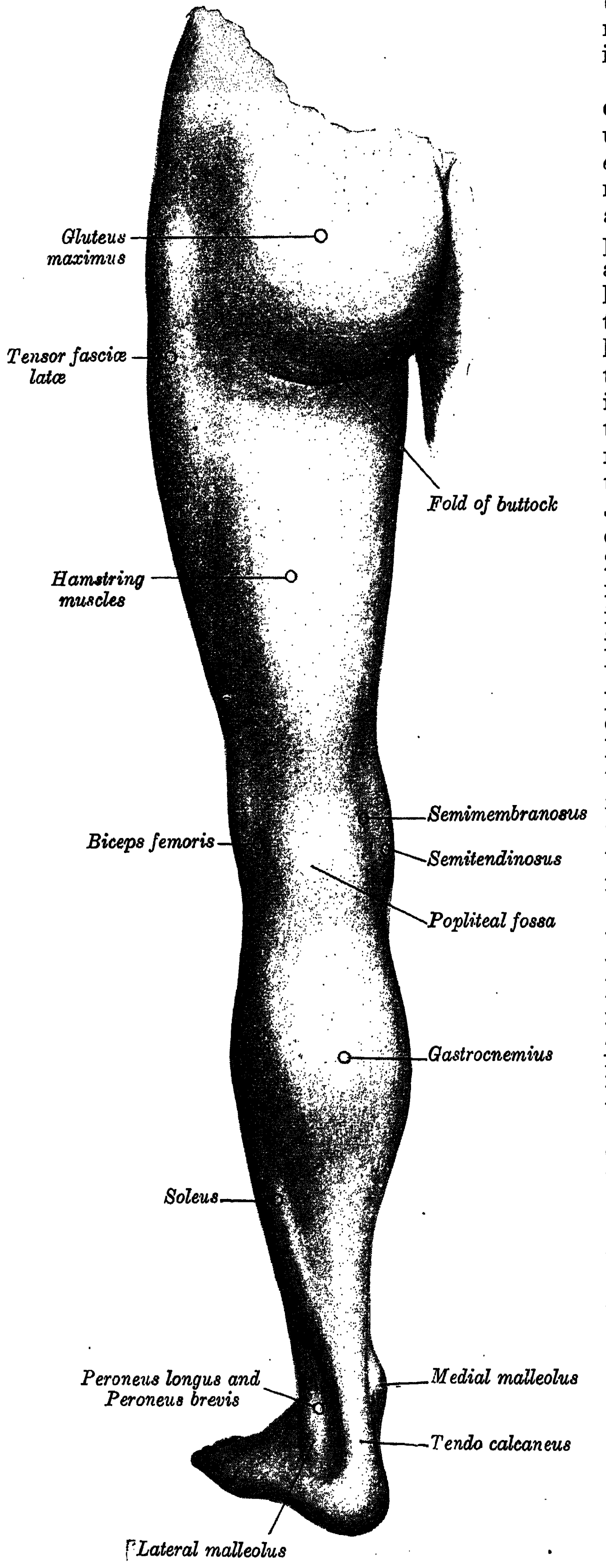
The rounded fleshy mass which occupies the upper part of the back of the thigh is formed by the *biceps femoris*, on the lateral side, and the *semitendinosus* and the *semimembranosus*, on the medial

Fig. 1303.—The back of the left lower limb, showing the surface markings for the bones, vessels, and nerves.



side. These muscles stand out boldly when the knee is flexed against resistance, and can then be traced upwards till they disappear under cover of the gluteus maximus to reach the ischial tuberosity.

Fig. 1304.—The back of the left lower limb.



Surface relations of other structures.—The upper border of the *gluteus maximus* muscle commences on the iliac crest about 3 cm. lateral to the posterior superior spine and runs downwards and laterally to the apex of the greater trochanter; its lower border corresponds to a line drawn from the ischial tuberosity, through the midpoint of the gluteal fold, to a point 9 cm. below the greater trochanter. The *sciatic nerve* (fig. 1303) enters the gluteal region 2·5 cm. lateral to the midpoint of the line joining the posterior superior iliac spine to the ischial tuberosity. It can be represented by a broad line drawn downwards and laterally from this point to cross the line joining the ischial tuberosity to the apex of the greater trochanter just medial to its mid-point. It is then continued vertically down the back of the thigh to the upper angle of the popliteal fossa, where it divides into the *medial* and *lateral popliteal nerves*, if it has not already done so at a higher level.

The *inferior gluteal artery* enters the buttock to the medial side of the point at which the sciatic nerve emerges from the pelvis. The *superior gluteal artery* emerges from the pelvis at the junction of the upper and middle thirds of a line joining the posterior superior iliac spine to the apex of the greater trochanter.

It should be observed that the line joining the posterior superior iliac spine to the ischial tuberosity

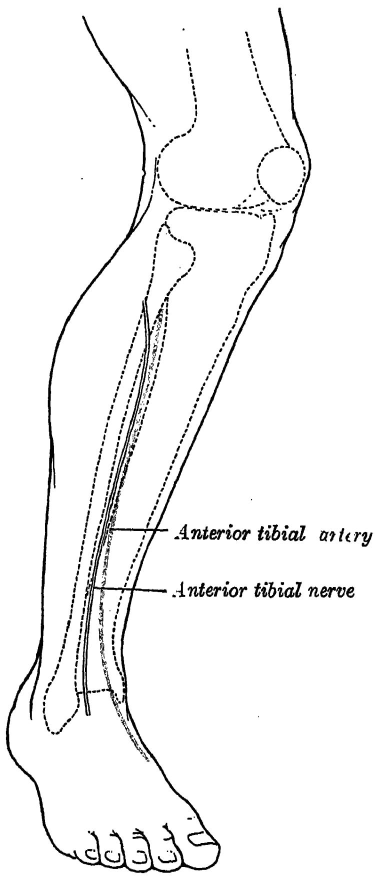
passes through both the posterior inferior iliac spine and the spine of the ischium (fig. 1303).

A line drawn from the anterior superior iliac spine to the most prominent part of the tuberosity of the ischium crosses the apex of the greater trochanter and the centre of the acetabulum ; it is frequently termed Nélaton's line. A line joining the apices of the greater trochanters should be parallel to the line joining the two anterior superior iliac spines. These lines are occasionally useful for clinical purposes.

The Leg and Ankle Regions

Surface landmarks.—The flat, anteromedial aspect of the leg conforms to the subcutaneous *medial surface of the tibia*. Above, this surface merges into the medial condyle of the tibia and below it is continuous with the visible prominence of the *medial malleolus*. The sinuous *anterior border of the tibia*, or shin, can be felt distinctly in most of its extent, but, below, it is somewhat masked by the tendon of the tibialis anterior, which lies to its lateral side. The *long saphenous vein* can often be seen as it runs upwards and backwards across the medial surface of the tibia, a little above the medial malleolus. It then ascends along the medial side of the leg to the knee, where it crosses the medial condyle of the femur.

Fig 1305.—The lateral surface of the right leg, showing the surface markings for the bones, the anterior tibial and dorsalis pedis arteries, and the anterior tibial nerve.



The *lateral malleolus of the fibula* (fig. 1305) forms a conspicuous projection on the lateral side of the ankle. It descends to a lower level than the medial malleolus and is placed on a more posterior plane. The lateral aspect of the lateral malleolus is continuous above with an elongated, triangular area of the shaft of the fibula, which is also subcutaneous. Immediately in front of the base of the lateral malleolus, the lateral part of the anterior margin of the lower end of the tibia can be made out, and the line of the *ankle joint* can be gauged from it.

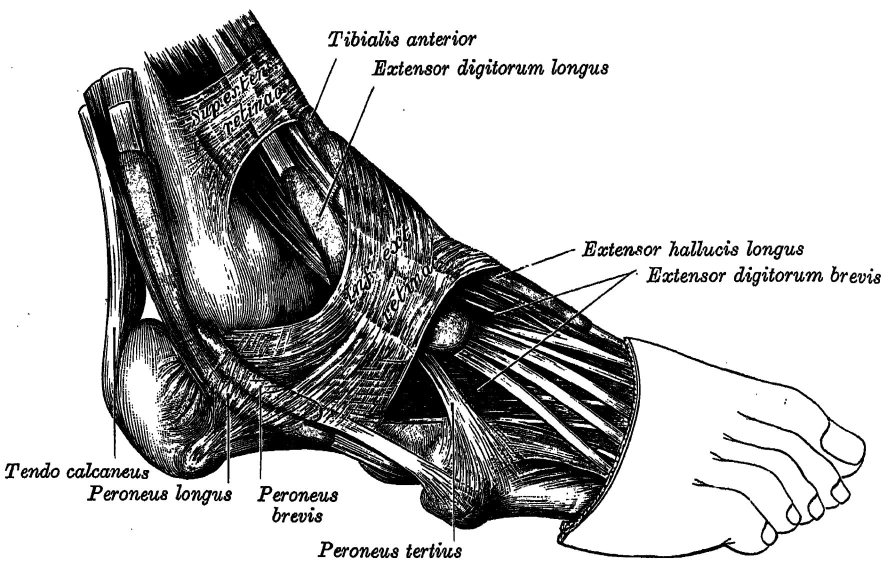
The muscles in the anterior osteofascial compartment of the leg form a gentle prominence over the upper two-thirds of its anterolateral aspect, and this prominence is accentuated when the foot is actively dorsiflexed and inverted. In the lower third of the leg, the muscles give place to their tendons. The tendon of the *tibialis anterior* can be seen just lateral to the anterior border of the tibia and traced downwards and medially across the front of the ankle to the medial side of the foot ; the other tendons cannot be examined satisfactorily above the ankle.

During active eversion and plantar flexion of the foot, the *peroneus longus* muscle (fig. 1302) can be seen as a narrow ridge on the lateral aspect of the leg. It hides the peroneus brevis, and both muscles cover the lateral aspect of the fibula, rendering its examination difficult. The tendon of the peroneus longus can be felt behind the triangular subcutaneous area of the fibula, but it disappears behind the lateral malleolus, where it is bound down by the superior peroneal retinaculum.

The bulky prominence of the calf of the leg is formed by the *gastrocnemius* and the *soleus*, both of which can be identified when the foot is plantar-flexed against resistance, or when the heel is raised from the ground, e.g. in standing on tiptoes. The medial head of the gastrocnemius descends to a lower level than the lateral head. The soleus projects from under cover of the gastrocnemius (fig. 1304), especially on the lateral side, and its fleshy belly extends to a lower level. Both muscles end below in the conspicuous *tendo calcaneus*, which can be gripped between the finger and thumb and followed down to its insertion into the posterior aspect of the calcaneum.

Immediately above the medial malleolus and close to the medial border of the tibia, the tendons of the *tibialis posterior* and *flexor digitorum longus* can

FIG. 1306.—The synovial sheaths of the tendons round the ankle. Lateral aspect. (From a preparation by J. C. B. Grant.)



be felt when the foot is actively inverted and plantar-flexed, but they are not conspicuous landmarks.

Surface relations of other structures.—The *anterior tibial artery* (fig. 1305) can be represented by a line which begins 2·5 cm. below the medial side of the head of the fibula and runs downwards and slightly medially to the midpoint between the two malleoli. Deeply placed above, the vessel is relatively superficial at the ankle, where it lies behind the tendon of the extensor hallucis longus. The *anterior tibial nerve* (deep peroneal nerve) commences on the lateral aspect of the neck of the fibula ; it is directed downwards and medially and soon comes into relationship with the anterior tibial artery, which it accompanies to the ankle. The *musculo-cutaneous nerve* (superficial peroneal nerve) also begins on the lateral aspect of the neck of the fibula ; it descends to a point on the anterior border of the peroneus longus, at the junction of the middle and lower thirds of the leg, where it pierces the deep fascia and divides into medial and lateral branches, which gradually diverge as they descend to reach the dorsum of the foot.

The *superior extensor retinaculum* (transverse crural ligament) (fig. 1306) can be represented as a band, 3 cm. deep, which passes from the anterior border of the triangular subcutaneous area of the fibula to the lower part of the anterior border of the tibia. As the tendon of the *tibialis anterior* descends behind the medial part of the ligament, it is provided with a synovial sheath which extends, both upwards and downwards, beyond the limits of the ligament.

The *posterior tibial artery* corresponds to a line drawn from the middle line on the back of the calf, at the level of the neck of the fibula, to a point midway

between the medial malleolus and the tendo calcaneus. The same line can be utilised to represent the *posterior tibial nerve.*

The *synovial sheaths* which envelop the tendons of the peroneus longus and brevis are shown in fig. 1306.

THE FOOT

Surface landmarks.—When the toes are dorsi-flexed, the *extensor digitorum brevis* forms a small elevation on the dorsum of the foot, a little in front of the lateral malleolus. At its posterior end the anterior part of the upper surface of the calcaneum can be identified, when the muscle is relaxed. When the foot is passively inverted, the upper and lateral part of the *head of the talus* can be both seen and felt ; it lies 3 cm. in front of the lower end of the tibia, and is obscured by the extensor tendons when the toes are dorsi-flexed. The tendon of the *tibialis anterior,* which stands out conspicuously on the medial side during dorsi-flexion of the ankle joint combined with inversion of the foot, can be traced downwards and medially to the *medial cuneiform bone.* When the toes are dorsi-flexed, the tendon of the *extensor hallucis longus* can be identified lateral to the tibialis anterior, and still more laterally—immediately in front of the lateral part of the lower end of the tibia—the *extensor digitorum longus* and the *peroneus tertius* tendons are crowded together as they pass through the fibrous loop of the inferior extensor retinaculum (cruciate ligament) (p. 650). After traversing the loop, the tendons diverge to their insertions. The *synovial sheaths* which envelop these tendons are shown in fig. 1306.

The dorsal venous arch forms a conspicuous feature on the dorsum of the foot, especially when it is warm, e.g. after a hot bath ; it curves, convex forwards, across the metatarsus. The long saphenous vein arises from its medial end and runs upwards and backwards in front of the medial malleolus (p. 1471), while the short saphenous vein arises from its lateral end and passes backwards below, and then upwards behind, the lateral malleolus.

The dorsal aspects of the bodies of the *metatarsal bones* can be felt more or less distinctly, but they tend to be obscured by the extensor tendons of the toes. Half-way along the lateral border of the foot, the tubercle on the base of the *fifth metatarsal bone* forms a distinct projection, which can be both seen and felt.

The flat, *lateral surface of the calcaneum* can be palpated on the lateral aspect of the heel and can be traced forwards, below the lateral malleolus, where it is hidden by the tendons of the peroneus longus and brevis. The *peroneal tubercle,* when present and pronounced, can be felt 2 cm. below the tip of the lateral malleolus ; immediately above it the peroneus brevis tendon can be traced forwards to the tubercle on the base of the fifth metatarsal bone, when the foot is actively everted and plantar-flexed.

On the medial side of the foot, the *sustentaculum tali* can be felt 2 cm. vertically below the medial malleolus ; it is partly obscured by the flexor digitorum longus tendon and the flexor retinaculum (fig. 1307). Behind and below the sustentaculum tali, the medial aspect of the calcaneum can be felt indistinctly. The *tuberosity of the navicular bone* is the most conspicuous bony landmark on the medial side and sole of the foot. Usually visible, it can always be felt 2·5 cm. in front of the sustentaculum tali. The medial cuneiform bone has already been identified, and its joint with the first metatarsal bone can be felt as a narrow groove in its upper and medial part (Pl. XII).

When the foot is placed on the ground it rests on the posterior part of the inferior surface of the calcaneum, the heads of the metatarsal bones and, to a lesser extent, on its lateral border. The *instep,* which corresponds to the medial longitudinal arch of the foot (p. 516) is elevated from the ground. The *tubercles* of the calcaneum can be examined, but they are obscured by the tough fibro-fatty pad which covers them. The heads of the metatarsal bones, also covered with a thick pad, form the ball of the foot ; at this level the foot is widest, owing to the slight splay of the metatarsal bones as they pass forwards.

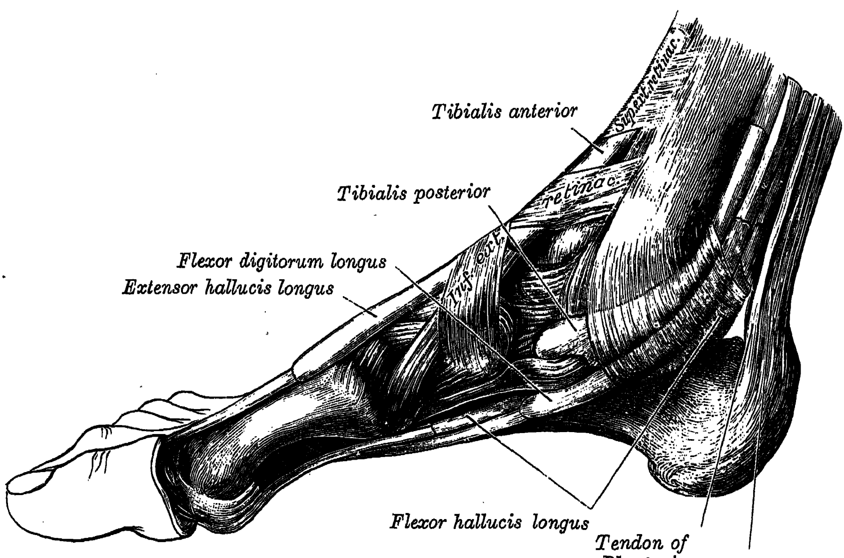
On the dorsum of the foot the skin is thin, loosely connected to the subjacent parts and containing a few hairs ; on the plantar aspect, and especially

over the heel, the epidermis is of great thickness and hairs and sebaceous glands are absent, as in the palm of the hand.

Surface relations of other structures.—The stem of the *inferior extensor retinaculum* (cruciate crural ligament) (p. 650) is attached to the anterior part of the upper surface of the calcaneum. It can be represented by a band, about 1·5 cm. wide, which passes medially on to the dorsum of the foot. On the medial side of the tendons of the extensor digitorum longus, the band divides into two diverging limbs, each 1 cm. wide. The upper limb passes to the medial malleolus; the lower passes round the medial aspect of the foot to gain the plantar aspect. The *dorsalis pedis artery* corresponds to a line drawn from the midpoint between the two malleoli to the proximal end of the first intermetatarsal space (fig. 1305).

The *calcaneocuboid joint* lies 2 cm. behind the tubercle on the base of the fifth metatarsal bone, and is practically in line with the *talonavicular joint*, the

FIG. 1307.—The synovial sheaths of the tendons round the ankle. Medial aspect. (From a preparation by J. C. B. Grant.)



position of which may be gauged from the head of the talus (p. 1473). These two joints together constitute the *transverse tarsal joint*. The *tarsometatarsal joints* lie on a line joining the tubercle of the fifth metatarsal bone to the tarsometatarsal joint of the great toe. When the latter joint cannot be felt on the medial border of the foot, its position may be indicated 2·5 cm. in front of the tuberosity of the navicular bone. The joint between the second metatarsal and the intermediate cuneiform bone lies 2 mm. to 3 mm. behind the line of the other tarsometatarsal joints (Pl. XII). The *metatarsophalangeal joints* lie 2·5 cm. behind the webs of the toes.

The *flexor retinaculum* (laciniate ligament) (fig. 1307) forms a broad band, 2·5 cm. wide, which passes downwards and backwards from the medial malleolus to the medial aspect of the heel; its lower border runs from the tip of the malleolus to the medial tubercle of the calcaneum. The *tibialis posterior tendon* lies under cover of the flexor retinaculum close to its tibial attachment and then curves forwards in the interval between the medial malleolus and the sustentaculum tali to reach the tuberosity of the navicular bone. The *flexor digitorum longus tendon* curves forwards below the tibialis posterior, lying on the medial aspect of the sustentaculum tali; from there it passes forwards and laterally to the centre of the sole of the foot, where it breaks up into tendons for the lateral four toes. The *flexor hallucis longus tendon* lies below the sustentaculum tali and, as it passes forwards to the great toe, it crosses the line of the flexor

digitorum longus opposite the interval between the sustentaculum tali and the tuberosity of the navicular bone, i.e. below the *plantar calcaneonavicular ligament*, which can be represented in this interval. The synovial sheaths which envelop these tendons are shown in fig. 1307.

The *medial plantar artery* and *nerve* commence under cover of the flexor retinaculum, midway between the medial malleolus and the prominence of the heel. From this point a line drawn forwards in the direction of the first interdigital cleft as far as the navicular bone represents, with sufficient accuracy, both the nerve and the artery. The *lateral plantar artery* and *nerve* can be represented by a line drawn from the same starting-point forwards and laterally to a point 2·5 cm. medial to the tubercle of the fifth metatarsal bone. A line drawn medially from that point, with a slight forward convexity, to the proximal end of the first intermetatarsal space represents the *plantar arch* and the *deep branch of the lateral plantar nerve*.
